JOHNS HOPKINS
MEDICINE

# TEXTBOOK OF CARDIOTHORACIC SURGERY

SECOND EDITION

Mc Graw Hill Education

# Johns Hopkins Textbook of Cardiothoracic Surgery

**Notice**

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

# Johns Hopkins Textbook of Cardiothoracic Surgery

## *Second Edition*

Edited By

**David D. Yuh, MD, FACC, FACS**
Professor and Chief, Section of Cardiac Surgery
Department of Surgery
Yale University School of Medicine
New Haven, Connecticut

Surgical Director
Yale-New Haven Hospital Heart and Vascular Center
New Haven, Connecticut

Former Associate Professor of Surgery,
Division of Cardiac Surgery
Department of Surgery
Johns Hopkins University School of Medicine
and The Johns Hopkins Hospital
Baltimore, Maryland

**Luca A. Vricella, MD, FACS**
Associate Professor of Surgery and Pediatrics
Director, Pediatric Cardiac Surgery and Heart Transplantation
Johns Hopkins University School of Medicine
Baltimore, Maryland

**Stephen C. Yang, MD**
The Arthur B. and Patricia B. Modell Professor in Thoracic Surgery
Division of Thoracic Surgery
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

**John R. Doty, MD**
Adjunct Professor of Surgery
Division of Cardiothoracic Surgery
Intermountain Heart Institute at Intermountain Medical Center
University of Utah
Salt Lake City, Utah

This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

*To my wife, Dr. Bonnie Hiatt, for accepting my many flaws and idiosyncrasies and for giving me my most cherished gifts, Natalie and Christopher. You each make my life worth living.*

—David D. Yuh, MD, FACC, FACS

*To my wife Simona, for the endless sacrifice of living twenty years with a surgeon … and for brightening every day of my life with her presence, love and partnership.*

—Luca A. Vricella, MD, FACS

*To my mentors, students, residents, and colleagues—from whom I've learned so much. And for the real teachers in life—my parents Muriel and Harry Yang, my wife Marivic, and children Kristin, Andy, and Alex.*

—Stephen C. Yang, MD

*To my mentors at Georgetown University, The Johns Hopkins Hospital, and Intermountain Medical Center for their patience and dedication to my surgical education, and to my wife and family for their kindness and understanding during this journey.*

—John R. Doty, MD

# CONTENTS

*Contributors* xi
*Foreword* xxiii
*Preface* xxv

## I GENERAL THORACIC SURGERY 1

**1. Preoperative Evaluation of the Thoracic Surgical Patient 3**
*Kelly K. Nagasawa and John R. Doty*

**2. Thoracic Trauma 9**
*George J. Koenig Jr. and David T. Efron*

**3. Pulmonary Physiology, Function Tests, and Bronchoscopic Techniques 25**
*Lonny Yarmus and David J. Feller-Kopman*

**4. Congenital Pulmonary Disorders 41**
*Anne C. Fischer and Eric Griffiths*

**5. Benign Diffuse Pulmonary Disorders 49**
*Christian A. Merlo*

**6. Thoracic Infections 63**
*Kaushik Mandal*

**7. Surgical Management of Emphysema 89**
*Alex G. Little*

**8. Tracheal Diseases 97**
*Dan J. Raz, Todd S. Weiser, and Douglas J. Mathisen*

**9. Primary Lung Cancer 119**
*Min P. Kim and Ara A. Vaporciyan*

**10. Pulmonary Metastasis 145**
*DuyKhanh P. Ceppa and Betty C. Tong*

**11. Lung and Heart–Lung Transplantation 157**
*Ashish S. Shah*

**12. Esophageal Physiology, Function Tests, and Endoscopic Techniques 169**
*Daniela Jodorkovsky, John O. Clarke, and Kerry B. Dunbar*

**13. Congenital Esophageal Anomalies 183**
*Nishant D. Patel and Avedis Meneshian*

**14. Gastroesophageal Reflux Disease and Esophageal Motility Disorders 191**
*Shelly Bansal, Brian Goodman, and Edmund S. Kassis*

**15. Esophageal Perforation 205**
*Clinton D. Kemp and Stephen C. Yang*

**16. Esophageal Cancer 215**
*Jules Lin and Mark B. Orringer*

**17. Mediastinal Disease 229**
*Lee Plantmason, Natalie Lui, and Pierre Theodore*

**18. Chest Wall Tumors 243**
*Robert A. Meguid and Malcolm V. Brock*

**19. Congenital Chest Wall Anomalies 267**
*Ibrahim Sultan and Stephen C. Yang*

**20. Benign Pleural Disorders 289**
*Joshua T. Taylor and Maurice A. Smith*

**21. Benign and Malignant Pleural Tumors 301**
*Siva Raja, Carol F. Farver, Sudish C. Murthy, and David Mason*

**22. Diaphragmatic Disorders 309**
*Jarrod D. Predina and Sunil Singhal*

## II ADULT CARDIAC SURGERY 321

**23. Cardiovascular Function and Physiology 323**
*Jeffrey M. Dodd-o*

**24. Cardiopulmonary Bypass 341**
*Edward H. Kincaid and John W. Hammon*

**25. Myocardial Protection 359**
*Constantine L. Athanasuleas and Gerald D. Buckberg*

**26. Postoperative Management of the Cardiac Surgical Patient 371**
*Rashna Ginwalla, Nauder Faraday, and Glenn Whitman*

**27. Primary Coronary Artery Bypass Surgery 387**
*G.D. Rushing and David D. Yuh*

**28. Off-Pump Coronary Artery Bypass 407**
*Eric A. Peck and Paul Sergeant*

**29. Reoperative Coronary Artery Bypass Surgery 421**
*Christopher J. Barreiro, George J. Arnaoutakis, and Jay G. Shake*

**30. Management of Concomitant Carotid and Coronary Artery Disease 431**
*Daniel J. Durand, Svati Singla Long, and David D. Yuh*

**31. Mechanical Complications of Myocardial Infarction 439**
*Ryan R. Davies, Michael P. Robich, and Michael A. Coady*

**32. Aortic Valve Replacement 501**
*William M. Yarbrough and John S. Ikonomidis*

**33. Aortic Root Replacement 525**
*Kaushik Mandal and Duke E. Cameron*

**34. Mitral Valve Pathophysiology 539**
*Tomasz A. Timek and James I. Fann*

**35. Mitral Valve Replacement 551**
*Stephen J. Huddleston and David D. Yuh*

**36. Mitral Valve Repair for Degenerative Disease 561**
*Gurjyot Bajwa, Tomislav Mihaljevic, and A. Marc Gillinov*

**37. Tricuspid Valve Disease 571**
*David L. Joyce*

**38. Surgical Treatment of Endocarditis 581**
*John R. Doty and William T. Caine*

**39. Ascending and Arch Aneurysms of the Aorta 591**
*Anthony D. Caffarelli, Pieter J. A. van der Starre, and R. Scott Mitchell*

**40. Thoracoabdominal Aneurysms 625**
*Ying Wei Lum and Glenn S. Roseborough*

**41. Aortic Dissection 647**
*Thoralf M. Sundt III*

**42. Endovascular Repair of Thoracic Aortic Pathology 663**
*Timothy J. George and James H. Black III*

**43. Surgical Therapies for Atrial Fibrillation 681**
*Timo Weimar and Ralph J. Damiano Jr.*

**44. Pacemaker and Defibrillator Therapy in Cardiac Surgery Patients 695**
*Brad S. Sutton, Kenneth C. Bilchick, and Ronald D. Berger*

**45. Surgical Treatment of Chronic Pulmonary Thromboembolic Disease 715**
*Michael M. Madani and Stuart W. Jamieson*

**46. Role of Surgery in Management of Hypertrophic Cardiomyopathy 731**
*Hartzell V. Schaff*

**47. Pericardial Disease 741**
*Eric J. Okum and Abe De Anda Jr.*

**48. Primary Cardiac Tumors 753**
*Brian T. Bethea and Adam Richter*

**49. The Immunobiology of Thoracic Transplantation 769**
*Marc K. Halushka and William M. Baldwin III*

**50. Cardiac Transplantation 783**
*Kenneth K. Liao and Sara J. Shumway*

**51. Mechanical Circulatory Support 797**
*Clinton D. Kemp and John V. Conte*

**52. Surgical Ventricular Remodeling 835**
*Clinton D. Kemp and John V. Conte*

**53. Stem Cells for Cardiac Surgical Disease 849**
*Peter V. Johnston and Gary Gerstenblith*

**54. Minimally Invasive Cardiac Surgery 861**
*D. Kalavrouziotis and Francois Dagenais*

**55. Cardiac Catheterization and Interventions 873**
*Todd A. Dorfman and Jon R. Resar*

**56. Echocardiography in Cardiac Surgery 893**
*Colleen Harrington, Samia Mora, and Katherine C. Wu*

**57. Cardiac Magnetic Resonance Imaging 921**
*Jens Vogel-Claussen and David A. Bluemke*

**III CONGENITAL CARDIAC SURGERY 941**

**58. Milestones in Congenital Cardiac Surgery 943**
*Luca A. Vricella, Vincent L. Gott, and Duke E. Cameron*

**59. The Anatomy of Congenital Cardiac Malformations 955**
*Robert H. Anderson and Andrew C. Cook*

**60. Perioperative Critical Care of the Pediatric Cardiac Surgical Patient 973**
*Stacie B. Peddy, Marissa A. Brunetti, and Jamie McElrath Schwartz*

**61. Cardiopulmonary Bypass in the Pediatric Patient 983**
*Jacob Ostrowsky and Ross Ungerleider*

**62. Palliative Operations for Congenital Heart Disease 991**
*Tara Karamlou and Gordon A. Cohen*

**63. Patent Ductus Arteriosus 1001**
*Tain-Yen Hsia, Jeffrey J. Wu, and Richard Ringel*

**64. Atrial Septal Defects and Partial Anomalous Pulmonary Venous Connection 1009**
*Dario Troise, Richard Ringel, and Francesco Paolo Annecchino*

**65. Ventricular Septal Defects 1029**
*David L.S. Morales, Brandi B. Scully, and Charles D. Fraser Jr.*

**66. Atrioventricular Septal Defects 1043**
*Mazyar Kanani and Martin J. Elliott*

**67. Aortopulmonary Window 1063**
*Victor O. Morell and Ergin Kocyildirim*

**68. Tetralogy of Fallot 1069**
*Osami Honjo and Glen S. Van Arsdell*

**69. Pulmonary Atresia with Ventricular Septal Defect and Major Aortopulmonary Collaterals 1085**
*Malcolm J. MacDonald and Frank L. Hanley*

**70. Pulmonary Stenosis and Pulmonary Atresia with Intact Ventricular Septum 1095**
*Cara L. Lawrence, Deborah J. Kozik, and Mark D. Plunkett*

**71. Double Outlet Right Ventricle 1113**
*Jess Thompson and Joseph A. Dearani*

**72. Truncus Arteriosus 1127**
*Tara Karamlou, D. Michael McMullan, and Gordon A. Cohen*

**73. Total Anomalous Pulmonary Venous Connection 1141**
*Ergin Kocyildirim and Victor O. Morell*

**74. Transposition of the Great Arteries 1147**
*Richard G. Ohye, Ming-Sing Si, Jennifer C. Hirsch-Romano, Zuhab A. Qamar, and Edward L. Bove*

**75. Congenitally Corrected Transposition 1161**
*Emile A. Bacha*

**76. Hypoplastic Left Heart Syndrome 1171**
*Peter J. Gruber and Thomas L. Spray*

**77. Tricuspid Atresia and the Functionally Single Ventricle 1183**
*Carin A. van Doorn, Victor T. Tsang, and Marc R. de Leval*

**78. Surgery for Left Ventricular Outflow Tract Obstruction in Children 1193**
*Tara Karamlou, Lester C. Permut, Marco Ricci, and Gordon A. Cohen*

**79. Coarctation of the Aorta and Interrupted Aortic Arch 1215**
*Mark D. Rodefeld*

**80. Cor Triatriatum 1233**
*Giancarlo Crupi*

**81. Valvular Disease in Children 1243**
*Christian P. Brizard and Yves d'Udekem d'Acoz*

**82. Cardiac Surgical Intervention in Pediatric Patients with Connective Tissue Disorders 1267**
*Giorgio Zanotti, Duke E. Cameron, and Luca A. Vricella*

**83. Surgery for Congenital Coronary Artery Anomalies 1277**
*Julie A. Brothers and J. William Gaynor*

**84. Vascular Rings and Pulmonary Artery Sling 1295**
*Carl Lewis Backer, Michael C. Mongé, and Hyde M. Russell*

**85. Ebstein's Anomaly 1311**
*Viktor Hraška, Boulos Asfour, and Joachim Photiadis*

**86. Congenital Anomalies of the Sinuses of Valsalva and Aortico–Left Ventricular Tunnel 1325**
*Torin P. Fitton, Christopher M. Sciortino, and Luca A. Vricella*

**87. Extracorporeal Membrane Oxygenation in Pediatric Cardiac Care 1331**
*Tara Karamlou, D. Michael McMullan, Harris P. Baden, Howard Jeffries, and Gordon A. Cohen*

**88. Ventricular Assist Devices in Children 1351**
*Kristen Nelson and Luca A. Vricella*

**89. Pediatric Cardiac Transplantation 1363**
*Amy L. Rahm, Nahidh W. Hasaniya, Leonard L. Bailey, Anees J. Razzouk, and Richard E. Chinnock*

**90. Management of Adults with Congenital Heart Disease 1377**
*Kaushik Mandal and Nihal A. Weerasena*

***Index 1399***

# CONTRIBUTORS

**Robert H. Anderson, MD, PhD, FRCPath**
Emeritus Professor of Paediatric Cardiac Morphology
Institute of Child Health
University College London
London, United Kingdom
*Chapter 59: The Anatomy of Congenital Cardiac Malformations*

**Francesco Paolo Annecchino, MD**
Consultant Cardiac Surgeon
Pediatric Cardiac Surgery Unit
Giovanni XXIII Pediatric Hospital
University of Bari
Bari, Italy
*Chapter 64: Atrial Septal Defects and Partial Anomalous Pulmonary Venous Connection*

**George J. Arnaoutakis, MD**
Surgery Resident
Division of Cardiac Surgery
Johns Hopkins School of Medicine
Baltimore, Maryland
*Chapter 29: Reoperative Coronary Artery Bypass Surgery*

**Glen S. Van Arsdell, MD**
Professor and Head, Cardiovascular Surgery
Department of Surgery
Hospital for Sick Children, University of Toronto
Toronto, Canada
*Chapter 68: Tetralogy of Fallot*

**Boulos Asfour, MD**
Professor
Chief of Cardiovascular Surgery
German Pediatric Heart Centre
Asklepios Clinic
Sankt Augustin, Germany
*Chapter 85: Ebstein's Anomaly*

**Constantine L. Athanasuleas, MD**
Professor of Surgery
Department of Surgery, Division of Cardiothoracic Surgery
University of Alabama at Birmingham
Birmingham, Alabama
*Chapter 25: Myocardial Protection*

**Emile A. Bacha, MD**
Professor of Surgery and Chief
Department of Cardiac, Thoracic and Vascular Surgery
Columbia University, NewYork Presbyterian, Morgan Stanley Children's Hospital
New York, New York
*Chapter 75: Congenitally Corrected Transposition*

**Carl Lewis Backer, MD**
Division Head, Cardiovascular-Thoracic Surgery
Ann & Robert H. Lurie Children's Hospital of Chicago
A.C. Buehler Professor of Surgery
Department of Surgery
Northwestern University Feinberg School of Medicine
Chicago, Illinois
*Chapter 84: Vascular Rings and Pulmonary Artery Sling*

**Harris P. Baden, MD**
Chief, Pediatric Cardiac Critical Care
Department of Pediatrics
Seattle Children's Hospital
The University of Washington School of Medicine
Seattle, Washington
*Chapter 87: Extracorporeal Membrane Oxygenation in Pediatric Cardiac Care*

**Leonard L. Bailey, MD**
Distinguished Professor
Department of Cardiovascular and Thoracic Surgery
Loma Linda University Medical Center and Children's Hospital
Loma Linda, California
*Chapter 89: Pediatric Cardiac Transplantation*

**Gurjyot Bajwa, MD**
Assistant Professor
Division of Cardiothoracic Surgery
Department of Surgery
Jefferson Medical College
Philadelphia, Pennsylvania
*Chapter 36: Mitral Valve Repair for Degenerative Disease*

**William M. Baldwin III, MD, PhD**
Professor
Department of Immunology
The Cleveland Clinic
Cleveland, Ohio
*Chapter 49: The Immunobiology of Thoracic Transplantation*

**Shelly Bansal, MD**
Fellow
Department of Cardiothoracic Surgery
The Ohio State University Medical Center
Columbus, Ohio
*Chapter 14: Gastroesophageal Reflux Disease and Esophageal Motility Disorders*

**Christopher J. Barreiro, MD**
Cardiac Surgeon
Department of Cardiac Surgery
Mid-Atlantic Cardiothoracic Surgeons, Ltd.,
Sentara Heart Hospital
Norfolk, Virginia
*Chapter 29: Reoperative Coronary Artery Bypass Surgery*

**Ronald D. Berger, MD, PhD, FHRS**
Professor of Medicine and Biomedical Engineering
Department of Medicine
Johns Hopkins Medical Institutions
Baltimore, Maryland
*Chapter 44: Pacemaker and Defibrillator Therapy in Cardiac Surgery Patients*

**Brian T. Bethea, MD**
Assistant Professor
Department of Cardiothoracic and Vascular Surgery
University of Texas Southwestern
Dallas, Texas
*Chapter 48: Primary Cardiac Tumors*

**Kenneth C. Bilchick, MD, MS**
Assistant Professor of Medicine
Department of Medicine, Cardiovascular Division
University of Virginia Health System
Charlottesville, Virginia
*Chapter 44: Pacemaker and Defibrillator Therapy in Cardiac Surgery Patients*

**James H. Black III, MD**
Associate Professor of Surgery
Division of Vascular Surgery
The Johns Hopkins Hospital
Baltimore, Maryland
*Chapter 42: Endovascular Repair of Thoracic Aortic Pathology*

**David A. Bluemke, MD, PhD, MsB**
Director
Senior Investigator, National Institute of Biomedical Imaging and Bioengineering
Professor of Radiology and Medicine
Johns Hopkins University School of Medicine
Radiology and Imaging Sciences
Johns Hopkins University School of Medicine
Baltimore, Maryland
*Chapter 57: Cardiac Magnetic Resonance Imaging*

**Edward L. Bove, MD**
Professor
Department of Cardiac Surgery
University of Michigan C. S. Mott Children's Hospital
Ann Arbor, Michigan
*Chapter 74: Transposition of the Great Arteries*

**Christian P. Brizard, MD**
Associate Professor
Department of Paediatrics
Director, Cardiac Surgery Unit
The Royal Children's Hospital Melbourne
Melbourne, Australia
*Chapter 81: Valvular Disease in Children*

**Malcolm V. Brock, MD**
Associate Professor
Division of Thoracic Surgery
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland
*Chapter 18: Chest Wall Tumors*

**Julie A. Brothers, MD, FAAP**
Assistant Professor
Division of Cardiology
University of Pennsylvania School of Medicine/
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania
*Chapter 83: Surgery for Congenital Coronary Artery Anomalies*

**Marissa A. Brunetti, MD**
Clinical Instructor
University of Pennsylvania School of Medicine/
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania
*Chapter 60: Perioperative Critical Care of the Pediatric Cardiac Surgical Patient*

**Gerald D. Buckberg, MD**
Professor of Surgery
Department of Cardiothoracic Surgery
David Geffen School of Medicine at UCLA
Los Angeles, California
*Chapter 25: Myocardial Protection*

**Anthony D. Caffarelli, MD**
Attending Surgeon
Department of Thoracic Surgery
Hoag Memorial Hospital
Newport Beach, California
*Chapter 39: Ascending and Arch Aneurysms of the Aorta*

**William T. Caine, MD**
Adjunct Assistant Professor
Division of Cardiothoracic Surgery
Intermountain Heart Institute at Intermountain Medical Center
Salt Lake City, Utah
*Chapter 38: Surgical Treatment of Endocarditis*

**Duke E. Cameron, MD**
Professor and Cardiac Surgeon in Chief
Division of Cardiac Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland
*Chapter 33: Aortic Root Replacement*
*Chapter 58: Milestones in Congenital Cardiac Surgery*
*Chapter 82: Cardiac Surgical Intervention in Pediatric Patients with Connective Tissue Disorders*

**DuyKhanh P. Ceppa, MD**
Assistant Professor, Division of Cardiothoracic Surgery
Department of Surgery
Indiana University School of Medicine
Indianapolis, Indiana
*Chapter 10: Pulmonary Metastasis*

**Richard E. Chinnock, MD**
Professor
Department of Pediatrics
Loma Linda University Medical Center and Children's Hospital
Loma Linda, California
*Chapter 89: Pediatric Cardiac Transplantation*

**John O. Clarke, MD**
Assistant Professor of Medicine
Division of Gastroenterology and Hepatology
Johns Hopkins University School of Medicine
Baltimore, Maryland
*Chapter 12: Esophageal Physiology, Function Tests, and Endoscopic Techniques*

**Michael A. Coady, MD, MPH**
Chief of Cardiac Surgery
Department of Cardiac Surgery
Stamford Hospital
Stamford, Connecticut
*Chapter 31: Mechanical Complications of Myocardial Infarction*

**Gordon A. Cohen, MD, PhD, MBA**
Julien I.E. Hoffman MD Chair of Cardiac Surgery
Professor and Chief
Division of Pediatric Cardiac Surgery
UCSF School of Medicine
San Francisco, California
*Chapter 62: Palliative Operations for Congenital Heart Disease*
*Chapter 72: Truncus Arteriosus*
*Chapter 78: Surgery for Left Ventricular Outflow Tract Obstruction in Children*
*Chapter 87: Extracorporeal Membrane Oxygenation in Pediatric Cardiac Care*

**John V. Conte, MD**
Professor of Surgery
Division of Cardiac Surgery
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland
*Chapter 51: Mechanical Circulatory Support*
*Chapter 52: Surgical Ventricular Remodeling*

**Andrew C. Cook, PhD**
Senior Lecturer
Institute of Cardiovascular Science
University College London
London, United Kingdom
*Chapter 59: The Anatomy of Congenital Cardiac Malformations*

**Giancarlo Crupi, MD**
Senior Staff Surgeon
Pediatric and Congenital Heart Surgery
Papa Giovanni XXIII Hospital
Bergamo, Italy
*Chapter 80: Cor Triatriatum*

**Yves d'Udekem d'Acoz, MD, PhD**
Associate Professor
Department of Paediatrics
Deputy Director, Cardiac Surgery Unit
The Royal Children's Hospital, Melbourne
Melbourne, Australia
*Chapter 81: Valvular Disease in Children*

**Francois Dagenais, MD**
Chief of Cardiac Surgery
Department of Cardiac Surgery
Quebec Heart and Lung Institute
Quebec City, Quebec
*Chapter 54: Minimally Invasive Cardiac Surgery*

**Ralph J. Damiano Jr., MD**
John M. Shoenberg Professor of Surgery, Chief of Cardiac Surgery
Division of Cardiothoracic Surgery
Washington University School of Medicine, Barnes-Jewish Hospital
St. Louis, Missouri
*Chapter 43: Surgical Therapies for Atrial Fibrillation*

**Ryan R. Davies, MD**
Cardiothoracic Surgeon
Department of Cardiothoracic Surgery
Nemours Cardiac Center, A.I. duPont Hospital for Children
Wilmington, Delaware

Assistant Professor of Surgery
Department of Surgery
Thomas Jefferson University
Philadelphia, Pennsylvania
*Chapter 31: Mechanical Complications of Myocardial Infarction*

**Abe DeAnda Jr., MD**
Associate Professor of Cardiothoracic Surgery
Director, Thoracic Aortic Aneurysm Program
Chief of Cardiothoracic Surgery
Department of Cardiothoracic Surgery
New York University – Langone Medical Center
New York, New York
*Chapter 47: Pericardial Disease*

**Joseph A. Dearani, MD**
Professor of Surgery
Chair, Division of Cardiovascular Surgery
Mayo Clinic and Foundation
Rochester, Minnesota
*Chapter 71: Double Outlet Right Ventricle*

**Jeffrey M. Dodd-o, MD, PhD**
Associate Professor
Anesthesiology and Critical Care Medicine
Johns Hopkins Medical Institutions
Baltimore, Maryland
*Chapter 23: Cardiovascular Function and Physiology*

**Carin A. van Doorn, MD, FRCSC/Th**
Consultant Cardiothoracic Surgeon
Department of Cardiothoracic Surgery
Skejby University Hospital
Aarhus, Denmark
*Chapter 77: Tricuspid Atresia and the Functionally Single Ventricle*

**Todd A. Dorfman, MD**
Cardiologist
Department of Centennial Heart
Summit Medical Center
Hermitage, Tennessee
*Chapter 55: Cardiac Catheterization and Interventions*

**John R. Doty, MD**
Adjunct Professor of Surgery
Division of Cardiothoracic Surgery
Intermountain Heart Institute at Intermountain Medical Center
University of Utah
Salt Lake City, Utah
*Chapter 1: Preoperative Evaluation of the Thoracic Surgical Patient*
*Chapter 38: Surgical Treatment of Endocarditis*

**Kerry B. Dunbar, MD, PhD**
Assistant Professor of Medicine
Medicine—Division of Gastroenterology and Hepatology
University of Texas Southwestern Medical Center,
Dallas VA Medical Center
Dallas, Texas
*Chapter 12: Esophageal Physiology, Function Tests, and Endoscopic Techniques*

**Daniel J. Durand, MD**
Adjunct Faculty
Russell H. Morgan Department of Radiology
and Imaging Sciences
The Johns Hopkins School of Medicine
Baltimore, Maryland
*Chapter 30: Management of Concomitant Carotid and Coronary Artery Disease*

**David T. Efron, MD, FACS**
Associate Professor of Surgery
Department of Surgery
Anesthesia and Critical Care Medicine/The Johns Hopkins Hospital
Chief
Division of Acute Care Surgery
Trauma, Critical Care, Emergency and General Surgery
The Johns Hopkins Hospital
Director of Adult Trauma
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland
*Chapter 2: Thoracic Trauma*

**Martin J. Elliott, MD, FRCS**
Professor
Department of Cardiothoracic Surgery
Great Ormond Street Hospital for Children NHS Trust
London, United Kingdom
*Chapter 66: Atrioventricular Septal Defects*

**James I. Fann, MD**
Professor
Department of Cardiothoracic Surgery
Stanford University School of Medicine
Stanford, California
*Chapter 34: Mitral Valve Pathophysiology*

**Nauder Faraday, MD, MPH**
Professor of Anesthesiology/Critical Care Medicine and Surgery
Director, Perioperative Genomic and Translational Research
Johns Hopkins University School of Medicine
Baltimore, Maryland
*Chapter 26: Postoperative Management of the Cardiac Surgical Patient*

**Carol F. Farver, MD**
Staff Pathologist
Department of Anatomic Pathology
The Cleveland Clinic
Cleveland, Ohio
*Chapter 21: Benign and Malignant Pleural Tumors*

**David J. Feller-Kopman, MD, FCCP**
Director, Bronchoscopy & Interventional Pulmonology
Section of Interventional Pulmonology
Division of Pulmonary Critical Care Medicine
The Johns Hopkins University School of Medicine
Baltimore, Maryland
*Chapter 3: Pulmonary Physiology, Function Tests, and Bronchoscopic Techniques*

**Anne C. Fischer, MD, PhD**
Surgeon in Chief, Beaumont Children's Hospital
Department of Surgery
Professor and Chief, Pediatric Surgery
Department of Surgery
Beaumont Health System
Royal Oak, Michigan
*Chapter 4: Congenital Pulmonary Disorders*

**Torin P. Fitton, MD**
Senior Surgeon
Department of Cardiothoracic Surgery
Lahey Hospital & Medical Center
Burlington, Massachusetts
*Chapter 86: Congenital Anomalies of the Sinuses of Valsalva and Aortico–Left Ventricular Tunnel*

**Charles D. Fraser Jr., MD**
Surgeon-in-Chief
Department of Surgery
Texas Children's Hospital
Chief of Congenital Heart Surgery, Texas Children's Hospital
Professor of Surgery and Pediatrics
Congenital Heart Surgery
Baylor College of Medicine
Houston, Texas
*Chapter 65: Ventricular Septal Defects*

**J. William Gaynor, MD**
Associate Professor
Department of Cardiothoracic Surgery
University of Pennsylvania School of Medicine/
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania
*Chapter 83: Surgery for Congenital Coronary Artery Anomalies*

**Timothy J. George, MD**
General Surgery Resident
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland
*Chapter 42: Endovascular Repair of Thoracic Aortic Pathology*

**Gary Gerstenblith, MD**
Professor of Medicine
Division of Cardiology
The Johns Hopkins School of Medicine
Baltimore, Maryland
*Chapter 53: Stem Cells for Cardiac Surgical Disease*

**A. Marc Gillinov, MD**
Staff Surgeon
Department of Thoracic and Cardiovascular Surgery
The Cleveland Clinic
Cleveland, Ohio
*Chapter 36: Mitral Valve Repair for Degenerative Disease*

**Rashna Ginwalla, MD**
Fellow
Trauma, Surgical Critical Care & Emergency General Surgery
University of Arizona Medical Center
Tucson, Arizona
*Chapter 26: Postoperative Management of the Cardiac Surgical Patient*

**Brian Goodman, MD**
Fellow
Department of Cardiothoracic Surgery
The Ohio State University Medical Center
Columbus, Ohio
*Chapter 14: Gastroesophageal Reflux Disease and Esophageal Motility Disorders*

**Vincent L. Gott, MD**
Professor of Surgery Emeritus
Former Surgeon-in-Chief
Division of Cardiac Surgery
The Johns Hopkins Hospital
Baltimore, Maryland
*Chapter 58: Milestones in Congenital Cardiac Surgery*

**Eric Griffiths, MD**
Cardiothoracic Fellow
Department of Cardiac Surgery
Childrens Hospital Boston
Boston, Massachusetts
*Chapter 4: Congenital Pulmonary Disorders*

**Peter J. Gruber, MD, PhD**
Section Chief
Department of Pediatric Cardiothoracic Surgery
University of Utah and Primary Children's Hospital
Salt Lake City, Utah
*Chapter 76: Hypoplastic Left Heart Syndrome*

**Marc K. Halushka, MD, PhD**
Associate Professor
Department of Pathology
Johns Hopkins Medical Institutions
Baltimore, Maryland
*Chapter 49: The Immunobiology of Thoracic Transplantation*

**John W. Hammon, MD**
Professor, Cardiothoracic Surgery, Emeritus
Wake Forest University School of Medicine
Winston-Salem, North Carolina
*Chapter 24: Cardiopulmonary Bypass*

**Frank L. Hanley, MD**
Lawrence Crowley, MD Endowed Professor in Child Health
Department of Cardiothoracic Surgery
Stanford University School of Medicine
Director, Children's Heart Center
Lucile Packard Children's Hospital at Stanford
Stanford, California
*Chapter 69: Pulmonary Atresia with Ventricular Septal Defect and Major Aortopulmonary Collaterals*

**Colleen Harrington, MD**
Postdoctoral Fellow
Division of Cardiology
Johns Hopkins Medical Institutions
Baltimore, Maryland
*Chapter 56: Echocardiography in Cardiac Surgery*

**Nahidh W. Hasaniya, MD, PhD**
Associate Professor
Department of Cardiovascular and Thoracic Surgery
Loma Linda University Medical Center and Children's Hospital
Loma Linda, California
*Chapter 89: Pediatric Cardiac Transplantation*

**Jennifer C. Hirsch-Romano, MD, MS**
Assistant Professor
Department of Cardiac Surgery
University of Michigan C. S. Mott Children's Hospital
Ann Arbor, Michigan
*Chapter 74: Transposition of the Great Arteries*

**Osami Honjo, MD, PhD**
Staff Surgeon, Cardiovascular Surgery
Department of Cardiovascular Surgery
The Hospital for Sick Children, University of Toronto
Toronto, Ontario, Canada
*Chapter 68: Tetralogy of Fallot*

**Viktor Hraška, MD, PhD**
Chief of Cardiovascular Surgery
German Pediatric Heart Centre
Asklepios Clinic
Sankt Augustin, Germany
*Chapter 85: Ebstein's Anomaly*

**Tain-Yen Hsia, MD, MSc**
Consultant Cardiothoracic Surgeon
Cardiorespiratory Unit
Great Ormond Street Hospital for Children,
NHS Foundation Trust
London, United Kingdom
*Chapter 63: Patent Ductus Arteriosus*

**Stephen J. Huddleston, MD, PhD**
Cardiothoracic Surgeon
Department of Cardiothoracic Surgery
St. Luke's Hospital
Duluth, Minnesota
*Chapter 35: Mitral Valve Replacement*

**John S. Ikonomidis, MD, PhD**
Horace G. Smithy Professor
Department of Surgery
Chief, Division of Cardiothoracic Surgery
Medical University of South Carolina
Charleston, South Carolina
*Chapter 32: Aortic Valve Replacement*

**Stuart W. Jamieson, MD, FRCS, FACS**
Endowed Chair and Distinguished Professor
Chief, Cardiovascular and Thoracic Surgery
Division of Cardiothoracic Surgery
University of California San Diego, Medical Center
San Diego, California
*Chapter 45: Surgical Treatment of Chronic Pulmonary Thromboembolic Disease*

**Howard Jeffries, MD, MPH, MBA**
Clinical Professor
Department of Pediatrics
University of Washington School of Medicine,
Seattle Children's Hospital
Seattle, Washington
*Chapter 87: Extracorporeal Membrane Oxygenation in Pediatric Cardiac Care*

**Daniela Jodorkovsky, MD**
Assistant Professor of Medicine
Division of Gastroenterology and Hepatobiliary Diseases
New York Medical College
Valhalla, New York
*Chapter 12: Esophageal Physiology, Function Tests, and Endoscopic Techniques*

**Peter V. Johnston, MD**
Assistant Professor of Medicine
Division of Cardiology
Johns Hopkins University School of Medicine
Baltimore, Maryland
*Chapter 53: Stem Cells for Cardiac Surgical Disease*

**David L. Joyce, MD**
HealthEast Heart Care
Department of Cardiovascular Surgery
St. Joseph's Hospital
St. Paul, Minnesota
*Chapter 37: Tricuspid Valve Disease*

**D. Kalavrouziotis, MD, PhD**
Assistant Professor
Department of Cardiac Surgery
Quebec Heart and Lung Institute
Quebec City, Quebec
*Chapter 54: Minimally Invasive Cardiac Surgery*

**Mazyar Kanani, PhD, FRCS**
Consultant
Congenital Cardiothoracic Surgery
Great Ormond Street Hospital for Children NHS Trust
London, United Kingdom
*Chapter 66: Atrioventricular Septal Defects*

**Tara Karamlou, MD, MSc**
Assistant Professor of Surgery
Division of Pediatric Cardiac Surgery
Benioff Children's Hospital
University of California San Francisco
San Francisco, California
*Chapter 62: Palliative Operations for Congenital Heart Disease*
*Chapter 72: Truncus Arteriosu*
*Chapter 78: Surgery for Left Ventricular Outflow Tract Obstruction in Children*
*Chapter 87: Extracorporeal Membrane Oxygenation in Pediatric Cardiac Care*

**Edmund S. Kassis, MD**
Assistant Professor of Surgery, Division of Thoracic Surgery
Department of Surgery
The Ohio State University Medical Center
Columbus, Ohio
*Chapter 14: Gastroesophageal Reflux Disease and Esophageal Motility Disorders*

**Clinton D. Kemp, MD**
Cardiothoracic Surgery Fellow
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland
*Chapter 15: Esophageal Perforation*
*Chapter 51: Mechanical Circulatory Support*
*Chapter 52: Surgical Ventricular Remodeling*

**Min P. Kim, MD, FACS**
Assistant Professor
Department of Surgery
Weill Cornell Medical College
The Methodist Hospital
Houston, Texas
*Chapter 9: Primary Lung Cancer*

**Edward H. Kincaid, MD**
Associate Professor of Surgery
Department of Cardiothoracic Surgery
Wake Forest University School of Medicine
Winston-Salem, North Carolina
*Chapter 24: Cardiopulmonary Bypass*

**Ergin Kocyildirim, MD**
Assistant Professor of Surgery
Department of Cardiothoracic Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania
*Chapter 67: Aortopulmonary Window*
*Chapter 73: Total Anomalous Pulmonary Venous Connection*

**George J. Koenig Jr., DO, MS**
Assistant Professor in Surgery
Acute Care Surgery
Thomas Jefferson University
Philadelphia, Pennsylvania
*Chapter 2: Thoracic Trauma*

**Deborah J. Kozik, DO**
Assistant Professor
Department of Surgery
Division of Cardiothoracic Surgery
University of Kentucky College of Medicine
Lexington, Kentucky
*Chapter 70: Pulmonary Stenosis and Pulmonary Atresia with Intact Ventricular Septum*

**Cara L. Lawrence, MD**
Department of Surgery
Division of Cardiothoracic Surgery
University of Kentucky College of Medicine
Lexington, Kentucky
*Chapter 70: Pulmonary Stenosis and Pulmonary Atresia with Intact Ventricular Septum*

**Marc R. de Leval, MD, FRCS**
Professor of Cardiothoracic Surgery
Department of Cardiothoracic Surgery
Great Ormond Street Hospital for Children NHS trust
London, United Kingdom
*Chapter 77: Tricuspid Atresia and the Functionally Single Ventricle*

**Kenneth K. Liao, MD, PhD**
Associate Professor of Surgery, Surgical Director Heart Transplantation
Department of Surgery
University of Minnesota
Minneapolis, Minnesota
*Chapter 50: Cardiac Transplantation*

**Jules Lin, MD**
Assistant Professor of Surgery
Department of Surgery
Section of Thoracic Surgery
University of Michigan Medical Center
Ann Arbor, Michigan
*Chapter 16: Esophageal Cancer*

**Alex G. Little, MD**
Elizabeth Berry Gray Chair and Professor
Department of Surgery
Boonshoft School of Medicine
Wright State University
Dayton, Ohio
*Chapter 7: Surgical Management of Emphysema*

**Svati Singla Long, MD**
Radiologist
Women's Imaging
Raleigh Radiology
Raleigh, North Carolina
*Chapter 30: Management of Concomitant Carotid and Coronary Artery Disease*

**Natalie Lui, MD**
Surgical Resident
Department of Surgery
UCSF School of Medicine
San Francisco, California
*Chapter 17: Mediastinal Disease*

**Ying Wei Lum, MD**
Assistant Professor
Division of Vascular Surgery & Endovascular Therapy
Johns Hopkins School of Medicine
Baltimore, Maryland
*Chapter 40: Thoracoabdominal Aneurysms*

**Malcolm J. MacDonald, MD**
Clinical Assistant Professor
Department of Cardiothoracic Surgery
Division of Pediatric Cardiac Surgery
Falk Cardiovascular Research Center
Stanford, California
*Chapter 69: Pulmonary Atresia with Ventricular Septal Defect and Major Aortopulmonary Collaterals*

**Michael M. Madani, MD, FACS**
Professor
Division of Cardiothoracic Surgery
University of California San Diego, Medical Center
San Diego, California
*Chapter 45: Surgical Treatment of Chronic Pulmonary Thromboembolic Disease*

**Kaushik Mandal, MD, MPH, MS, FESC, FRCS(CTh)**
Assistant Professor
Division of Cardiac Surgery
The Johns Hopkins Medical Institutions
Baltimore, Maryland
*Chapter 6: Thoracic Infections*
*Chapter 33: Aortic Root Replacement*
*Chapter 90: Management of Adults with Congenital Heart Disease*

**David Mason, MD**
Staff Surgeon
Department of Thoracic and Cardiovascular Surgery
The Cleveland Clinic
Cleveland, Ohio
*Chapter 21: Benign and Malignant Pleural Tumors*

**Douglas J. Mathisen, MD**
Chief
Department of Cardiothoracic Surgery
Massachusetts General Hospital
Boston, Massachusetts
*Chapter 8: Tracheal Diseases*

**D. Michael McMullan, MD**
Associate Professor of Surgery
Department of Pediatric Cardiac Surgery
Seattle Children's Hospital
University of Washington
Seattle, Washington
*Chapter 72: Truncus Arteriosu*
*Chapter 87: Extracorporeal Membrane Oxygenation in Pediatric Cardiac Care*

**Robert A. Meguid, MD, MPH**
Assistant Professor of Surgery
Section of General Thoracic Surgery
Division of Cardiothoracic Surgery
University of Colorado Denver School of Medicine
Aurora, Colorado
*Chapter 18: Chest Wall Tumors*

**Avedis Meneshian, MD**
Assistant Professor of Surgery
Division of Thoracic Surgery
Department of Surgery
Johns Hopkins Medical Institutions
Baltimore, Maryland
*Chapter 13: Congenital Esophageal Anomalies*

**Christian A. Merlo, MD, MPH**
Assistant Professor of Medicine
Division of Pulmonary and Critical Care Medicine
The Johns Hopkins University School of Medicine
Baltimore, Maryland
*Chapter 5: Benign Diffuse Pulmonary Disorders*

**Tomislav Mihaljevic, MD**
Chief of Staff, Chair
Heart and Vascular Institute
Cleveland Clinic Abu Dhabi
Abu Dhabi, United Arab Emirates
*Chapter 36: Mitral Valve Repair for Degenerative Disease*

**R. Scott Mitchell, MD**
Professor of Cardiovascular Surgery
Department of Cardiothoracic Surgery
Stanford University School of Medicine
Stanford, California
*Chapter 39: Ascending and Arch Aneurysms of the Aorta*

**Michael C. Mongé, MD**
Attending Surgeon
Division of Cardiovascular-Thoracic Surgery
Ann & Robert H. Lurie Children's Hospital of Chicago
Department of Surgery
Northwestern University Feinberg School of Medicine
Chicago, Illinois
*Chapter 84: Vascular Rings and Pulmonary Artery Sling*

**Samia Mora, MD, MHS**
Assistant Professor of Medicine
Harvard Medical School
Associate Physician
Cardiovascular Medicine
Brigham and Women's Hospital
Boston, Massachusetts
*Chapter 56: Echocardiography in Cardiac Surgery*

**David L.S. Morales, MD**
Professor and Chair of Pediatric Cardiothoracic Surgery
Department of Pediatric Cardiothoracic Surgery
University of Cincinnati College of Medicine
Chief, Pediatric Cardiothoracic Surgery
Department of Pediatric Cardiothoracic Surgery
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio
*Chapter 65: Ventricular Septal Defects*

**Victor O. Morell, MD**
Associate Professor of Surgery and Chief
Division of Pediatric Cardiothoracic Surgery
Children's Hospital of Pittsburgh
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania
*Chapter 67: Aortopulmonary Window*
*Chapter 73: Total Anomalous Pulmonary Venous Connection*

**Sudish C. Murthy, MD, PhD**
Staff Surgeon
Department of Thoracic and Cardiovascular Surgery
The Cleveland Clinic
Cleveland, Ohio
*Chapter 21: Benign and Malignant Pleural Tumors*

**Kelly K. Nagasawa, MD**
Chief Resident in Surgery
Division of Cardiothoracic Surgery
University of Utah Affiliated Hospitals
Salt Lake City, Utah
*Chapter 1: Preoperative Evaluation of the Thoracic Surgical Patient*

**Kristen Nelson, MD**
Assistant Professor of Anesthesiology/Critical Care Medicine and Pediatrics
Department of Anesthesiology/Critical Care Medicine
Johns Hopkins University School of Medicine
Baltimore, Maryland
*Chapter 88: Ventricular Assist Devices in Children*

**Richard G. Ohye, MD**
Associate Professor
Department of Cardiac Surgery
University of Michigan C. S. Mott Children's Hospital
Ann Arbor, Michigan
*Chapter 74: Transposition of the Great Arteries*

**Eric J. Okum, MD**
Attending Cardiothoracic Surgeon
Tri Health Heart Institute
Adjunct Associate Professor
University of Cincinnati College of Medicine
Cincinnati, Ohio
*Chapter 47: Pericardial Disease*

**Mark B. Orringer, MD**
Professor of Surgery
Department of Surgery
Section of Thoracic Surgery
University of Michigan Medical Center
Ann Arbor, Michigan
*Chapter 16: Esophageal Cancer*

**Jacob Ostrowsky, CCP**
Perfusionist
Department of Pediatric Cardiothoracic Surgery
Rainbow Babies and Children's Hospital
Cleveland, Ohio
*Chapter 61: Cardiopulmonary Bypass in the Pediatric Patient*

**Nishant D. Patel, MD**
Resident
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland
*Chapter 13: Congenital Esophageal Anomalies*

**Eric A. Peck, MD**
Cardiothoracic Surgeon
Department of Cardiothoracic Surgery
California Cardiac Surgeons
Bakersfield, California
*Chapter 28: Off-Pump Coronary Artery Bypass*

**Stacie B. Peddy, MD, MS**
Assistant Professor of Anesthesiology and Critical Care
Department of Anesthesiology and Critical Care Medicine
The Children's Hospital of Philadelphia
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania
*Chapter 60: Perioperative Critical Care of the Pediatric Cardiac Surgical Patient*

**Lester C. Permut, MD, FACS**
Clinical Associate Professor of Surgery
Division of Cardiac Surgery
Seattle Children's Hospital
University of Washington School of Medicine
Seattle, Washington
*Chapter 78: Surgery for Left Ventricular Outflow Tract Obstruction in Children*

**Joachim Photiadis, MD**
Senior Staff Surgeon
German Pediatric Heart Centre
Asklepios Clinic
Sankt Augustin, Germany
*Chapter 85: Ebstein's Anomaly*

**Lee Plantmason, MD**
Resident Physician
Department of Emergency Medicine
University of Southern California Keck School of Medicine
Los Angeles, California
*Chapter 17: Mediastinal Disease*

**Mark D. Plunkett, MD**
Chief, Frank C. Spencer Endowed Chair
Department of Surgery
Division of Cardiothoracic Surgery
University of Kentucky College of Medicine
Lexington, Kentucky
*Chapter 70: Pulmonary Stenosis and Pulmonary Atresia with Intact Ventricular Septum*

**Jarrod D. Predina, MD**
Resident
Department of Surgery
Massachusetts General Hospital, Harvard Medical School
Boston, Massachusetts
*Chapter 22: Diaphragmatic Disorders*

**Zuhab A. Qamar, BA**
Department of Cardiac Surgery
University of Michigan C. S. Mott Children's Hospital
Ann Arbor, Michigan
*Chapter 74: Transposition of the Great Arteries*

**Amy L. Rahm, MD**
Division of Cardiothoracic Surgery
Department of Surgery
UC Davis Medical Center
Sacramento, California
*Chapter 89: Pediatric Cardiac Transplantation*

**Siva Raja, MD, PhD**
Associate Staff
Department of Thoracic and Cardiovascular Surgery
The Cleveland Clinic
Cleveland, Ohio
*Chapter 21: Benign and Malignant Pleural Tumors*

**Dan J. Raz, MD**
Assistant Professor
Department of Thoracic Surgery
City of Hope Medical Center
Duarte, California
*Chapter 8: Tracheal Diseases*

**Anees J. Razzouk, MD**
Professor
Department of Cardiovascular and Thoracic Surgery
Loma Linda University Medical Center and Children's Hospital
Loma Linda, California
*Chapter 89: Pediatric Cardiac Transplantation*

**Jon R. Resar, MD**
Associate Professor of Medicine, Director Adult Cardiac Catheterization Laboratory and Interventional Cardiology
Department of Medicine/Cardiology
Johns Hopkins University School of Medicine
Johns Hopkins Hospital
Baltimore, Maryland
*Chapter 55: Cardiac Catheterization and Interventions*

**Marco Ricci, MD, MBA**
Professor of Surgery
Chief, Division of Cardiothoracic Surgery
Department of Surgery
University of New Mexico Health Science Center
Albuquerque, New Mexico
*Chapter 78: Surgery for Left Ventricular Outflow Tract Obstruction in Children*

**Adam Richter, MD**
Resident in Surgery
Department of Surgery
University of Texas Southwestern
Dallas, Texas
*Chapter 48: Primary Cardiac Tumors*

**Richard Ringel, MD**
Associate Professor of Pediatrics
Department of Pediatrics
Johns Hopkins School of Medicine
Baltimore, Maryland
*Chapter 63: Patent Ductus Arteriosus*
*Chapter 64: Atrial Septal Defects and Partial Anomalous Pulmonary Venous Connection*

**Michael P. Robich, MD, MSPH**
Fellow in Cardiothoracic Surgery
Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic Foundation
Cleveland, Ohio
*Chapter 31: Mechanical Complications of Myocardial Infarction*

**Mark D. Rodefeld, MD**
Associate Professor of Surgery
Department of Surgery
Indiana University School of Medicine
Indianapolis, Indiana
*Chapter 79: Coarctation of the Aorta and Interrupted Aortic Arch*

**Glenn S. Roseborough, MD, FACS, RVT**
Medical Director
Vascular Division of Salem CardioVascular Associates
Salem, Oregon
*Chapter 40: Thoracoabdominal Aneurysms*

**G.D. Rushing, MD**
Clinical Associate
Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic Foundation
Cleveland, Ohio
*Chapter 27: Primary Coronary Artery Bypass Surgery*

Stuart W. Harrington Professor of Surgery
Division of Cardiovascular Surgery
Mayo Clinic
Rochester, Minnesota
*Chapter 46: Role of Surgery in Management of Hypertrophic Cardiomyopathy*

**Jamie McElrath Schwartz, MD**
Attending Physician
Department of Anesthesiology and Pain Medicine
Children's National Medical Center
Washington, DC
*Chapter 60: Perioperative Critical Care of the Pediatric Cardiac Surgical Patient*

**Christopher M. Sciortino, MD**
Assistant Professor of Surgery
Division of Cardiac Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland
*Chapter 86: Congenital Anomalies of the Sinuses of Valsalva and Aortico–Left Ventricular Tunnel*

**Brandi B. Scully, MD**
Surgeon
Department of Surgery
Baylor College of Medicine
Houston, Texas
*Chapter 65: Ventricular Septal Defects*

**Paul Sergeant, MD, PhD**
Professor
Cardiac Surgery
Gasthuisberg University Hospital
Leuven, Belgium
*Chapter 28: Off-Pump Coronary Artery Bypass*

**Ashish S. Shah, MD**
Associate Professor of Surgery
Department of Surgery
The Johns Hopkins Hospital
Baltimore, Maryland
*Chapter 11: Lung and Heart–Lung Transplantation*

**Jay G. Shake, MD**
Assistant Professor
Department of Surgery
Scott & White Healthcare
Texas A & M Health Science Center
Temple, Texas
*Chapter 29: Reoperative Coronary Artery Bypass Surgery*

**Sara J. Shumway, MD**
Professor of Surgery, Surgical Director Lung Transplantation, Vice Chief, Division of Cardiothoracic Surgery
Department of Surgery
University of Minnesota
Minneapolis, Minnesota
*Chapter 50: Cardiac Transplantation*

**Ming-Sing Si, MD**
Assistant Professor
Department of Cardiac Surgery
University of Michigan C. S. Mott Children's Hospital
Ann Arbor, Michigan
*Chapter 74: Transposition of the Great Arteries*

Edward D. Churchill Professor of Surgery
Chief, Division of Cardiac Surgery, Department of Surgery
Massachusetts General Hospital, Harvard Medical School
Boston, Massachusetts
*Chapter 41: Aortic Dissection*

**Brad S. Sutton, MD, MBA**
Assistant Professor of Medicine and Business
Department of Medicine
University of Louisville School of Medicine
Louisville, Kentucky
*Chapter 44: Pacemaker and Defibrillator Therapy in Cardiac Surgery Patients*

**Joshua T. Taylor, MD**
General Surgery Resident
Department of Surgery
Vanderbilt University
Nashville, Tennessee
*Chapter 20: Benign Pleural Disorders*

**Pierre Theodore, MD**
Associate Professor of Surgery
Division of Adult Cardiothoracic Surgery
Department of Surgery
UCSF School of Medicine
San Francisco, California
*Chapter 17: Mediastinal Disease*

**Jess Thompson, MD, MSc**
Resident
Division of Cardiovascular Surgery
Mayo Clinic and Foundation
Rochester, Minnesota
*Chapter 71: Double Outlet Right Ventricle*

**Tomasz A. Timek, MD**
Assistant Clinical Professor
West Michigan Cardiothoracic Surgeons and Spectrum Health
Michigan State University
Grand Rapids, Michigan
*Chapter 34: Mitral Valve Pathophysiology*

**Betty C. Tong, MD, MHS**
Assistant Professor
Division of Cardiovascular and Thoracic Surgery
Department of Surgery
Duke University Medical Center
Durham, Indiana
*Chapter 10: Pulmonary Metastasis*

**Dario Troise, MD**
Staff Cardiac Surgeon
Pediatric Cardiac Surgery Unit
Giovanni XXIII Pediatric Hospital, University of Bari
Bari, Italy
*Chapter 64: Atrial Septal Defects and Partial Anomalous Pulmonary Venous Connection*

**Victor T. Tsang, MS, MSc, FRCS**
Chief of Surgery
Department of Cardiothoracic Surgery
Great Ormond Street Hospital for Children NHS Trust
London, United Kingdom
*Chapter 77: Tricuspid Atresia and the Functionally Single Ventricle*

**Ross Ungerleider, MD, MBA**
Professor of Surgery
Pediatric Cardiovascular Surgery
Brenner Children's Hospital
Wake Forest University School of Medicine
Winston-Salem, North Carolina
*Chapter 61: Cardiopulmonary Bypass in the Pediatric Patient*

**Ara A. Vaporciyan, MD, FACS, MHPE**
Professor
Department of Thoracic and Cardiovascular Surgery
The University of Texas M.D. Anderson Cancer Center
Houston, Texas
*Chapter 9: Primary Lung Cancer*

**Jens Vogel-Claussen, MD**
Associate Professor of Radiology
Department of Radiology
Institute for Diagnostic and Interventional Radiology
Hanover, Germany
*Chapter 57: Cardiac Magnetic Resonance Imaging*

**Luca A. Vricella, MD, FACS**
Associate Professor of Surgery and Pediatrics
Director, Pediatric Cardiac Surgery and Heart Transplantation
Johns Hopkins University School of Medicine
Baltimore, Maryland
*Chapter 58: Milestones in Congenital Cardiac Surgery*
*Chapter 82: Cardiac Surgical Intervention in Pediatric Patients with Connective Tissue Disorders*
*Chapter 86: Congenital Anomalies of the Sinuses of Valsalva and Aortico–Left Ventricular Tunnel*

**Giorgio Zanotti, MD**
Chief Resident
Department of Surgery
Duke University Medical Center
Durham, North Carolina
*Chapter 82: Cardiac Surgical Intervention in Pediatric Patients with Connective Tissue Disorders*

# FOREWORD

Paradoxically, our information age has flooded us with an unprecedented volume of medical information (the proverbial "drinking from a firehose"), yet clarity and wisdom still seem as rare as a desert oasis. This long-awaited second edition of the *Johns Hopkins Textbook of Cardiothoracic Surgery* is an arrival welcomed by all surgeons in our specialty, from the novice to the seasoned, who are thirsty for the insight and perspective vested in each chapter. The subtle title change from "manual" to "textbook" belies the substantial additions and enhancements that mark the second edition, including new chapters and authors, key concepts, color accenting, and expanded bibliographies. This work takes its place as one of the most comprehensive yet readable books on the subject and is the best example I know to support the argument that the printed textbook is alive and well, and in great demand.

Although born at Hopkins under Dr Yuh's leadership while he was on our faculty, the project has grown to include experts from many institutions, which parallels the collaborative and information-sharing spirit of our profession. This is particularly so with cardiothoracic surgeons, who delight over sketches of operations drawn on dinnertime napkins and who earn deep satisfaction from warning each other about pitfalls and unseen hazards of procedures and practice. David Yuh and his co-editors Luca Vricella, Steve Yang, and John Doty deserve rich praise for shepherding this effort to collect so much wisdom within a single cover.

Finally, although it may seem odd that a Hopkins book is edited by a Yale surgeon, straddling of these two great institutions by prominent physician educators has precedence in Halsted, Welch, Cushing, Gott, and Reitz, to name just a few. Indeed, three of the four cardiac chiefs at Hopkins since Blalock were Yale graduates. Johns Hopkins and Yale have many similar attributes, not the least of which is a deep tradition and commitment to medical education and the training of young physicians. We are remembered best by the lives we touch, those of our patients and our students.

*Duke E. Cameron, MD*
*Cardiac Surgeon-in-Charge*
*The Johns Hopkins Hospital*

# PREFACE

Much has changed since first edition of the *Johns Hopkins Manual of Cardiothoracic Surgery* was published in 2007. First, the tried and true Halstedian-based paradigm of cardiothoracic surgical residency training as an 8- to 10-year apprenticeship has been challenged by new duty hour restrictions, intense scrutiny of clinical outcomes, and a seemingly endless parade of evidence-based quality measures and documentation requirements. Whether one deems these changes as progress or not, it is clear that they have affected the environment in which today's residents must learn the craft of cardiothoracic surgery, placing a premium on the time during which they can develop and reinforce their knowledge base from real-life clinical scenarios. Second, the advent of new integrated cardiothoracic surgical residency programs, taking trainees right out of medical school, have made integrated, practical, and concise references with content readily accessible to uninitiated medical graduates even more valuable. Finally, tremendous advances in new technologies, including catheter-based valve delivery systems, less-invasive surgical techniques, new mechanical circulatory devices, and hybrid approaches in the treatment of cardiothoracic disease have added to the already considerable knowledge base that cardiothoracic trainees must assimilate.

We have been gratified that the first edition of the *Johns Hopkins Manual of Cardiothoracic Surgery* occupies a place among highly respected textbooks in our field and, in fact, serves as a sourcebook for the Thoracic Surgical Directors Association web-based curriculum. The second edition of this textbook, renamed the *Johns Hopkins Textbook of Cardiothoracic Surgery*, remains a comprehensive single-volume textbook covering topics in adult cardiac, congenital cardiac, and general thoracic surgery. It is intended as a core reference for all caregivers in the field of cardiothoracic surgery. We again formatted the book to facilitate review, prefacing most chapters with a "Key Concepts" section highlighting the epidemiology, pathophysiology, clinical features, diagnostic and treatment strategies, and outcomes for each topic. Additionally, based on our own critique of the first edition and thoughtful suggestions from its readers, we have made substantial improvements in the new edition, including colorized figures throughout the book, board-review questions and answers, and a greater emphasis on decision-making flow charts that are particularly useful in preparing for oral board examinations.

The content of this textbook reflects the rapidly changing field of cardiothoracic surgery. In addition to the basic curriculum required for certification, we endeavored to include advanced concepts, controversial issues, and new technologies. For example, we have included completely reworked chapters covering Primary Lung Tumors, Mitral Valve Repair, and Mechanical Circulatory Support, as well as entirely new chapters covering Surgical Therapies for Atrial Fibrillation, Cardiac Surgery in Adults with Congenital Heart Disease, and Stem Cell Therapies for Cardiovascular Disease.

As its title implies, most of the contributors to the *Johns Hopkins Textbook of Cardiothoracic Surgery* consist of current or past faculty, residents, fellows, and students at The Johns Hopkins Hospital. The fact that, in the course of our daily routines, we sometimes forget that many of our colleagues are nationally and internationally recognized experts in their respective fields owes to their humility and collegiality. Nevertheless, striving to produce the most authoritative textbook possible, we solicited many experts outside of the Hopkins community. We remain indebted to all of our contributors who generously donated their time and effort to make this a truly collaborative project.

In addition to the contributing authors, we owe thanks to many other individuals. We greatly appreciate the patience and support of our editors and production staff at McGraw-Hill, in particular Christie Naglieri, Brian Belval, and Armen Ovsepyan, as well as the staff at Electronic Publishing Services. We are equally indebted to Kimberly Behrens in the Division of Cardiac Surgery at Hopkins, who took on the onerous and painstaking task of coordinating the many components of this book along with reminding contributors and, yes, Editors to keep on schedule. Also within the Division, Donna Riley, Diane Alejo, Lori Garrison, and Genie Sessa provided invaluable support and friendship. Finally, we wish to express our profound respect and admiration for our colleagues and staff on the cardiac and general thoracic surgical services at The Johns Hopkins Hospital who, in addition to being the very best in their professions, are among the most giving and thoughtful individuals that one could hope to work with.

The sheer magnitude of work involved with assembling the first edition gave us pause in considering embarking on a second edition. We hope that you, like us, are glad that we did. Finally, we all would like to express our profound love and appreciation to our families who, rather than question our sanity, continued to support and encourage us in this undertaking.

# Preoperative Evaluation of the Thoracic Surgical Patient

*Kelly K. Nagasawa*
*John R. Doty*

**KEY CONCEPTS**

- Role of preoperative evaluation
  - The role of the preoperative evaluation is to (1) determine the risk and morbidity associated with the proposed operation and (2) identify any patient conditions or factors that can be treated to mitigate the risk of morbidity and mortality.
- History and physical examination
  - The examination should focus on pulmonary and cardiac conditions, as these represent the most common complications after thoracic surgery.
- Functional and performance status
  - The patient's ability to withstand and recover from a major thoracic operation should be assessed prior to surgery. Standard tests such as the Karnofsky score, Zubrod score, DASI questionnaire, stair climbing, and shuttle walk are all useful metrics.
- Pulmonary and cardiac testing
  - Pulmonary function testing remains the cornerstone of preoperative evaluation. $FEV_1$, DLCO, and postoperative predicted values are important predictors of outcomes. Assessment of cardiovascular risk should include noninvasive testing in patients with a history of cardiac disease and more invasive testing as indicated.
- Risk stratification models
  - Mathematical models using the Epithor and Society of Thoracic Surgeons General Thoracic Database can provide reasonably accurate risk stratification for patients undergoing major thoracic surgery.

## INTRODUCTION

Preoperative evaluation of the prospective thoracic surgical patient is a complex process, as patients presenting for major noncardiac thoracic surgery today tend to be older, have underlying chronic obstructive lung disease, and often have multiple comorbidities. Pulmonary and cardiovascular complications occur frequently in the postoperative period and should be aggressively identified and mitigated where possible. The ability to predict and stratify which patients are at a higher risk of complications allows appropriate patient selection and helps guide operative approaches. Preoperative evaluation, therefore, serves two purposes: (a) determining the risk and morbidity associated with the proposed surgical procedure and (b) identifying any patient conditions or factors that could be addressed in the preoperative period to decrease the risk of morbidity and mortality.[1]

## HISTORY AND PHYSICAL EXAMINATION

There is no substitute for a thorough history and physical examination combined with the sound clinical judgment of an experienced physician. There are several specific components in the history of a potential thoracic surgical patient that should be investigated. These important components include presenting symptoms, previous diagnosis of cardiopulmonary disease, comorbid conditions such as diabetes mellitus, renal and liver dysfunction, current medications and allergies, tobacco use, and alcohol use.[1] As the most frequent complications are pulmonary and cardiovascular, the history should focus on these areas.

The physical examination should likewise focus on several signs that indicate important comorbidities. Examination begins with an assessment of overall appearance, looking

especially for evidence of cachexia and generalized wasting. Cervical and supraclavicular lymphadenopathy can indicate metastatic disease. Cardiovascular examination should note murmurs (valvular disease), arrhythmias (atrial fibrillation), and presence of peripheral edema (congestive heart failure). Pulmonary examination should note respiratory rate, use of accessory respiratory muscles, and presence of wheezing or rales. Abdominal examination can confirm the presence of regional tenderness, organomegaly, masses, or adenopathy. The extremities should be examined for equality of pulses, cyanosis, or clubbing. Neurologic examination should focus on motor strength and gait, both of which are important because deficits can affect postoperative mobilization and rehabilitation.

## ASSESSMENT OF PERFORMANCE AND FUNCTIONAL STATUS

Following the history and physical examination, it is critical to estimate the patient's performance and functional status. Performance status assesses the patient's ability to partake in activities of everyday life. The two most common methods are the Karnofsky score[2] and Zubrod (Eastern Cooperative Oncology Group [ECOG]) system.[3] Patients with a Karnofsky score of 80 to 100 percent or an ECOG score of 0 to 1 have essentially normal risk of morbidity and mortality. As the performance status declines, the operative risk increases.

The functional status assesses the patient's current ability to perform physical activity. This can be done with a physical test of locomotion (e.g., 6-min walk or stair climbing), cardiopulmonary exercise testing (CPEx), or self-administered questionnaires such as the Duke Activity Status Index (DASI).[4] A healthy adult should be able to walk at least 1600 ft in 6 min and climb at least five flights of stairs. An alternative to stair climbing is the shuttle walk. Patients who are unable to perform at least 25 shuttles are considered a prohibitive operative risk because this equates to a maximal oxygen uptake of less than 10 mL/kg/min.[5] Oxygen desaturation during testing is considered significant when the $Spo_2$ drops by 4 percent or more with activity.[6,7]

## LABORATORY STUDIES

Standard blood work should include a complete blood count, electrolyte panel, and clotting parameters. Liver function tests and serum calcium levels should be checked in patients with suspected or confirmed malignancy.

## PULMONARY FUNCTION TESTING

Pulmonary function testing is the cornerstone of risk assessment for patients undergoing pulmonary resection. Unfortunately, no single pulmonary function test can perfectly predict the likelihood of postoperative morbidity or mortality. Slinger and Darling[8] have therefore proposed a simple "3-legged stool" of prethoracotomy respiratory assessment that provides a more robust foundation for preoperative respiratory assessment. This algorithm evaluates pulmonary function in three areas: respiratory mechanics (forced expiratory volume in 1 s [$FEV_1$]), parenchymal function (diffusing capacity for carbon monoxide [DLCO]), and cardiopulmonary interaction ($Vo_2max$).

In 2007, the American College of Chest Physicians stated that a patient may proceed directly to surgical resection with no further pulmonary testing if the preoperative $FEV_1$ is greater than 2 L for pneumonectomy candidates and greater than 1.5 L for lobectomy candidates.[9] In addition to providing an estimate of operative risk, preoperative values of $FEV_1$ and DLCO can be used to calculate predicted postoperative values for both $FEV_1$ (ppo-$FEV_1$) and DLCO (ppo-DLCO), which are themselves predictors of operative risk. The ppo-$FEV_1$ can be calculated using the equation of ppo-$FEV_1$ = $FEV_1 \times (1 - [\text{segments resected}/19]/100)$.[10] The ppo-DLCO is calculated using a similar equation.[11] Patients with postoperative $FEV_1$ or a postoperative DLCO greater than 40 percent are generally considered low-risk surgical patients. Although no single test can unilaterally predict the likelihood of major postoperative morbidity, ppo-DLCO has been shown to be a strong predictor of postoperative morbidity and mortality following pulmonary resection.[12]

CPEx is recommended when the ppo-$FEV_1$ or ppo-DLCO is less than 40 percent, or if the product of ppo-FEV1 × ppo-DLCO is less than 1650. The most commonly used result of CPEx is the $MVo_2$, which is the most specific predictor of postoperative pulmonary complications following pulmonary resection.[13] Patients with an $MVo_2$ greater than 15 to 20 mL/kg/min are at low or "acceptable" risk for postoperative morbidity or mortality. Conversely, a patient is considered high risk for surgery if the $MVo_2$ is less than 10 to 12 mL/kg/min.[14]

It is imperative that any patient being considered for major noncardiac thoracic surgery also undergo assessment of cardiovascular risk, as cardiac complications are the second most common cause of morbidity and mortality in the thoracic surgical patients. In general, patients who are on any cardiac medication have a history of a cardiac condition (prior myocardial infarction, congestive heart failure, diabetes, and cerebrovascular disease), or are unable to climb more than two flights of stairs should be referred for cardiology evaluation. The American Heart Association recommends noninvasive testing as a minimum for such patients, with additional invasive testing and intervention as indicated.

## RISK STRATIFICATION

The information and data gathered through history and physical examination, laboratory testing, and pulmonary function testing guide a more educated assessment of the

patient's risk of morbidity and mortality associated with a specific major thoracic surgical procedure. The surgeon can now perform a risk assessment using one of the several available scoring systems. Although no single system is superior, these risk models help in selecting appropriate patients for surgery and educating the patient on general relative risk.

The largest and most validated global risk scoring system is the Thoracoscore. This model was created using a logistic regression analysis of over 15,000 patients from the Epithor database. The Thoracoscore is calculated using nine patient variables significantly associated with the occurrence of in-hospital deaths. These nine variables included age, gender, American Society of Anesthesiology rating (ASA) score, performance status dyspnea score, priority of surgery, extent of surgery, malignant diagnosis, performance status, and composite comorbidity score. An increasing risk profile in a patient is significantly associated with a higher risk of death.

Patients at least 65 years old were found to be at three times higher risk of in-hospital death compared with patients under the age of 55. Malignant pathology and pneumonectomy are also associated with over three times higher risk of mortality. Increasing number of associated comorbidities was also found to increase mortality. There were also 10 major comorbidities that accounted for 95 percent of the documented associated morbidities. These comorbidities can be loosely grouped into pulmonary (smoking, chronic obstructive pulmonary disease [COPD]), cardiovascular (arterial hypertension, heart disease, diabetes mellitus, peripheral vascular disease, and obesity), and chronic impairment (history of cancer, alcoholism).[15]

Kozower and colleagues examined the Society of Thoracic Surgeons General Thoracic Database (STS-GTDB) to create three different models of perioperative risk of lung cancer resection: mortality, morbidity, and combined mortality and morbidity. Data from 18,000 lung cancer resections were used to identify 12 risk factors for mortality following lung cancer resection. These 12 factors were pneumonectomy, bilobectomy, ASA rating, Zubrod performance status, renal dysfunction, induction chemoradiation therapy, steroids, age, urgent procedures, male gender, $FEV_1$, and body mass index.[16] Of these factors, poor performance status (high Zubrod score, poor physical status [high ASA rating]), and induction chemoradiation had the largest impact on morbidity and mortality.

Wright and colleagues also used the STS-GTDB to examine prolonged length of hospital stay (PLOS) as a surrogate of complications following lobectomy for lung cancer. Data from nearly 5000 patients were used to identify risk factors for PLOS. The risk factors associated with PLOS have considerable overlap with the Kozower models and include age, Zubrod score, male gender, ASA score, insulin-dependent diabetes mellitus, renal dysfunction, induction therapy, and percentage predicted $FEV_1$.[17] Table 1-1 summarizes these three risk stratification systems with their various risk factors.

**TABLE 1-1: Summary of Risk Factors for Noncardiac Thoracic Surgery**

| Model | Thoracoscore (Falcoz) | Kozower | Wright |
|---|---|---|---|

| Risk factors | Age<br>Dyspnea score<br>Male gender<br>ASA rating<br>Priority of surgery<br>Extent of surgery<br>Malignant diagnosis<br>Composite comorbidity score<br>Performance status | Age<br>Zubrod score<br>Male gender<br>ASA rating<br>Renal dysfunction<br>Induction therapy<br>$FEV_1$<br>Steroids<br>Body mass index<br>Pneumonectomy<br>Bilobectomy<br>Urgent procedure | Age<br>Zubrod score<br>Male gender<br>ASA rating<br>Renal dysfunction<br>Induction therapy<br>% predicted $FEV_1$<br>Diabetes mellitus |

## CONCLUSION

The preoperative evaluation of the thoracic surgical patient is a complex process. Although each patient is different, the evaluation process should progress in the same systematic fashion each time. The process always starts with a thorough history and physical examination, followed by laboratory studies and pulmonary function testing. The preoperative assessment ultimately provides the information of each patient's risk of morbidity and mortality and aids both the surgeon and patient in operative decision making.

## PREOPERATIVE EVALUATION OF THE THORACIC SURGICAL PATIENT BOARD REVIEW QUESTIONS (CHAPTER 1)

1. Which of the following is correct regarding assessment of preoperative performance and functional status?
   A. A Karnofsky score of 10 percent is associated with a low risk of death.
   B. A Zubrod score of 10 is considered normal risk.
   C. A healthy adult should be able to climb one flight of stairs.
   D. Less than 25 shuttles is considered a prohibitive operative risk.
   E. A drop in oxygen saturation of 2 percent during activity is significant.

2. Which is true regarding pulmonary function testing?
   A. If the preoperative $FEV_1$ is greater than 1 L in a lobectomy candidate, no further testing is required.
   B. Predicted postoperative $FEV_1$ greater than 25 percent is a low-risk surgical patient.
   C. Predicted postoperative DLCO greater than 20 percent is a low-risk surgical patient.
   D. $MVO_2$ is the most specific predictor of postoperative pulmonary complications following pulmonary resection.
   E. Patients with an $MVO_2$ greater than 15 to 20 mL/kg/min are high risk for postoperative morbidity or mortality.

3. Which is correct regarding cardiac assessment of the thoracic surgical patient?
   A. Cardiac complications are an uncommon cause of complications after surgery.
   B. Patients with stable congestive heart failure do not require additional testing.
   C. Cardiac catheterization is the initial screening modality.
   D. Diabetes is not a risk factor for cardiac complications.
   E. A patient that cannot climb more than two flights of stairs should have formal cardiology evaluation.

4. Which of the following is not associated with increased mortality in the Thoracoscore model?
   A. ASA rating
   B. Female gender
   C. Malignant diagnosis
   D. Performance status
   E. Age

5. Which of the following is not associated with increased mortality in the STS-GTDB models?
   A. ASA rating
   B. Age
   C. Liver dysfunction
   D. Zubrod score
   E. Induction therapy

## ANSWERS

1. **Answer: D.** The inability to perform 25 shuttles has been correlated with a maximal oxygen uptake of less than 10 mL/kg/min and signifies prohibitive operative risk. A high Karnofsky score (80–100%) or low Zubrod score (0–1) is associated with low mortality. A healthy adult should be able to climb five flights of stairs. A drop in oxygen saturation of 4 percent or more during activity is considered significant.
2. **Answer: D.** Maximal oxygen uptake ($MVO_2$) is the most specific predictor of postoperative pulmonary complications following pulmonary resection. It is acceptable to proceed directly to surgical resection with no further pulmonary testing if the preoperative $FEV_1$ is greater than 2 L for pneumonectomy candidates and greater than 1.5 L for lobectomy candidates. Patients with predicted postoperative $FEV_1$ or predicted postoperative DLCO greater than 40 percent are generally considered low-risk surgical patients. Patients with an $MVO_2$ greater than 15 to 20 mL/kg/min are at low or "acceptable" risk for postoperative morbidity or mortality.
3. **Answer: E.** A patient that cannot climb more than two flights of stairs should have formal cardiology evaluation. Cardiac complications are the second most common cause of morbidity and mortality in the thoracic surgical patient. Patients with a history of a cardiac condition, including congestive heart failure and diabetes, should also be referred for cardiology evaluation. Noninvasive testing is the initial screening modality, with cardiac catheterization reserved for appropriate indications.

4. **Answer: B.** Male, not female gender, is associated with increased mortality. The other risk factors in the Thoracoscore model are age, dyspnea score, ASA rating, priority of surgery, extent of surgery, malignant diagnosis, composite comorbidity score, and performance status.

5. **Answer: C.** Renal, not hepatic, dysfunction is associated with increased mortality. Other risk factors in the STS-GTDB models include age, Zubrod score, ASA rating, induction therapy, and $FEV_1$.

# 2 Thoracic Trauma

*George J. Koenig Jr.*
*David T. Efron*

## KEY CONCEPTS

- Epidemiology
  - Twenty percent of all trauma patients sustain chest injuries.
- Pathophysiology
  - Thoracic injuries, like with all traumas, can result from blunt or penetrating mechanism. Fractures and soft tissue injuries are common. Compromised breathing remains a particularly urgent concern in these patients, which is unique to thoracic injuries and demonstrates common physiologic signs regardless of cause. Structures that can be injured include the protective bony thorax (ribs, sternum, scapula, and spinal column). The diaphragm inferiorly, and the soft tissue content of the thorax (heart, lungs, esophagus, and great vessels). Severe cardiovascular compromise can also result from injury to the chest.
- Clinical features
  - Outside of the pain of injury, obvious clinical compromise that results from thoracic injury includes primarily signs of respiratory embarrassment and hemodynamic instability. Presenting symptoms vary according to the injured structure. Potential symptoms include dyspnea, tachypnea, and pain on palpation. Signs include contusions, penetrating wounds, subcutaneous emphysema, crepitance, distant or unequal breath sounds on auscultation, muffled heart sounds, tracheal deviation, jugular venous distension, absent upper extremity pulses, shock, and distal neurologic deficit.
- Diagnostics
  - Physical examination including vital signs as part of the primary survey remains the initial most important diagnostic evaluation. Chest x-ray, upright where possible, is desirable. This will delineate injury to most bony structures, identify hemopneumothoraces, raise suspicion about mediastinal injury, and potentially aid in determination of trajectory of penetrating injuries. The patient's hemodynamic status and mechanism of injury guide further diagnostic workup. Focused assessment with sonography for trauma (FAST) ultrasound can identify presence of fluid or the absence thereof in the pericardial sac. Thoracic computed tomography (CT) scan and CT angiography are valuable and reliable in assessing injuries to the great vessels in stable patients at risk and helpful in determining at-risk structures given the trajectory of the penetrating injury. Esophagoscopy, bronchoscopy, and esophagography all play a role in assessing the integrity of these structures and identifying the need for operative repair. In some situations, diagnosis is made necessarily at the time of therapeutic intervention as in the placement of a chest tube for signs of a tension pneumothorax, relief of pericardial tamponade via an emergency department (ED) thoracotomy in an arrested patient, or pericardial window at laparotomy.
- Treatment
  - As with all trauma patients, the best approach in management is delineated by ATLS guidelines. Addressing the need for a secure airway and ensuring adequate breathing and circulation necessitates rapid assessment of the thorax, diagnosis, and intervention for life-threatening abnormalities. Further management depends on structure-specific injuries.
- Outcomes
  - Outcomes for thoracic trauma are widely varied, are injury and mechanism dependent, and vary tremendously according to patient presentation and the specific structures that are injured.

## INTRODUCTION

Approximately 20 percent of all trauma patients sustain injury to their thorax. Thoracic injuries are often obvious on presentation as with penetrating trauma from gunshot wounds or stab wounds. Sequelae may also be easier to identify due to the presence of subcutaneous emphysema or sucking chest wounds. Alternatively, thoracic injury may be indolent in nature as in some cases of blunt trauma where signs of injury may be more subtle, presenting solely with tachypnea or tachycardia. Understanding the mechanism of injury can increase awareness of potential injuries and help direct the diagnostic evaluation. Physical examination is essential in determining injuries as part of your initial assessment.

Guidelines promoted by the Advanced Trauma Life Support (ATLS) course offered by the American College of Surgeons remain the best approach to the care of injured patients. Control of airway, breathing, and circulation is of paramount importance to the successful management of thoracic trauma. After ensuring adequate control of the airway, the entire chest should be exposed. Bilateral chest rise and fall should be observed. The lungs should be auscultated to assess breath sounds. The front, back, and both axillae should be evaluated for external signs of trauma. Other physical findings such as tracheal position, heart sounds, and jugular venous status should be noted. Electrocardiographic leads should be placed and the rhythm determined. A chest x-ray should be obtained. All of this is accomplished as part of the ATLS primary survey.

Several further diagnostic tests are routinely used in the workup of thoracic trauma. The selection of these tests is based on the clinical condition, the mechanism of injury, and the examiner's suspicion of a particular injury. Ultrasound imaging is a simple and rapid method of identifying pericardial fluid and assessing cardiac wall motion,[1] and can be used to detect the presence of a pneumothorax.[2] In hemodynamically stable patients, thoracic computed tomography (CT), aortography, esophagography/esophagoscopy, and transesophageal ultrasound may also have a role in the diagnosis of thoracic injury. Ultimately, thoracotomy may be necessary for both diagnosis and therapy. It is important to note that patients with thoracic trauma frequently demonstrate multisystem trauma. The workup and therapy need to focus on addressing the most life-threatening injuries first, potentially not involving the thorax.

This chapter discusses the diagnosis and management of common thoracic injuries with a focus on the pathophysiologic perturbation that results from trauma. A structure-specific approach is presented (e.g., heart injury, lung injury, etc.), recognizing that injuries to multiple structures often occur simultaneously and need to be concomitantly managed.

## INJURIES TO THE BONY THORAX

The bony thorax comprises the sternum and manubrium anteriorly, a solid rib cage anterolaterally, and the vertebral column posteriorly. The upper thorax is also superficially covered by the scapulae posteriorly, and the clavicles are positioned along the anterior apices bilaterally. These structures combine to confer substantial protection to the underlying soft tissues. The vast majority of information regarding injuries to the bony thorax can be obtained from physical examination and the initial chest x-ray, followed by further radiographic imaging.

## RIB FRACTURES

Injury to the rib cage can range from simple rib fractures to flail segments that can alter breathing mechanics. Simple rib fractures are generally well tolerated. In the absence of underlying pathology, the treatment consists of pain control, incentive spirometry (IS), and aggressive pulmonary toilet. However, multiple rib fractures pose a greater challenge with pain control and can result in major morbidity in the older trauma patient (Fig. 2-1).[3] Morbidities include the need for intubation, development of pneumonia, and prolonged ventilator support. Mortality has been reported to be as high as 22 percent in elderly patients with multiple rib fractures.[4] The risk of death for all ages increases with the number of rib fractures. A large study using the National Trauma Databank showed a significant break point for mortality when more than six ribs were fractured.[5]

In patients with multiple fractures, early epidural analgesia should be considered. High thoracic epidural analgesia has been shown to improve outcomes.[6] The Eastern Association of the Surgery of Trauma Practice management

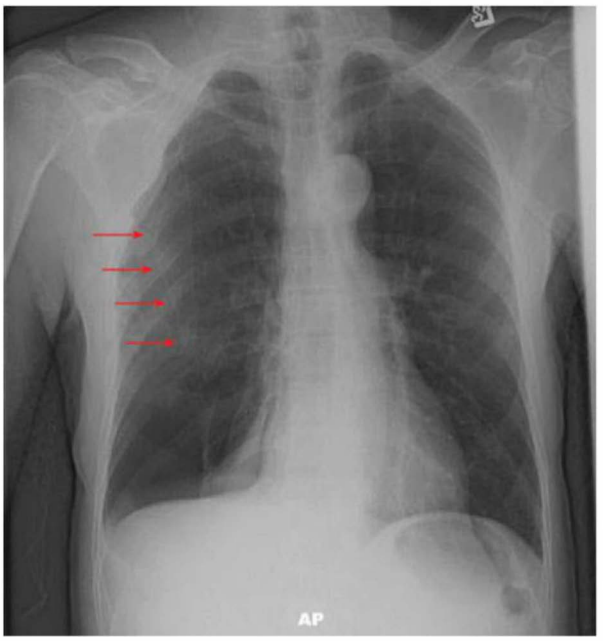

**FIGURE 2-1** Chest x-ray demonstrating multiple right-sided rib fractures (1–9).

guidelines for pain management in blunt thoracic trauma presents Level I recommendations that epidural anesthesia is effective and Level II recommendations that thoracic epidurals should be placed for patients >65 years with four or more rib fractures (when not contraindicated, a thoracic epidural should be used) and considered in younger patients with the same injuries.[7]

Vital capacity and IS can be used to determine if adequate pain control has been achieved. Morbidity and mortality improves if IS is ≥15 mL/kg while achieving adequate pain control. Appropriate analgesia allows the patient to better expand the lung. It also prevents significant atelectasis and helps the patient clear secretions, thereby reducing the risk of pneumonia. In addition to epidural and intercostal blocks, nonsteroidal anti-inflammatory drugs and opioid analgesics play an important role in obtaining adequate pain control.[8]

The location of rib fractures is very important in the workup of the multiply injured patient. Fracture of the upper ribs (first, second, and third) suggests that a significant force was transmitted to the thorax and consequently an increased risk of concomitant great vessel injury; fractures should heighten the suspicion for these injuries and guide diagnostic investigation accordingly. In stable patients, the investigation of choice to evaluate possible great vessel injury is a CT angiogram.[9] Alternatively, fracture of the lower ribs (eighth, ninth, and tenth) should raise the suspicion of injury of solid abdominal organs.

A segment of chest wall that is fractured in multiple places, resulting in an area of the bony thorax that is "free" from rigid fixation, is termed a flail chest. Small flail segments may be tolerated with good analgesia. Posterior flail segments benefit from several natural points of fixation (such as the overlying scapula) and do not contribute to respiratory embarrassment. However, larger flail segments, especially those encountered anteriorly and laterally, may compromise pulmonary function by blunting the negative inspiratory force of spontaneous inspiration. The negative pressure of the descending diaphragm preferentially collapses the chest wall, preventing aeration of the lung. In these cases, the treatment is positive pressure ventilation (PPV) (pneumatic stabilization) until the chest wall mechanics improves. Often, oxygenation is additionally impaired by the underlying pulmonary contusion that nearly always accompanies such an injury. The underlying pulmonary contusion and the protracted recovery usually govern the length of time needed for mechanical ventilation.

Occasionally, the flail segment requires fixation to maintain the integrity of the chest wall to allow ventilation and healing and re-establish lung volume. In addition, some ribs, fractured inward, may pose a threat to intrathoracic structures from sharp edges. A number of commercial systems of plates (both flat and U-shaped) are available for this.

## INJURIES TO THE THORACIC SPINE

Common causes of thoracic spinal fractures include falling from a height, motor vehicle accidents, and penetrating trauma. The entire spinal column is inspected and palpated on secondary survey. Crepitus or tenderness found on examination, suspicion due to mechanism, or the inability to obtain an adequate examination due to other distracting injuries should prompt additional radiographic study. CT scans are the preferred imaging modality for the detection of spinal fractures due to the speed of acquisition and the increased sensitivity and specificity.[10] Because of the mechanisms of injury, many of these patients routinely have CT scans of their chest, abdomen, and pelvis to diagnose injuries within the chest or abdomen. Reconstructions of the thoracic spine can be created from these CT scans, further increasing sensitivity of detection of spine fractures.[11]

These CT reconstructions are helpful in determining if a fracture of the thoracic spine is stable or unstable. Fractures of the vertebral body or transverse process are common whereas unstable fractures are not. There have been several classification systems to describe unstable fractures. The most commonly used classification system was described by Denis et al.[12] This classification system divides the spine into three columns (anterior, posterior, and middle). Disruption of two of the three columns is definitive for an unstable fracture. Unstable fractures require spinal precautions and eventual fixation. Assessment of the spinal canal and injury of the cord often requires magnetic resonance imaging (MRI).

In penetrating trauma, there is no role for the administration of steroids for spinal cord injuries. However, in blunt trauma, the administration of steroids for patients with neurologic deficits is controversial.[13] The basis for their administration was derived from a post hoc analysis of the data collected in the National Acute Spinal Cord Injury Study (NACIS).[14,15] This led to the following recommendations. A bolus of methylprednisolone should be administered within 8 h of injury at a dose of 30 mg/kg/h. If the diagnosis is made within 3 h of injury, the infusion of methylprednisolone should be continued for 23 h at a dose of 5.4 mg/kg/h. If the steroid is started between 3 and 8 h, the infusion should be maintained for 48 h.

However, the results from this post hoc analysis have not been able to be duplicated. In addition, other studies have shown harm from steroid administration.[16] Higher rates of respiratory tract infections, sepsis, urinary tract infections, and wound site infections have been associated with the administration of methylprednisolone. Subsequent evidence-based reviews of the literature have also not shown a benefit.[17-19] The lack of sufficient evidence prompted the deletion of steroid administration for spinal cord injury from the 8th edition of the ATLS course.

## OTHER THORACIC BONY INJURIES

Sternal fractures are most often treated conservatively and do require additional treatment (Fig. 2-2); however, the presence of a sternal fracture can be a strong indicator of severe force injury and should raise awareness for associated injuries, such as blunt aortic, cardiac, and pulmonary injury. Scapular fractures also rarely contribute to the life-threatening nature of chest trauma. Similar to sternal fractures, their presence is a strong indicator of severe force

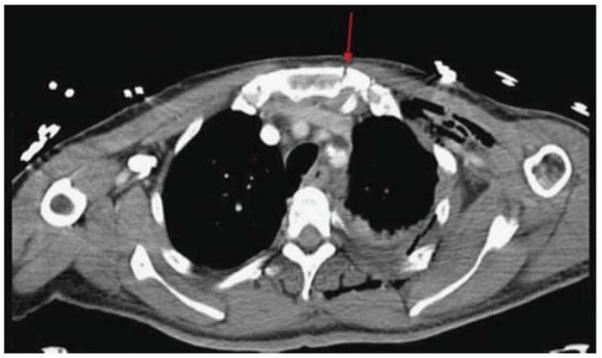

**FIGURE 2-2** Chest CT scan demonstrating a nondisplaced sternal fracture.

injury that should raise suspicion of simultaneous injury to the great vessels. The treatment is typically conservative, focused on pain management.

## LUNG INJURIES

### Pulmonary Contusion

Pulmonary contusion is common after mechanisms of injury that impart substantial kinetic energy to the thorax. In blunt trauma, pulmonary contusion results from the transmission of force across the bony thorax. Due to the elastic nature of immature bone, children may present with a large pulmonary contusion with little evidence of bony thoracic injury. Penetrating injury results in contusion from both the direct tissue lacerations (especially injury to peripheral pulmonary vasculature) and the dissipation of the kinetic energy of the missile.

Alveolar hemorrhage and pulmonary parenchymal destruction typically manifest themselves within hours of injury and usually resolve within approximately 7 days. Clinical symptoms, including respiratory distress with hypoxemia and hypercarbia, worsen for the first 24 to 48 h.[20] The diagnosis of pulmonary contusion is made by the combination of pulmonary dysfunction and radiographic findings (Fig. 2-3A). CT of the chest has been shown to be superior to plain film in identifying a pulmonary contusion (Fig. 2-3B) and may help predict the likelihood of pneumonia, acute respiratory distress syndrome (ARDS), or mechanical ventilation. The main goals of management are pain control, judicious fluid administration, careful hemodynamic monitoring, and aggressive pulmonary toilet. Older patients are particularly susceptible to complications following pulmonary contusion.[21]

### Penetrating Lung Injury

The majority of patients with penetrating lung injury can be managed with tube thoracostomy alone.[22] However, 20 percent of those that require thoracotomy will need some form of lung resection.[23] The extent of the lung resection has been shown to be an independent predictor of hospital mortality. The worst outcomes are seen with pneumonectomy.[24] The higher mortality has encouraged the development of techniques to facilitate rapid and minimal resections. These techniques have used staplers for nonanatomic lobectomy and tractotomy.

Stapled pulmonary tractotomy has been shown in several series to provide rapid and effective exposure to bleeding pulmonary parenchymal vessels and transected bronchi.[25] Unilateral lung isolation is required. This technique can be performed with either single- or double-lumen endotracheal intubations. Most traumas do not allow the luxury of time and stability that is required to place a double-lumen

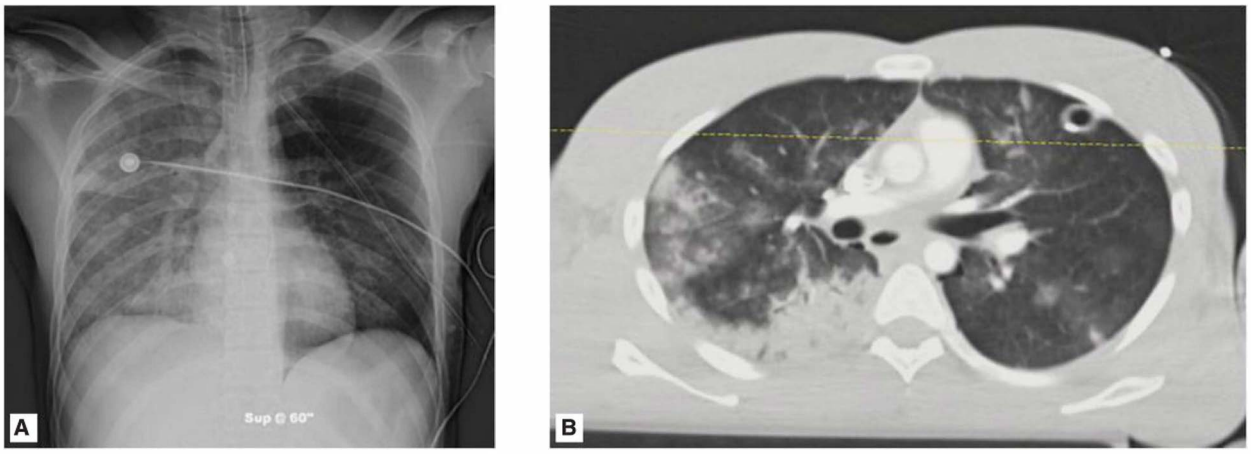

**FIGURE 2-3** **A.** Chest x-ray demonstrating bilateral pulmonary contusions (right > left) following severe blunt trauma from a motor vehicle collision. **B.** Chest CT scan of the same patient (A) demonstrating the pulmonary contusions.

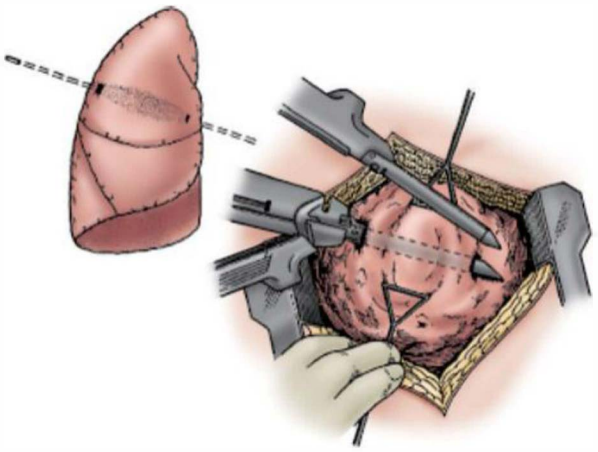

**FIGURE 2-4** Use of GIA stapler to perform tractotomy.

endotracheal tube. If the surgeon is working on the left chest, right mainstem placement of the tube effectively isolates the left lung from ventilation. Conversely, while working on the right chest, a bronchial blocker can be placed in the right bronchus to isolate the right side. These maneuvers may be of benefit if tolerated by the patient because of the reduced positive pressure to the injured lung.

Using a Duval lung clamp placed parallel to the tract of the bullet, the stapling device is positioned so that one of the arms is placed through the entrance and exit wounds of the lungs. When the stapler fires, the bullet tract is exposed fully, allowing the surgeon to directly suture bleeding vessels and transected bronchi (Figs. 2-4 and 2-5). Pulmonary tractotomy for hemorrhage has dramatically decreased the number of patients requiring anatomic resection for trauma.

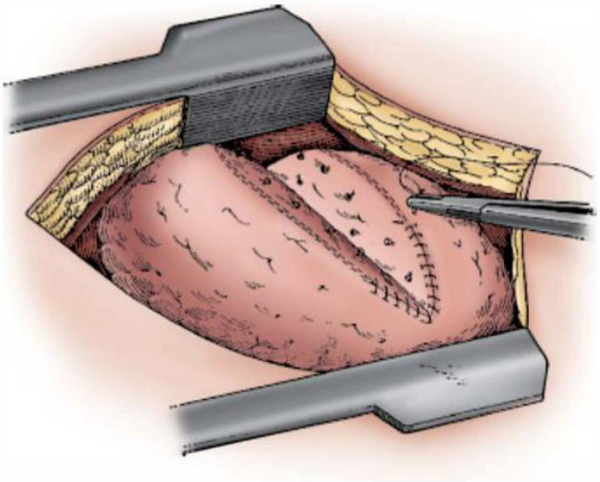

**FIGURE 2-5** Open tractotomy demonstrating access to the deep pulmonary parenchymal vessels and bronchial structures.

An underappreciated and potentially devastating consequence of thoracotomy for ongoing thoracic bleeding is systemic air embolism. The typical trauma patient has depressed intravascular volumes from major ongoing hemorrhage. In addition, the pulmonary architecture is destroyed from the traumatic insult. Both of these circumstances in combination with PPV allow air to escape the small airways and enter the bronchial veins, ultimately leading to a systemic air embolism. While the contributing factors are unavoidable, a heightened sense of urgency and rapid transport to the operating room before intubation is advised. Decreasing the length of time of increased airway pressures prior to controlling ongoing pulmonary bleeding minimizes this risk. Furthermore, when the thorax is entered, occlusion of the pulmonary hilum with a vascular clamp or with the surgeon's fingers can impede the continuous passage of air into the coronary, cerebral, and other systemic arteries.

## Tracheobronchial Injuries

Tracheobronchial injury is uncommon, but immediately life threatening. The true incidence of tracheobronchial injuries is difficult to define since a large portion of these patients will die prior to arrival at a hospital due to the loss of their airway. Based on autopsy reports, it is estimated that 2.5 to 3.2 percent of patients who die as a result of trauma have associated tracheobronchial injuries.[26] More than 80 percent of tracheobronchial injuries are due to blunt trauma located within 2.5 cm of the carina.[27] Tracheobronchial injury can present with subcutaneous emphysema, pneumothorax, massive air leak after tube thoracostomy, or hemoptysis.

In addition to tracheobronchial injury, it is important to recognize the potential for other associated injuries. A delay in the diagnosis of these injuries can potentially affect the overall morbidity and mortality of these patients.[28] Blunt trauma is often associated with multisystem trauma involving not only the chest, but the head, abdomen, and bony structures. Cervical trauma of the airway frequently involve the esophagus, the recurrent laryngeal nerves, the cervical spine and spinal cord, the larynx, and the carotid arteries and jugular veins.[29]

Immediate recognition and stabilization of airway injuries is the first priority in trauma. The diagnosis and management should proceed simultaneously. Patients with respiratory distress and the clinical suspicion of an airway injury should be intubated immediately, preferably with guidance of a flexible bronchoscope. In the unstable patient, you should proceed with direct laryngoscopy and oral intubation with in-line cervical stabilization. Intubation should be followed by diagnostic bronchoscopy. For a bronchial laceration, placement of the endotracheal tube into the uninjured side facilitates repair and improves oxygenation. The operative approach depends on the location of injury. Posterior tracheal injury is repaired via a right posterolateral thoracotomy. The anterior and superior aspects of the upper trachea are best approached via median sternotomy; the distal

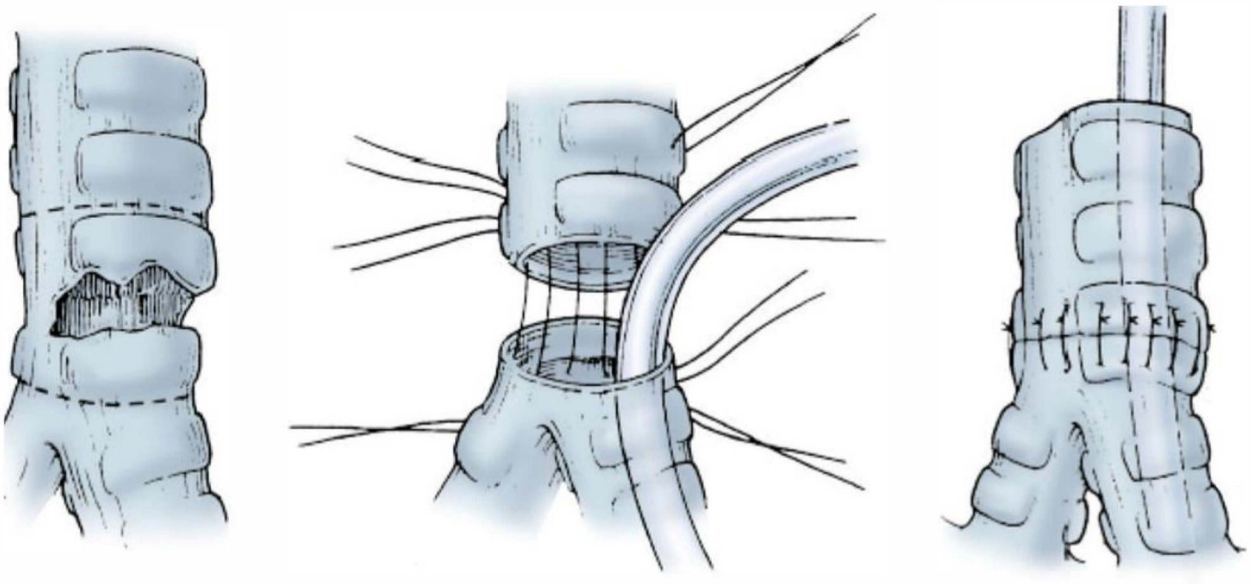

**FIGURE 2-6** Repair of tracheobronchial injuries.

trachea, carina, and left mainstem through the right chest; and the distal left and right bronchi by their respective thoracotomies. Repair is performed with nonabsorbable sutures, with care taken to reapproximate the mucosa (Fig. 2-6).

## CARDIAC INJURIES

### Blunt Cardiac Injury

Blunt cardiac injury (BCI) occurs when an anterior force compresses the chest. The transmitted force and the compression of the heart between the sternum and anterior thoracic spine is the predominant mechanism for BCI. Other mechanisms such as sudden deceleration, where the heart moves freely and strikes the sternum, can also cause BCI. Both of these mechanisms are seen during motor vehicle accidents where an unrestrained driver is propelled forward into the steering wheel. The sudden deceleration of the body and the compression of the chest contuse the heart. Patients sustaining blunt cardiac trauma have been reported to develop cardiac complications, including pump failure, dysrhythmias, myocardial infarction, myocardial rupture, valvular dysfunction, pericarditis, and tamponade.[30]

The true incidence of BCI remains unknown as there is no diagnostic gold standard. Often, the presence of a myocardial contusion is defined by the particular method employed to detect it rather than by the presence of cardiac complications. Electrocardiograms (ECG), cardiac enzymes, and echocardiogram have all been used to identify BCI. However, the lack of a clinical gold standard makes it difficult to consistently define and difficult to interpret the literature. Postmortem, BCI is seen as a well-demarcated hemorrhagic area of the anterior wall of the right ventricle.

Current consensus suggests that patients who present with a mechanism consistent for BCI should have an ECG. The most common dysrhythmia seen with BCI is sinus tachycardia or atrial fibrillation. Other findings include new bundle branch block, ST segment depressions, or ST segment elevations.[31] If an abnormality is present on the ECG, the patient should be admitted for monitoring for 24 to 48 h. Hemodynamically unstable patients should have an echocardiogram performed.[32] There remains controversy regarding cardiac enzymes. At present there are not enough data to recommend using cardiac enzymes for screening of BCI.

### Penetrating Cardiac Injury

Penetrating cardiac trauma remains a highly lethal but potentially salvageable injury.[33] Approximately 90 percent of victims with penetrating cardiac wounds die before reaching the hospital.[34] Patients arriving at the trauma center with vital signs who receive a prompt diagnosis and surgical intervention have substantially better survival rates. Other factors predicting improved survival include stab wounds versus gunshot wounds, single-chamber versus multiple-chamber injury, and the location of thoracotomy (operating room vs. ED (emergency department)).[35,36] Death occurs as a result of cardiac tamponade or exsanguination. The diagnosis of cardiac injury should be entertained in any patients with a precordial penetrating wound. The term "cardiac box" has been used to describe an area of the trunk in which penetrating injuries risk injuring

the heart. It is defined laterally by the midclavicular lines (MCLs), superiorly by the clavicles, and inferiorly by the costal margins.

The diagnosis of tamponade by physical examination can be challenging, since the classic triad of tamponade (hypotension, muffled heart tones, and jugular venous distension) is only present in one-third of patients presenting with the diagnosis and the busy, noisy trauma bay makes physical diagnosis difficult. The presence of penetrating chest trauma in a moribund patient is an indication to proceed with a median sternotomy or left anterolateral thoracotomy. In stable patients, the subxiphoid pericardial view, as part of the focused abdominal sonography for trauma or FAST, can aid in determining the diagnosis of tamponade.[37,38] An equivocal or positive FAST examination necessitates an operative pericardial window. The presence of hemothorax can confound the results of the FAST. The decompression of blood from the pericardial sac into the chest cavity can result in a false negative. In this subset of patients, it may be reasonable to proceed with a pericardial window irrespective of the FAST results. Pericardial windows can be accomplished through either a subxiphoid approach or a transdiaphragmatic approach. The transdiaphragmatic approach is useful if there are concurrent intra-abdominal injuries requiring laparotomy. Regardless of the approach, the chest should be prepped and draped in preparation for a sternotomy.

Pericardial tamponade due to penetrating cardiac injury is the desired lesion that every surgeon looks for when executing the heroic maneuver of ED thoracotomy as it is amenable to repair. Once access is gained to the left chest, a craniocaudad incision is made along the pericardium to deliver the heart and evacuate the hemopericardium while avoiding transection of the phrenic nerve. Potential survivors are the patients who regain cardiac activity and blood pressure. Finger occlusion of the cardiac laceration allows for transport to the operating room for definitive repair.

We prefer to use a 3-0 polypropylene suture on a large (SH or MH) needle to achieve definitive repair. Pledgets facilitate approximation of the laceration and are crucial in the repair of laceration adjacent to coronary vessels. Survivors of cardiac injuries have a small but significant percentage of valvular and septal defects and warrant postoperative echocardiography.[39]

## AORTIC INJURY

The overwhelming majority of patients with aortic injury from penetrating trauma present with exsanguination and impending death. Epidemiologic studies have shown that more than 90 percent of thoracic great vessel injuries are due to penetrating trauma.[40] However, most of these injuries are lethal. Even in the most efficient trauma system or trauma center, there is little hope for salvage.[41]

Alternatively, blunt aortic injury (BAI) is the most common cardiovascular seen in trauma patients.[42] The national incidence of BAI is 0.3 percent of all trauma admissions, and is associated with significant morbidity and mortality.[43] BAI is second to head injury as the leading cause of death after vehicle crashes.[44] The vast majority of these injuries are produced from the deceleration mechanism encountered in motor vehicle accidents. However, they may also occur from falls, pedestrian accidents, and crushing chest wounds.

BAI should be considered in all patients sustaining injuries due to motor vehicle accidents. High-risk occupant characteristics include age ≥60, front-seat occupancy, or unrestrained. High-risk collision characteristics include front- or near-side motor vehicle crash, abrupt deceleration ≥25 mph, crushing of the vehicle >16 in, or intrusion ≥6 in.[45] A chest x-ray should be the initial screening tool. The most common finding prompting further diagnostic workup includes a widened mediastinum, obscure aortic knob, left pleural effusion, first and/or second rib fracture, tracheal deviation, or depressed left bronchus (Fig. 2-7).[46]

There are several theories regarding the pathophysiologic features of BAI. The predominant mechanism of BAI is described as the force of deceleration concentrated at the junction of the fixed and nonfixed segments of the thoracic aorta. Although this is the predominant mechanism, many BAIs are probably caused by a combination of forces, including stretching, shearing, torsion, a "water hammer" (simultaneous occlusion of aorta and a sudden elevation in blood pressure), and the "osseous pinch" effect (entrapment of the aorta between the anterior chest wall and the vertebral column).[47] The isthmus is the most frequent site of rupture (50–70 percent) followed by ascending aorta or arch (18 percent), and the distal thoracic aorta (14 percent).[48,44]

In the last decade, there have been several significant changes in the diagnosis and management of BAI. Among

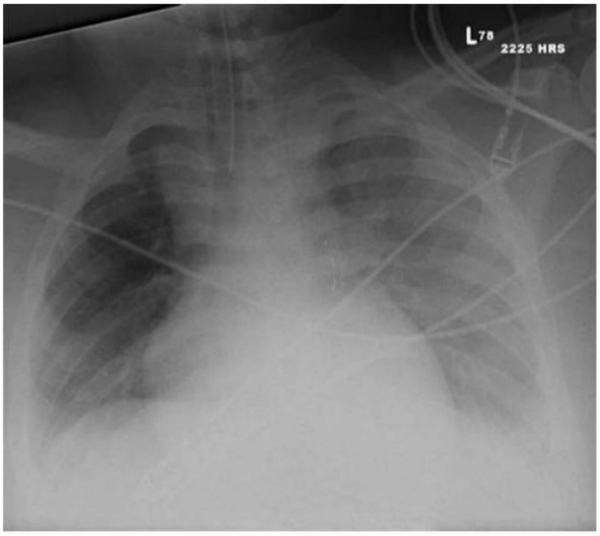

**FIGURE 2-7** Chest x-ray from a patient with a blunt aortic injury following a motor vehicle collision. Note the widened mediastinum, loss of aortic knob, and left pleural capping.

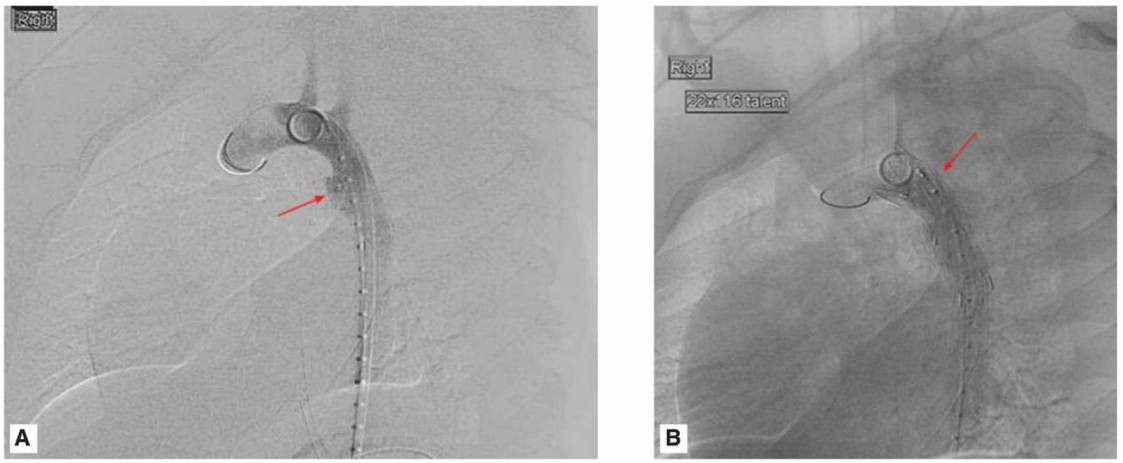

**FIGURE 2-8** **A.** Aortogram demonstrating aortic arch injury from the same patient (Fig. 2-7). Note extravasation of contrast distal to the left subclavian artery. **B.** Aortogram demonstrating endovascular stent in place with exclusion of aortic injury.

them are the liberal use of CT to screen for BAI, replacement of diagnostic angiography by CT, widespread use of β-blockers, planned delayed definitive repair, nonoperative management in selected cases, and introduction of endovascular stent-grafts.

Prompt repair of BAI is preferred when there are no other substantial injuries that would otherwise complicate the repair. However, studies have shown that operative management can be delayed safely to provide time for stabilization of the other injuries.[49] Medical control of blood pressure with β-blockers and nitroprusside is recommended until one is able to proceed with surgery. There are several techniques that have been employed to repair the aorta. While some authors have reported success with the clamp and sew technique, repair with some method of distal perfusion, either bypass or shunt, is preferred to prevent paraplegia. Partial left heart bypass has been shown to be associated with a decreased paraplegia rate in comparison to other techniques.[50]

Endovascular repair, previously used only in high-risk patients, has become the initial procedure of choice in many centers (Fig. 2-8A and B). It has been associated with a significantly lower mortality, but there appears to be a significant number of device-related complications.[51] The long-term results with endovascular repair are not known. The available studies are small and the follow-up is very limited.[52] Furthermore, in older ages, the thoracic aorta can become ectatic and tortuous, and theoretically, there is a risk of device failure. More study need to be completed on the use of endovascular stent grafts, despite their widespread adoption.

## INJURIES TO OTHER GREAT VESSELS

Most of the injuries to the great vessels are the result of penetrating trauma and require immediate intervention. Diagnostic investigation aimed at precise anatomic localization of injury is appropriate only for hemodynamically stable patients. Proximal vessel injuries (pulmonary hilar, innominate, and superior vena caval injuries) are often diagnosed at exploration for massive bleeding. More distal vessels (neck, subclavian, and axillary) may be visualized with duplex ultrasonography, CT angiography, and traditional arteriography. Unequal pulses, asymmetrical artery–artery indices, and expanding hematomas should all raise suspicion for arterial injury. Massive bleeding may be seen with both arterial and venous injury. As with other cases of massive hemorrhage, minimizing time between injury and definitive operative management is key to reducing mortality.

Because of the fixed nature of many vital structures in the mediastinum, suspicion as to which structures are injured is very important to the choice of surgical incision. Timely exposure is crucial for a successful outcome. Injury to the great vessels of the left chest (including left subclavian artery and vein and proximal aorta) typically presents with a massive hemothorax. However, depending on the tract of injury, it can be difficult to accurately predict the bleeding source. Left lateral thoracotomy is the incision of choice for lung parenchymal injuries and access to the descending aorta. A right thoracotomy is the exposure for similar injuries on that side. The subclavian vessels are best approached via an incision directly over the medial third of the clavicle extending from the clavicular head and curving down toward the deltopectoral groove.[53] The clavicle is stripped of its muscular attachments using a periosteal elevator and resected. If the injury is more proximal, this is combined with a median sternotomy. The median sternotomy provides excellent exposure to the most proximal branches of the aortic arch.

If an ED thoracotomy was selected as the initial approach due to massive blood loss, the access is limited to the upper chest. The thoracotomy incision can be extended to a trapdoor type of incision. The incision should be extended from the medial edge along the sternum to the sternal notch and laterally, superior to the left clavicle. The clavicle is then divided within the middle third. With the

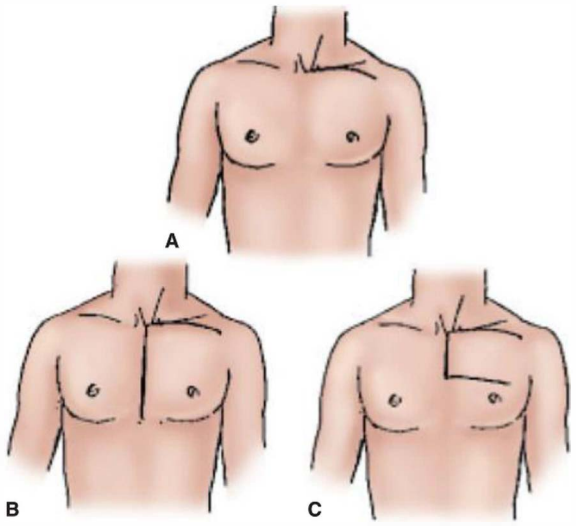

**FIGURE 2-9** Choices of incisions for the approach to injuries of the great vessels. Clavicular incision (**A**), combined clavicular incision and median sternotomy (**B**), and trap door incision (**C**).

segment laterally retracted, access to the distal aortic arch and subclavian vessels is facilitated. However, this incision is highly morbid, carries a significant risk of blood loss due to the extensive muscle division, and requires iatrogenic rib fracture. In addition, the exposure is not significantly better than the exposure achieved with a median sternotomy and clavicular extension. Care must be taken to avoid injury to the brachial plexus and phrenic nerve with this approach (Fig. 2-9).

All subclavian and axillary injuries should undergo repair except in the most severely unstable patients. Temporary shunting may be necessary in these patients. Repair may be achieved by primary anastomosis, autologous vein graft or patch, or interposition of a prosthetic graft. Subclavian vein injuries are repaired only if simple (no significant narrowing of the vessel or need for interposition or patch). Otherwise, ligation of the vein is generally well tolerated. Close monitoring is necessary for possible development of compartment syndrome secondary to limb edema. Prophylactic forelimb fasciotomies are typically not required.

Due to the difficulty and increased morbidity of achieving exposure to repair injuries to the thoracic outlet, recently there has been interest in using endovascular techniques. In unstable patients, the options are limited to immediate exploration. However, these injuries often result in a contained extrapleural hematoma due to the fibrous attachments surrounding the subclavian vessels.[54] In stable patients, a CT arteriogram should be performed to identify the location of the injury and evaluate the mediastinum. Rather than directly exploring the hematoma, an angiogram can be performed and a remote occlusion balloon can be used to obtain proximal control. This results in the conversion of an emergent operation to a semi-urgent operation.[55] Several authors have reported successful exclusion of vessel injuries with covered stentgrafts.[56,57] The initial reports indicate that comparable patency is achieved with less morbidity. Furthermore, the use of endovascular techniques does not preclude subsequent operative intervention or revision that can be performed in a more controlled fashion as an elective procedure.

## Esophageal Injuries

The incidence of esophageal injury after blunt or penetrating trauma is rare. The low incidence is related to several factors. The esophagus is protected by the bony shell of the thoracic cavity and deep location as it spans the entire length of the posterior mediastinum. In addition, esophageal injuries are often associated with other injuries, specifically vascular injuries, which require urgent attention and can lead to death prior to arrival at the hospital or missed diagnosis of small perforations. The treatment of blunt or sharp traumatic injuries to the esophagus is determined by several factors. The timing of the injury, the degree of the injury (contained versus noncontained perforation), and the location of the injury collectively guide subsequent intervention.[58] In penetrating trauma, the most common part of the esophagus injured is the cervical esophagus.

Inpatients who are clinically stable with no hemodynamic instability, the esophagus is best evaluated by esophagography. If the results are equivocal, esophagoscopy should be performed.[59] Clinical findings may include subcutaneous emphysema, mediastinal air, pleural effusion, or unexplained persistent fever for more than 24 h following injury.

As with other structures in the mediastinum, the level of injury dictates the operative approach. For proximal and midthoracic esophageal injury, a right posterolateral thoracotomy is used. Injury of the distal thoracic esophagus is best addressed via a left posterolateral thoracotomy. Esophageal injuries identified early are repaired primarily (in layers, if possible) and often reinforced with tissue-flap coverage (pleural tissue, intercostal muscle, or fundoplication). Those repaired in a delayed manner (>12 h) require wide drainage with multiple tube thoracostomies. Esophageal diversion is considered especially if there is evidence of mediastinitis.

## Diaphragmatic Injuries

Traumatic diaphragmatic injury can occur as a consequence of penetrating or blunt thoracoabdominal trauma. The incidence of diaphragmatic injuries is difficult to estimate because diaphragmatic hernias are often missed by diagnostic imaging and found as incidental findings later in life.[60] For blunt injury, usually seen on the left side, identification of the nasogastric tube in the left hemithorax on chest x-ray suggests herniation of the stomach and is diagnostic of diaphragmatic disruption. In the case of penetrating trauma, the diaphragmatic defect is often too small for herniation in

the acute setting. However, the unrecognized defect, exacerbated by the gradient between the negative intrathoracic pressure and positive intra-abdominal pressure, enlarges over time, resulting in subsequent herniation of intra-abdominal contents into the chest.[61] It is not uncommon for patients to present in the nonacute setting with a diaphragmatic hernia and a previous history of penetrating thoracoabdominal trauma.

Given the potentially dire sequelae of incarcerated bowel contained in a diaphragmatic hernia, operative exploration is recommended to evaluate the diaphragm in the case of left-sided thoracoabdominal trauma. In two prospective studies, patients with penetrating left thoracoabdominal trauma underwent surgical evaluation (laparotomy or thoracotomy for unstable patients, and laparoscopy for stable patients). The incidence of occult diaphragmatic injuries in stable patients was approximately 25 percent.[62,63] Right-sided penetrating diaphragmatic injuries are thought to be of little consequence because right-sided injury is rarely associated with herniation, and the large, fixed liver protects against herniation of intra-abdominal contents.

Both laparoscopy and thoracoscopy are useful techniques for evaluating the diaphragm after penetrating trauma.[64] Thoracoscopy provides excellent visualization of the posterior recesses of the thoracic cavity. This area of the diaphragm is not often seen well with the laparoscopy. Some surgeons advocate this as the preferred approach for posterior wounds from the posterior axillary line to the spine. Thoracoscopy offers several advantages for anterior lower chest wounds. An abdominal procedure can be avoided if the exploration is negative and residual blood and clots can be evacuated from the pleural space. In the absence of a pneumothorax, laparoscopy is the preferred approach. The advantages of laparoscopy are that it avoids an unnecessary thoracostomy tube and abdominal injuries can be assessed. Operative repair of the diaphragm can be performed by either approach if there is no evidence of other intra-abdominal injury.

## SPECIAL CONSIDERATIONS

### Pneumothorax

Pneumothorax is a frequent complication of both blunt and penetrating chest trauma. The entry of air in the pleural space results in partial or total collapse of the lungs, resulting in distant or absent breath sounds. Additional physical findings may include subcutaneous emphysema identified by crepitus over the injured side. Chest x-ray demonstrates opacity and absences of lung markings. The accumulation of air under pressure in the pleural space can lead to a tension pneumothorax. This condition can develop when injured tissue forms a one-way valve, allowing air to enter the pleural space and preventing it from escaping naturally. This is commonly called a "sucking" chest wound or open pneumothorax. To prevent the development of a tension pneumothorax, sterile occlusive gauze should be applied to the chest wall and taped on three sides. This creates a flutter valve that allows air to escape but not enter the pleural cavity. A tension pneumothorax can also result from PPV to an injured lung with an initially small air leak.

The result of a tension pneumothorax is massive overinflation of the affected side, causing a shift of the relatively pliable mediastinal structures toward the opposite side of the chest as well as the flattening of the diaphragm. The increase in thoracic pressure results in a decrease in venous return to the heart and a subsequent decrease in blood pressure. On physical examination, the trachea may appear deviated toward the opposite side.

The clinical picture associated with a tension pneumothorax should prompt immediate decompression without an x-ray in most cases. If a chest tube is not immediately available, a large-bore intravenous catheter can be used to access the chest cavity. The needle should be inserted in the second intercostal space in the MCL. This temporizing maneuver should be followed by the expeditious placement of a thoracostomy tube placed in the fifth intercostal space at the anterior axillary line.

Simple pneumothorax is treated by tube thoracostomy alone. For uncomplicated pneumothorax, moderate-sized (28F) tubes are appropriate. The presentation of an uncomplicated pneumothorax is rare because of associated intrapleural hemorrhage due to trauma. This necessitates the use of a larger tube (36F) to allow for better drainage.

### Hemothorax

Bleeding into the pleural space can occur with virtually any disruption of the tissues of the chest wall and pleura, or the intrathoracic structures (Fig. 2-10). Even minor injury to the chest wall can lead to a significant hemothorax.[65] In addition, intra-abdominal bleeding in patients with diaphragmatic injury can manifest as a hemothorax. The initial treatment of hemothorax is tube thoracostomy. A 36-F chest tube or larger should be placed to ensure effective evacuation of intrapleural blood and re-expansion of the lung. The re-expansion of the lung often tamponades the bleeding and further treatment is not required. However, if the hemothorax is massive or if the bleeding is ongoing, then the patient should be taken to the operating room for prompt thoracotomy and hemostasis. The indications for thoracotomy are discussed later in the Chest Tube Management section.

Following the insertion of a chest tube, a chest x-ray, upright if possible, should be obtained to evaluate placement of the tube and confirm evacuation of the hemothorax (Fig. 2-11). A potential pitfall exists in patients who rapidly accumulate clotted blood in the pleural space. The clotted blood can clog the tube, leading to a false impression that the ongoing bleeding is minimal. The presence of a retained hemothorax and persistent hypotension should raise suspicion that ongoing bleeding is present. Another potential pitfall is kinking of the chest tube resulting in occlusion. The simple maneuver of spinning the chest tube before securing

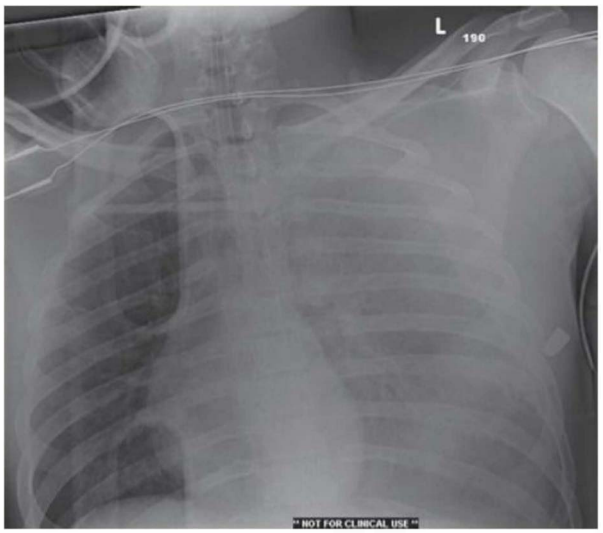

**FIGURE 2-10** Chest x-ray demonstrating massive hemothorax resulting from a gunshot wound.

it in place can eliminate this from occurring. Both of these clinical scenarios can be detected on x-ray, emphasizing the importance of obtaining a postprocedure x-ray.

## Video-Assisted Thoracic Surgery (VATS) for Residual Hemothorax

The majority of traumatic hemothoraces are adequately treated with tube thoracostomy. However, residual posttraumatic hemothorax may occur in 3 to 8 percent of patients.[66]

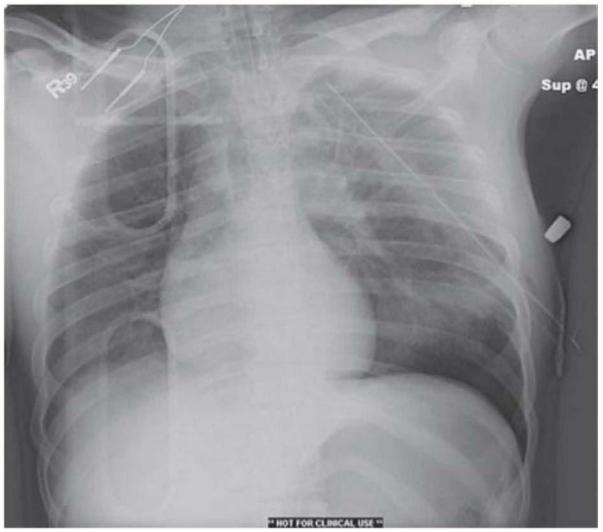

**FIGURE 2-11** Chest x-ray from the same patient (Fig. 2-10) following chest tube placement and resolution of the hemothorax.

The retained blood products are thought to be a major contributing factor in the development of an empyema and subsequent trapped lung.[67]

VATS has a therapeutic role in the evacuation of retained hemothorax. The evacuation of the retained blood products reduces the risk of contamination of the residual blood, development of an empyema, and the chronic changes of a fibrothorax. Subsequently, the need for an open decortication is reduced in these patients and their morbidity decreased. VATS evacuation has been shown to be best accomplished within 5 days after injury when the semisolid clot can be easily suctioned.[68] Patients that are considered for VATS evacuation of persistent hemothorax should be evaluated by CT of the chest, as this has been shown to be superior to chest x-ray in distinguishing free intrapleural blood from contusion, atelectasis, and intraparenchymal hemorrhage.[69]

## Chest Tube Management

Only 10 to 15 percent of all chest wounds require thoracotomy, whereas the remaining 85 percent can be managed with a closed tube thoracostomy.[70] Thoracotomy should be performed for hemodynamically unstable patients with chest trauma that are not responsive to adequate resuscitation. Other indications for thoracotomy are greater than 1500 mL of blood evacuated initially on chest tube insertion, ongoing blood loss (>200–300 mL/h for 4 h), and persistent hemothorax despite adequate drainage with two chest tubes (Table 2-1).

If the patient's condition permits, tube thoracostomy should be performed using sterile technique. A large-bore 36-F chest tube should be inserted in between the fourth and fifth inner costal space. For patients with hemopneumothorax, the chest tube can be removed when the output decreases to <200 mL/24 h and there is no recurrence of pneumothorax on water seal. Thoracoscopy should be considered for residual hemothorax.

A significant complication associated with tube thoracostomy, although rare, is empyema. In trauma patients, the risk is further increased due to the mechanism of the

**TABLE 2-1: Indications for Thoracotomy**

| |

| Evidence of diaphragmatic injury |
| Large chest wall defect requiring reconstruction |

trauma. When a bullet or knife penetrates the chest cavity and enters the pleural space, bacterial contamination occurs. The use of antibiotics to prevent the development of empyema has been suggested. Current recommendations based on consensus are that a first-generation cephalosporin should be administered prior to chest tube placement for traumatic hemopneumothorax, and continued for no longer than 24 h. Longer courses of therapy have not been shown to decrease the incidence of septic complications. Interestingly, the data suggest that there may be a reduction in the incidence of pneumonia but not empyema in trauma patients receiving prophylactic antibiotics when the chest tube is placed.[70]

## Emergency Department Thoracotomy

Emergency department resuscitative thoracotomy (EDRT) is an aggressive procedure to save a dying patient. This heroic lifesaving measure is reserved for patients with penetrating injury of the torso who have lost vital signs in transport to, or shortly after arriving at, the hospital. Prognostic factors that have been identified in the literature include mechanism and site of injury, presence of vital signs or signs of life at the scene and in the ED, total field time, and the expertise of the person performing the procedure.[71]

Patients sustaining penetrating trauma have a statistically better chance of survival after EDRT compared with cardiac

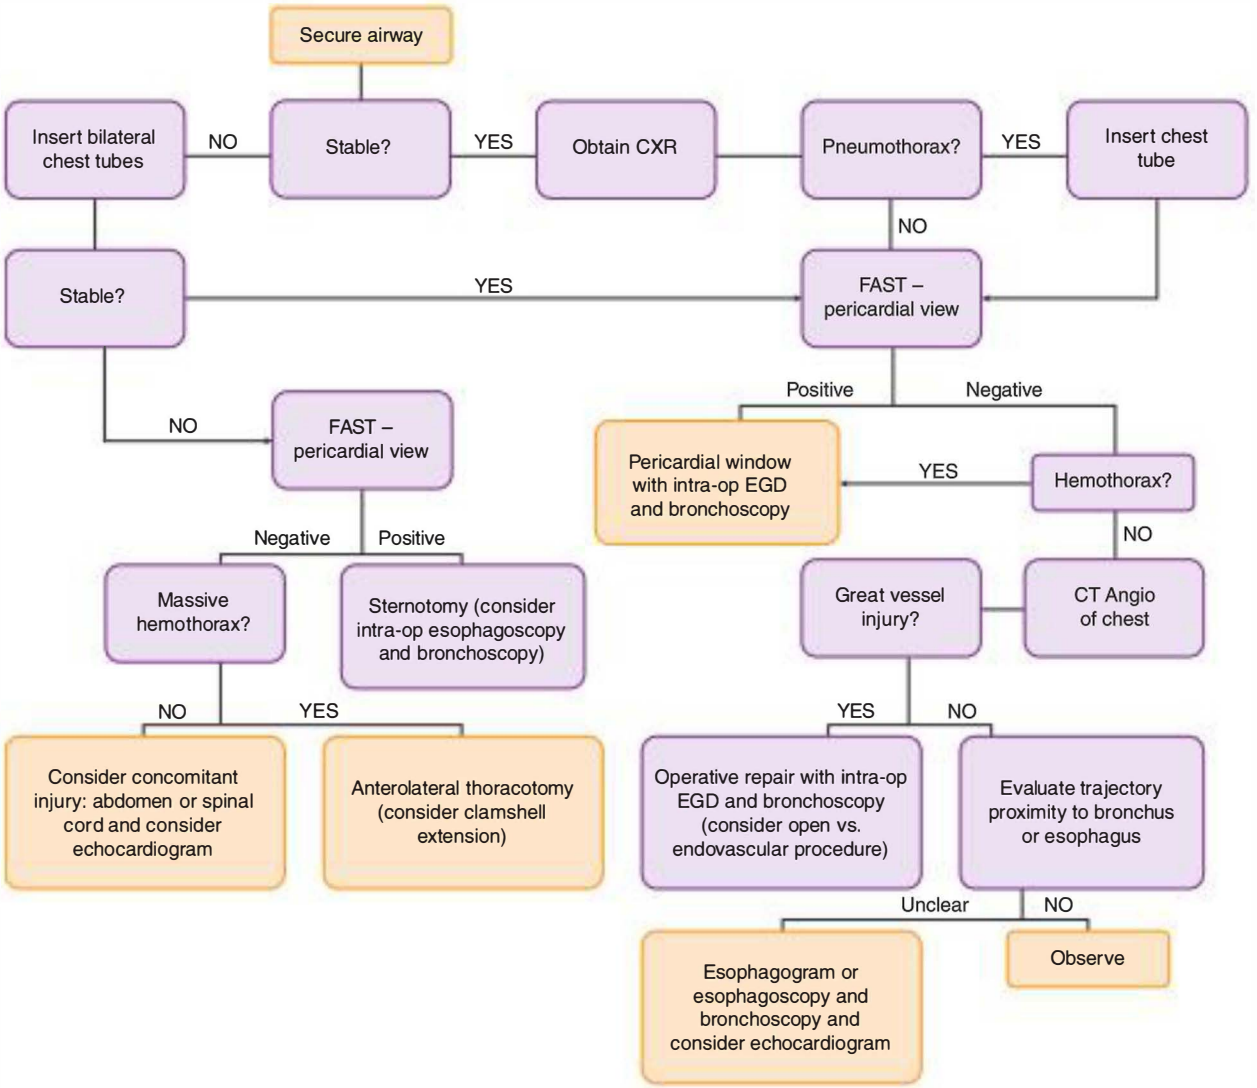

**FIGURE 2-12** Decision tree algorithm for the management of transmediastinal gunshot wounds.

arrest victims from blunt trauma. Greatest survival rates are achieved in the subset of patients with stab wounds to the right ventricle and with pericardial tamponade.[72] Among patients with penetrating trauma, those with stab wounds have a better survival rate than those suffering cardiac arrest from gunshot wounds.[73] Patients sustaining cardiac arrest subsequent to blunt trauma have an extremely poor prognosis (1–2 percent survival).[74]

After determining the need for an ED thoracotomy, the patient's left arm should be placed above the head to provide unimpeded access to the left chest. The thoracotomy incision should start on the right side of the sternum. This saves time if sternal transection is required for additional exposure. The initial incision is carried transversely across the chest, beneath the nipple, and curved slightly toward the patient axilla following the natural curvature of the rib cage. The intercostal muscles are divided sharply with care not to damage the underlying parenchyma. A right chest tube should be placed simultaneously by another member of the trauma team. A Finochietto retractor is placed and the intercostal space is widened for exposure. The pericardium is easily identified medially and inspected. A bulging pericardium is suggestive of pericardial tamponade and requires immediate decompression. The pericardial sac is open longitudinally to avoid injury to the left phrenic nerve. If there is no evidence of tamponade, the thorax is inspected for sites of bleeding and injury.

To optimize blood flow to the carotid and coronary circulation, the thoracic aorta is occluded either by an atraumatic vascular clamp or by direct compression against the vertebral column. Clamping the aorta has the advantage of freeing the surgeon's hands for other procedures such as cardiac massage. However, the esophagus can be easily injured in the process. An orogastric tube can be inserted to aid in the differentiation between the esophagus and the aorta. Direct compression avoids the risks of esophageal injury but necessitates an additional hand in an already limited field.

The initial execution of a clamshell thoracotomy should be performed in hypotensive patients with penetrating wounds to the right chest. This exposure provides immediate, direct access to a right-sided pulmonary or vascular injury while allowing access to the pericardium from the left side for open cardiac massage. When visualization of penetrating wounds in the aortic arch or major branches is needed, the superior sternum is additionally split in the midline. Recovery of hemodynamics allows for prompt travel to the OR for definitive repair.

## Transmediastinal Gunshot Wounds

Hemodynamically unstable patients with transmediastinal gunshot wounds typically receive rapid tube thoracostomy and are transported to the operating room. However, in stable patients, the order of the diagnostic workup has been debated. Historically, the assessment of the aorta preceded the investigation of the esophagus. This notion has been challenged because victims of gunshot wounds of the esophagus are more commonly stable from a hemodynamic standpoint than their counterparts with aortic injuries.[75] However, with the increased speed and resolution of CT, an accurate assessment of potential mediastinal injury can be obtained readily without the delay of an invasive procedure. CT provides a noninvasive means to evaluate missile trajectories and the great vessels.[76] Based on the CT findings, additional testing may be indicated such as esophagoscopy, bronchoscopy, or echocardiography (Fig. 2-12).

## THORACIC TRAUMA BOARD REVIEW QUESTIONS (CHAPTER 2)

1. A 55-year-old unrestrained driver involved in a high-speed motor vehicle collision sustains multiple right-sided rib fractures. Which statement is correct regarding the management of this patient?
   A. Incentive spirometry is not useful in predicting morbidity and mortality.
   B. A thoracic epidural catheter is contraindicated in the setting of multiple rib fractures.
   C. Tube thoracostomy should be performed prophylactically.
   D. Thoracic epidural analgesia has been shown to improve outcomes.
   E. Elderly patients with multiple rib fractures have lower morbidity and mortality compared with young patients.

2. Which patient should receive resuscitative thoracotomy in the emergency department?
   A. An 18-year-old man with hypotension from a penetrating anterior chest wound
   B. A 35-year-old restrained driver found pulseless at scene with no electrical activity on ECG on arrival to the trauma center
   C. A 23-year-old man with hypotension from penetrating left chest wound after intubation and positive pressure ventilation
   D. A 64-year-old woman with penetrating anterior chest wound who becomes tachycardic and then pulseless
   E. A 16-year-old man with no cardiac activity after 30-ft fall from ladder

3. A 36-year-old woman suffers a gunshot wound that enters the left chest and exits the right chest. She is hemodynamically stable with no respiratory distress. Chest x-ray shows no retained fragments, pleural effusion, or pneumothorax. What is the correct next step in management?
   A. FAST examination
   B. CT scan
   C. Barium swallow
   D. Sternotomy for exploration of the mediastinum
   E. Subxiphoid window

4. A 45-year-old man sustains multiple right-sided rib fractures after a 20-ft fall. A chest tube is inserted for a hemopneumothorax. Which of the following is *not* an indication for thoracotomy?
   A. Drainage of 2000 mL of blood after chest tube insertion.
   B. Persistent hemothorax after placement of a second chest tube.
   C. Ongoing blood loss exceeding 250 mL/h over 4 h.
   D. Hemodynamic instability.
   E. Air leak.

5. An 18-year-old restrained passenger complains of abdominal pain and shortness of breath after a side impact motor vehicle collision. There is opacification of the left chest on initial chest x-ray. What is the correct next step in management?
   A. Tube thoracostomy
   B. Barium swallow
   C. Exploratory laparoscopy
   D. Emergent laparotomy
   E. Insertion of nasogastric tube

## ANSWERS

1. **Answer: D.** Thoracic epidural analgesia has been shown to improve pain control and overall outcomes in older patients with multiple rib fractures. This approach is not contraindicated and may also be useful in younger patients. Incentive spirometry can be useful in predicting morbidity and mortality, which is higher in the elderly population. Tube thoracostomy should not be performed prophylactically.
2. **Answer: D.** ED thoracotomy is reserved for patients that lose vitals or signs of life en route to the trauma center or a have a witnessed arrest. Hypotension can result from hemothorax or pneumothorax, which requires placement of a chest tube rather than thoracotomy. The best outcomes are seen in patients that sustain a penetrating injury; there is debate about whether ED thoracotomy should be offered at all after a blunt injury.
3. **Answer: B.** A hemodynamically stable patient with a transmediastinal penetrating injury should be evaluated with CT, as this is the most rapid method to evaluate for both aortic and esophageal injury. Focused assessment of sonography for trauma (FAST) is useful for

pericardial effusion, which is unlikely in a stable patient. Barium swallow may be necessary, but only after CT scanning. Operative exploration is not indicated in this stable patient.

4. **Answer: E.** An air leak after insertion of a chest tube for multiple rib fractures is common and is not an indication for thoracotomy. Massive initial drainage (>1500 mL), persistent hemothorax, ongoing excessive chest tube output (>250 mL/h over 4 h), and hemodynamic instability despite adequate volume resuscitation are all indications for thoracotomy.
5. **Answer: E.** The patient's findings are concerning for diaphragmatic rupture, and insertion of a nasogastric tube will identify location of the stomach on a follow-up chest x-ray. If the nasogastric tube is above the expected location of the diaphragm, blunt injury of the diaphragm is suspected and additional evaluation initiated.

# Pulmonary Physiology, Function Tests, and Bronchoscopic Techniques

*Lonny Yarmus*
*David J. Feller-Kopman*

**KEY CONCEPTS**

- Epidemiology
  - Pulmonary complications occur in 5 to 10 percent of all surgical patients and have been shown to prolong hospital stay by 1 to 2 weeks. Approximately 25 percent of deaths within the first week after surgery are due to pulmonary complications.
- Pathophysiology
  - Pneumonia occurs in 10 to 40 percent of patients after major surgery and is associated with a mortality rate of 30 to 45 percent. General anesthesia can decrease lung volumes by 30 to 40 percent, and this decrease may persist for 1 to 2 weeks postoperatively.
- Clinical features
  - Cardiothoracic surgery is associated with the highest frequency of pulmonary complications. Risk factors include the type of surgery, general anesthesia, length of surgery and general anesthesia, smoking, chronic obstructive pulmonary disease, age, obesity, functional status, and a history of dyspnea.
- Diagnostics
  - Preoperative evaluation should include a directed history and physical examination to identify those patients at particular risk for pulmonary complications. Pulmonary function tests with spirometry and arterial blood gases (ABGs) should be obtained for any patient undergoing lung resection. For further risk stratification, cardiopulmonary exercise testing (CPET) is indicated in high-risk patients who do not have adequate predicted postoperative lung function. Alternatives to CPET include the shuttle-walk or stair-climb test.
  - Bronchoscopy is an essential tool in the preoperative work for diagnosis, staging, and surgical planning.
- Treatment
  - Inhaled bronchodilators may successfully reverse some cases of obstructive pulmonary disease.
- Outcomes
  - Preoperative pulmonary function evaluation can stratify patients for risk, thus identifying those who can safely undergo major cardiothoracic surgery and minimizing the risk of significant morbidity and mortality.
  - Appropriate nodal staging is essential in the workup of lung cancer patients and essential for surgical planning.

## INTRODUCTION

Pulmonary complications in the perioperative period remain a significant cause of morbidity and mortality and occur in 5 to 10 percent of all surgical patients. Not only have these complications been shown to prolong hospital stay by an average of 1 to 2 weeks but 25 percent of deaths within the first week after surgery are reportedly due to pulmonary complications.[1-4] One way to minimize these complications is with the appropriate use of preoperative testing. Both noninvasive preoperative testing such as pulmonary function testing and minimally invasive testing such as bronchoscopy can add valuable information to the workup of the preoperative cardiothoracic patient. In this chapter, we will review the burden of postoperative complications, basic pulmonary physiology, the preoperative

pulmonary workup for the cardiothoracic surgical patient, and the role of bronchoscopy for the diagnosis and staging of lung cancer.

## PERIOPERATIVE PULMONARY COMPLICATIONS

In the postoperative period, there are a wide range of pulmonary complications (Table 3-1) that can occur in patients with underlying lung disease. Postoperative pneumonia can occur in 10 to 40 percent of patients and is associated with a mortality rate of 30 to 45 percent after major surgical procedures. The benefits of a thorough preoperative evaluation include the identification of patients with underlying lung disease, modification of risk factors, optimization of medical management, avoidance of elective surgery in high-risk patients, and prevention of inappropriate surgical resection by appropriately staging for lung cancer.

There are multiple risk factors for postoperative pulmonary complications including patient related factors as well as the specific type of surgery and anesthesia. The location and type of surgery being performed are the major determinants of pulmonary complication risk. Cardiothoracic surgery has been repeatedly shown to have the highest frequency of pulmonary complications.[5] Anesthesia is also important in determining postoperative risks as it has been shown that general anesthesia can decrease lung volumes by 10 to 30 percent for which these changes may persist for 1 to 2 weeks postoperatively. The combination of thoracic surgery and general anesthesia often leads to decreased lung volumes, worsening gas exchange, and impairment in airway clearance, all of which may result in severe complications, especially in patients with underlying lung disease.

Patient-specific risk factors that have been identified are listed in Table 3-2. Appropriate identification and modification of reversible risk factors is an important component of the preoperative evaluation and one that can significantly reduce operative risk. One of the most important modifiable risk factors is smoking cessation several weeks prior to elective surgery;[6] cessation 2 weeks prior may in fact increase postoperative complications, likely as a result of the impaired mobilization of secretions.

**TABLE 3-1: Postoperative Pulmonary Complications**

| |

| Tobacco history |
| Chronic obstructive pulmonary disease |
| Restrictive lung disease |
| Age |
| Obesity |
| Functional status |
| Dyspnea |
| Impaired sensorium |

## INDICATIONS FOR PREOPERATIVE PULMONARY FUNCTION TESTING

Identifying patients who are at increased risk of pulmonary complications begins with a detailed history and physical examination. Any unexplained dyspnea at rest or on minimal exertion should warrant a more thorough evaluation prior to any elective surgical procedure. Smoking cessation should be recommended to all patients, ideally having them quit at least 2 weeks before the surgery. If a patient has any history of prior lung disease, significant tobacco use, or dyspnea with mild exertion, they warrant pulmonary function testing before any high-risk elective surgical procedure.

The American College of Physicians recommends preoperative pulmonary function testing for the following patients[7]:

- All patients with a history of tobacco use or dyspnea who are undergoing cardiothoracic or upper abdominal surgery.
- Any patient with unexplained dyspnea or pulmonary symptoms who is undergoing head, neck, orthopedic, or lower abdominal surgery.
- All patients undergoing lung resection.

Preoperative pulmonary function testing most often consists of spirometry, diffusion capacity, and sometimes arterial blood gas (ABG) analysis. Patients undergoing lung resection surgery are clearly at a particularly high risk of pulmonary complications and warrant a more thorough evaluation.

## PREOPERATIVE EVALUATION OF THE LUNG RESECTION CANDIDATE

There are several risk factors that have been identified to increase complications in patients undergoing lung resection. Lung resection surgery is associated with significant morbidity in up to 50 percent of patients and death in up to 8 percent.[8] The type of resection is a major determinant of

operative risk, with pneumonectomy having a greater operative morbidity and mortality than lobectomy.[9]

Both pulmonary function testing with spirometry and an ABG measurement should be obtained on all patients considered for lung resection surgery.[10] Baseline hypercapnia and hypoxia at rest or during exertion predicted an increased surgical morbidity.[11]

Spirometry is the most accurate and predictive pulmonary function test available. It can identify low-risk patients who can proceed directly to surgery as well as higher-risk patients who warrant further investigation. It is recommended that patients have a postoperative forced expiratory volume in 1 s ($FEV_1$) of greater than 0.8 L or 30 percent of predicted and also a postoperative diffusing capacity of carbon monoxide (DLCO) of greater than 40 percent predicted. If the preoperative $FEV_1$ is greater than 2.0 L for a pneumonectomy, or greater than 1.5 L for a lobectomy, no further pulmonary testing is required, and the patient can proceed directly to lung resection. All patients who have an $FEV_1$ below these cutoffs require more extensive evaluation prior to lung resection (Fig. 3-1). These additional tests are used to help predict postoperative pulmonary function. The quantitative perfusion scan is used to estimate the percent of functional lung that is being resected.[12] The estimate of postoperative pulmonary function is calculated with the following equation:

$$\text{Predicted } FEV_1 = \frac{\text{preoperative } FEV_1 \times (100 - \text{percent of lung to be removed})}{100}$$

$$= \frac{\text{preoperative } FEV_1 \times (19 - \text{number of segments to be removed})}{19}$$

The same equation can be used to calculate the predicted postoperative DLCO. Any patient with a predicted postoperative $FEV_1$ and DLCO above the minimum values outlined above should have a standard risk of pulmonary complications. A patient who does not have an adequate predicted postoperative lung function based on the above testing should not be denied surgery without further evaluation if he or she otherwise appears to be an appropriate surgical candidate. These higher-risk patients should undergo cardiopulmonary exercise testing (CPET) for further risk stratification. The measurement of the maximal oxygen consumption, $\dot{V}O_{2max}$, by CPET is the most specific predictor of postoperative pulmonary complications following lung resection surgery.[13] If the measured $\dot{V}O_{2max}$ is greater than 20 mL/kg/min, the risk of postoperative pulmonary complications is low, and the patient may be safely offered surgical resection. Patients with a $\dot{V}O_{2max}$ <15 mL/kg/min have a moderately increased risk of surgery, and a $\dot{V}O_{2max}$ less than 10 mL/kg/min is associated with a high surgical risk.

Since lung resection is the only cure for many patients with localized lung cancer, the strategies of pulmonary function testing have been designed to maximize their sensitivity in identifying all patients who can safely tolerate lung resection; these strategies must be tailored to the goals of the individual patient.

## ARTERIAL BLOOD GAS ANALYSIS

ABG analysis is a readily available test that provides useful information to identify the high-risk surgical patient. The ABG measurement should be performed at rest and breathing ambient air, if possible. The partial pressure of oxygen ($P_{O_2}$) reflects the adequacy of gas transfer from the alveoli to the blood and when, measured at sea level, the normal $P_{O_2}$ ranges from 85 to 100 mm Hg. The $P_{O_2}$ as a measurement of oxygenation should be interpreted in terms of the oxygen dissociation curve (Fig. 3-2). Since a majority of oxygen in the blood is bound to hemoglobin, relative changes in $P_{O_2}$ can reflect a wide range of changes in oxygen carrying capacity depending on the slope of the oxygen dissociation curve. Changes in $P_{O_2}$ on the steep part of the oxygen dissociation curve reflect large changes in blood oxygen content. In contrast, changes in $P_{O_2}$ on the flat part of the oxygen dissociation curve, $P_{O_2}$ greater than 70 mm Hg, lead to only minor differences in oxygen content. The alveolar–arterial oxygen gradient [A–a gradient = $P_iO_2 - (PaCO_2/R) - PaO_2$] is a more sensitive measurement of gas exchange problems. Since pulmonary function normally declines with age, the normal values for A–a gradient depend on the age of the patient and can be calculated based on the following equation.

$$\text{Normal A–a gradient} = 2.5 + \frac{1}{4}\text{age} \pm 2$$

An elevated A–a gradient can be due to ventilation/perfusion mismatching, diffusion defects, or shunt.

The partial pressure of carbon dioxide, $P_{CO_2}$, is a measurement of $CO_2$ production ($\dot{V}CO_2$) and alveolar ventilation ($\dot{V}_A$); that is, $PaCO_2 = \dot{V}CO_2/\dot{V}_A$. Therefore, an increase in $CO_2$ production or a decrease in alveolar ventilation leads to an increase in $P_{CO_2}$. Normally $P_{CO_2}$ is tightly regulated, with normal values at rest between 38 and 42 mm Hg, and is not affected by age. Hypercapnia can be due to a wide range of causes. Alveolar ventilation ($V_A$) is dependent on both minute ventilation ($V_E$) and dead-space ventilation ($V_D$) in the relationship where $V_T$ is the tidal volume:

$$V_A = V_E (1 - V_D/V_T)$$

Conditions such as emphysema or interstitial lung disease lead to an increase in $\dot{V}_D$ and a corresponding decrease in $\dot{V}_A$, which can result in hypercapnia with exertion or at rest. Hypoventilation can be due to a number of causes besides parenchymal lung disease, including musculoskeletal and neurologic causes. ABG analysis provides a simple measure of oxygenation and ventilation and the presence of hypoxia or hypercapnia should identify a higher-risk patient who warrants a more thorough evaluation.

## PREOPERATIVE PULMONARY FUNCTION TESTING

Spirometry was first used by John Hutchinson in 1848 and is the most common test performed in the pulmonary function laboratory. Spirometry measures the changes in volume and flow during tidal breathing, maximal forced expiration, and inhalation. The graphic interpretation of the test, the flow volume loop depicts both inspiration and expiration tracings. At least three tests are performed to ensure reproducible effort. Figure 3-3 shows the flow volume loops of a normal individual compared with the patterns seen in obstructive and restrictive lung disease. Spirometry provides several measurements that are important to understand, including the forced vital capacity (FVC), $FEV_1$, and $FEV_1$/FVC ratio. The FVC is a measure of the volume exhaled during the entire forced expiratory effort. The FVC is decreased in both obstructive and restrictive lung diseases. It can also be decreased as a result of chest wall deformities, pleural disease, or neuromuscular diseases. The $FEV_1$ measures the volume of gas exhaled in the first second of exhalation (Fig. 3-4). In restrictive lung disease, the $FEV_1$ is decreased in similar proportion to the FVC; therefore, the $FEV_1$/FVC ratio is normal or even increased. In contrast, patients with obstructive lung disease have difficulty emptying the air within the lungs because of an increased resistance to expiratory flow and a loss of elastic recoil, and the $FEV_1$ is decreased to a greater degree than the FVC. The expiratory flow limitation seen in obstructive lung disease leads to a characteristic decrease in the $FEV_1$/FCV ratio and a classic

"scooped out" expiratory flow-volume loop. Spirometry is the only pulmonary function test needed to make the diagnosis of obstructive lung disease, and an $FEV_1$/FVC ratio of less than the fifth percentile of predicted is the diagnostic criterion of the American Thoracic Society (ATS).[14] After a diagnosis of airway obstruction has been made, the severity of obstruction is usually determined by the percent predicted of the $FEV_1$, as shown in Table 3-3.

Spirometry is suggestive of restrictive lung disease when both FVC and $FEV_1$ are decreased but the $FEV_1$/FVC ratio is normal; however, measured lung volumes (a distinct test) must demonstrate a decreased total lung capacity to make the diagnosis. Spirometry can also be ordered with and without the use of inhaled bronchodilators to determine the amount of reversible airway obstruction. Reversible airway obstruction is defined as greater than a 12 to 15 percent improvement in the $FEV_1$ or FVC after treatment with an

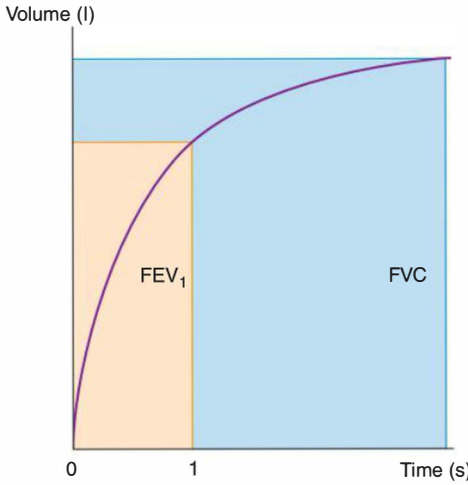

**FIGURE 3-4** Graphic representation of forced expiratory volume at 1 s ($FEV_1$) as related to forced vital capacity (FVC).

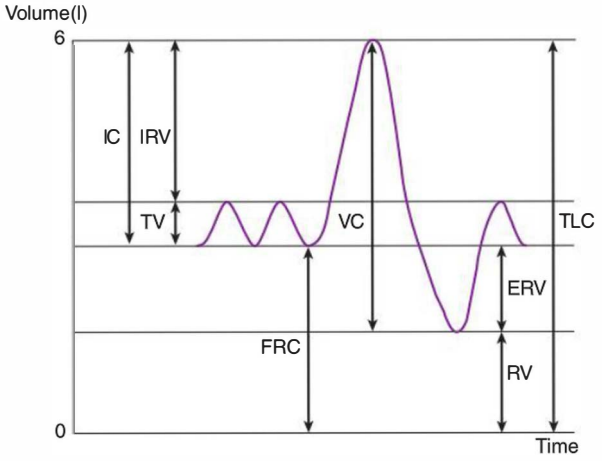

**FIGURE 3-5** Graphic representation of spirometric relationships. (From surgical tutor.org.) inhaled bronchodilator. The identification of patients with reversible airway obstruction can be an important component of a preoperative pulmonary evaluation, with a view to decreasing airway obstruction and minimizing surgical morbidity. Although spirometry is the most common of all the pulmonary function tests, more extensive testing of lung volumes or gas transfer is often needed.

Since spirometry measures only the volume of air exhaled (vital capacity, VC), it is unable to measure the residual volume (RV) or the total lung capacity (TLC). RV is the air left in the lung after a complete exhalation. TLC equals the RV plus the VC (Fig. 3-5). Several different techniques can be used to determine the TLC and RV. The three most common techniques to measure lung volume include inert gas dilution, nitrogen washout, and body plethysmography. A detailed discussion of each of these techniques is beyond the scope of this chapter; however, it is important to recognize that neither the inert gas technique nor the nitrogen washout technique measures the volume from poorly ventilated areas of the lung. Therefore, both these techniques can underestimate the TLC in patients with obstructive lung disease and air trapping, that is, patients with emphysema. Plethysmography will give an accurate measurement of lung volumes in these patients. As mentioned above, lung volumes are required to make the diagnosis of restrictive lung disease, which is defined by a TLC of less than 80 percent predicted and can result from a wide variety of causes, including pulmonary fibrosis, chest wall disorders, obesity, or neuromuscular disease. After confirming the presence of restriction, the VC is commonly used to quantify the severity of restriction, as shown in Table 3-4.

For patients with airway obstruction, the total lung capacity is usually normal or increased. Lung volumes are important for patients with airway obstruction and a decreased FVC to look for the presence of air trapping or coexistent restrictive lung disease. Air trapping is the inability to empty areas of the lung and consequent hyperinflation. Lung volumes in this setting demonstrate an elevated RV, greater than 130 percent predicted, and often an elevated TLC. A decreased TLC in the presence of airway obstruction indicates a combination of obstructive and restrictive disease. The combination of obstruction and restriction can make

**TABLE 3-3: Severity of Airflow Obstruction Based on $FEV_1$**

| $FEV_1$ | Severity of Obstruction |
|---|---|
| Greater than 70% predicted | Mild |
| 60–69% predicted | Moderate |
| 50–59% predicted | Moderately severe |
| 35–49% predicted | Severe |
| Less than 35% predicted | Very severe |

**TABLE 3-4: Severity of Restrictive Ventilatory Defect Based on Vital Capacity**

| Vital Capacity (VC) | Severity of Restriction |
|---|---|
| Greater than 60% predicted | Mild |
| 40–60% predicted | Moderate |
| Less than 40% predicted | Severe |

**TABLE 3-5: Typical Pulmonary Function Changes for Specific Diseases**

| Category | $FEV_1$/FVC | FVC | RV | DLCO |
|---|---|---|---|---|
| Asthma | Normal or ↓ | ↓ | Normal or ↑ | Normal |
| Emphysema | ↓ | Normal or ↓ | ↑ | ↓ |
| Chronic bronchitis | ↓ | ↓ | Normal | Normal |
| Interstitial lung disease | Normal or ↑ | ↓ | Normal | ↓ |
| Pulmonary hypertension | Normal | Normal | Normal | ↓ |
| Neuromuscular disease | Normal | ↓ | Normal or ↑ | Normal |

the determination of pulmonary function difficult to quantify but is important to recognize. Lung volumes are not indicated in all patients who undergo spirometry, but they can be useful in patients with a decreased FVC or in patients who are suspected of having restrictive lung disease of any cause.

The third most common test ordered from the pulmonary function lab is the diffusing capacity. It measures the transfer of gas from the air in the alveolar space to the hemoglobin of the red blood cells. Since it is technically difficult to measure the diffusion of oxygen, the pulmonary function lab measures the DLCO that closely mimics the transfer of oxygen and is used as a surrogate. A normal DLCO is approximately 20 to 30 mL/min/mm Hg and is influenced by age, sex, and height. Since the diffusion of gas is influenced by the oxygen-carrying capacity of blood, it is important to recognize the presence of anemia, which can significantly lower the measured DLCO. Pathologic conditions that can lower the DLCO to less than 80 percent predicted include pulmonary fibrosis, emphysema, pulmonary hypertension, right-to-left intracardiac shunt, and anemia. A few rare conditions can elevate the DLCO (greater than 130 percent predicted), which include asthma, alveolar hemorrhage, mild congestive heart failure (CHF), and left-to-right intracardiac shunt. The combination of spirometry, lung volumes, and DLCO can provide a wealth of information about the pathophysiology of lung diseases. Table 3-5 depicts the expected changes seen in different lung diseases.

In summary, the measurement of pulmonary function is readily available, minimally invasive, and can provide a large amount of information that can influence the perioperative and intraoperative management of patients with lung disease. It is important to remember that borderline pulmonary function tests should not exclude a patient from surgery if he or she is otherwise a good surgical candidate. More extensive exercise testing may be useful in patients with borderline pulmonary reserve who are being considered for lung resection.

## EXERCISE TESTING

Exercise testing can be used in a variety of clinical settings, including the assessment of patient suitability for lung resection. In this setting, exercise testing has been advocated for patients at moderate-to-high surgical risk whose pulmonary function, based on the preliminary evaluations, does not suggest adequate pulmonary reserve. Specifically, exercise testing may be useful in patients with obstructive lung disease and those with a postoperative predicted $FEV_1$ less than 1 L. It may also be informative in evaluating patients with a combination of obstructive and restrictive lung disease. Exercise testing can take several different forms. Simple tests such as the 6-min-walk or the stair-climb test have been evaluated in a small series of patients undergoing thoracotomy for lung cancer and have been shown to predict operative morbidity and mortality. During the 6-min-walk test, the subject walks on level ground at a brisk pace for 6 min and the distance covered is measured in feet. A stair-climb test measures the number of steps an individual can climb at a normal pace. One small study showed that a 6-min-walk distance of less than 1000 ft was predictive of complications within 90 days, with a positive predictive value of 85 percent and a negative predictive value of 100 percent. A stair-climb test result of less than 44 steps was also useful, with a positive predictive value of 91 percent and a negative predictive value of 80 percent.[28] The shuttle walk test has recently been validated to linearly correlate with $\dot{V}O_{2max}$, with a shuttle distance of 250 m, being equivalent to a $\dot{V}O_{2max}$ of 15 mL/kg/min.[15] For centers where formal CPET facilities are not easily accessible, these simple tests may be useful in carefully selected patients.

For most medical centers, more extensive testing can be performed with CPET, which offers the opportunity to measure the cellular, respiratory, and cardiovascular responses to exercise. CPET is underused because of a common lack of understanding of the test and the interpretation of the clinical information that it provides. There are a wide range of clinical situations in which CPET can be helpful. These include assessment of unexplained dyspnea or fatigue, disability evaluation, monitoring of response to treatment or rehabilitation programs, transplant evaluations, and preoperative risk assessment. To perform the test, a subject exercises on a stationary bike or treadmill, which calculates the work performed. While exercising, the individual is connected to a continuous electrocardiogram to monitor for arrhythmias or signs of myocardial ischemia. In addition, gas exchange is measured including oxygen ($O_2$) consumption and carbon dioxide ($CO_2$) production. Also spirometry

and ABG measurements can be obtained before, during, and after exercise. A complete discussion of the interpretation of CPET is beyond the scope of this chapter, and has been recently reviewed elsewhere.[32]

Some of the more useful physiologic measurements provided by CPET are discussed briefly below. The most basic measurements include responses to graded exercise in terms of blood pressure, heart rate, and respiratory rate. The frequent monitoring of vital signs can provide important information regarding the cardiovascular response to stress. Blood pressure and heart rate are measured every several minutes or continuously via an arterial catheter. Normal individuals should be able to exercise to a heart rate of greater than 80 percent of the predicted maximal heart rate. In an individual who is unable to reach 80 percent of maximum heart rate without reaching other limits, physical deconditioning may be the cause of dyspnea. The normal blood pressure response to exercise is a moderate increase. Large increases or inappropriate decreases in blood pressure with graded exercise can help to identify cardiovascular pathology. Spirometry can also be performed as part of CPET. It is often performed before and after CPET. Decreases in $FEV_1$ and $FEV_1$/FVC can identify exercise-induced bronchospasm as a cause of dyspnea.

Most of the data provided by CPET are obtained from the measurement of exhaled gas. These measurements are interpreted in the context of the work being performed on the stationery bike or treadmill, which is recorded as well. One of the more useful measurements provided by CPET is the maximal oxygen uptake during graded exercise ($\dot{V}O_{2max}$). Oxygen consumption is determined by the cardiac output, arterial oxygen content, and extraction of oxygen by the tissues. In interpreting a CPET, $\dot{V}O_2$ is one of the first results to look at because it indicates whether the patient's physiologic responses allow him or her to reach maximal aerobic function. A subject who is unable to reach 80 percent $\dot{V}O_{2max}$ with exercise is considered to have exercise limitation. If the aerobic function is limited, reflected in a $\dot{V}O_{2max}$ less than 80 percent predicted, other measurements can be used to determine the cause of the limitation. As stated earlier, $\dot{V}O_{2max}$ is also the most studied value for predicting surgical risk, especially for patients undergoing lung resection surgery.

For patients who are identified as having exercise limitations, CPET can be helpful in determining the etiology. Except for highly trained athletes, normal individuals are cardiac-limited in response to exercise. This limitation is indicated when the heart rate (HR) reaches above 80 percent of the predicted maximum. Most normal subjects have a ventilatory reserve of approximately 10 L/min or 10 to 30 percent of the ventilatory capacity. The maximum ventilatory capacity is predicted by using the maximum voluntary ventilation (MVV) determined by spirometry. The percent of ventilatory capacity reached with exercise is calculated by dividing the $\dot{V}_E$ by the MVV. An individual has reached his or her ventilatory limits when $\dot{V}_E$/MVV is greater than 80 percent. In addition to ventilatory limits, the respiratory system can be limiting because of problems with gas exchange or $\dot{V}$/Q mismatching. Several different measurements can be used to identify problems with gas exchange. The arterial $P\dot{O}_2$ normally increases with exercise owing to improved $\dot{V}$/Q matching and increasing $\dot{V}_E$. Abnormal responses to exercise include a decrease in arterial $PO_2$ or an increase in the A–a gradient. The arterial $P\dot{C}O_2$ normally decreases with exercise owing to the increased $\dot{V}_E$. An increase in the $P\dot{C}O_2$ with the increasing $\dot{V}_E$ seen with exercise is indicative of an abnormal increase in the dead space/tidal volume ratio ($\dot{V}_D/\dot{V}_T$). Abnormalities in gas exchange can be due to pathologies within the lung parenchyma or pulmonary vascular disease.

Another value that is frequently reported is the anaerobic threshold (AT). AT is the $\dot{V}O_2$ during exercise where aerobic metabolism is supplemented with anaerobic metabolism. The level is reflected by an increase in the lactic acid within the blood. Several different methods can be used to identify the AT. For patients with arterial catheters, frequent blood sampling can be performed to measure blood lactate levels. More commonly, the AT is extrapolated from measures of exhaled gas. The switch from aerobic to anaerobic metabolism leads to a cascade of physiologic events. Increasing blood lactate leads to a decrease in arterial pH, consumption of bicarbonate, and subsequent increase in $\dot{C}O_2$ production. This is reflected in a nonlinear increase in $\dot{V}O_2$ once the subject passes the AT. The acidosis also causes an increased ventilatory drive and an increased $\dot{V}_E$. A graph of $\dot{V}CO_2$ and $\dot{V}_E$ can be used to extrapolate the AT. The AT can be used to estimate the amount of exercise or work that an individual can perform for a sustained time period.

Finally, another useful measurement provided by CPET is the $O_2$ pulse, which is calculated by dividing the $\dot{V}O_2$ by the HR. It also is equal to the stroke volume (SV) multiplied by the arterial to mixed venous oxygen content difference $[c(a-v)O_2]$.

$$O_2 \text{ pulse} = \dot{V}O_2/HR = SV * c(a-v)O_2$$

With exercise, the $O_2$ pulse normally increases, mainly owing to increasing oxygen extraction by the muscles and increasing $c(a-v)O_2$. The $O_2$ pulse decreases and reaches its maximum at low levels of work in several settings, including CHF, anemia, arterial hypoxia, or elevated carboxyhemoglobin levels. These are just a few of the physiologic measurements provided by CPET. When used in the correct setting and interpreted by knowledgeable physicians, they can be extremely useful in a number of clinical settings.

## THE ROLE OF BRONCHOSCOPY IN THORACIC SURGERY

Lung cancer is the leading cause of cancer deaths in the United States, and will account for approximately 157,300 deaths in 2010, more than colon, breast, and prostate cancers combined.[16] It is estimated that 222,520 new cases of lung cancer will be diagnosed in 2010, and the incidence and number

of lung cancer deaths continues to increase amongst women in the United States.[17] It is estimated that over 90 percent of all lung cancer deaths in the United States each year are directly caused by tobacco abuse.[18] Bronchoscopy provides a minimally invasive approach for the diagnosis of mediastinal and hilar adenopathy, tumors in the central airway, and solitary parenchymal lesions. Advances in navigation such as electromagnetic and virtual bronchoscopic navigation (to be discussed later) have significantly improved the yield for peripheral tumors. Given the minimally invasive nature of the procedure, bronchoscopy is also an invaluable tool to the surgeon and pulmonologist for both the diagnosis and the management of airway tumors and disorders.

## STAGING SYSTEM FOR LUNG CANCER

The initial workup and diagnostic testing for lung cancer is focused on appropriate staging of the disease. Prognostic data including response to treatment and survival as well as guidance for treatment management have all been closely linked with appropriate staging of the disease. Lung cancer staging and pathology is divided into two main diagnostic groups: non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC)

The staging of NSCLC is defined by the TNM system. The tumor characteristics (T) focus on tumor size and presence and extent of tumor invasion into surrounding structures. Lymph node involvement (N) is defined as the presence or absence of metastasis to regional lymph nodes in defined anatomic locations. The distant metastasis criteria (M) is simply the presence or absence of distant metastatic disease or malignant pleural disease.[19,20] The TNM staging system is used to determine the clinical-diagnostic stage, surgical-pathologic stage, re-treatment stage, and autopsy stage as defined above.

The classic staging of SCLC is a two-stage system defined by limited or extensive stage disease. Limited disease is defined by a disease burden that is within a single radiation therapy portal window and found within the ipsilateral hemithorax. Extensive disease is defined by tumor burden beyond the ipsilateral hemithorax.[21]

## STAGING IMPLICATIONS ON TREATMENT AND SURVIVAL IN NSCLC

Using the TNM data, patient groups can be further classified into TNM subset groups. Each main group in this classification schema has similar treatment modalities and survival data. Unfortunately, the overall results of treatment response in NSCLC patients remain poor except for localized disease.[22] Surgical resection of patients with Stage I–IIb portends a better prognosis and the highest chance of potential cure. Radiation therapy has curative intent in a minority of NSCLC patients and is mostly used in conjunction with chemotherapy and/or palliation. Chemotherapy has multiple roles in the treatment of NSCLC from neoadjuvant chemotherapy and radiation prior to surgery, adjuvant therapy after resection, to palliation.[23] The 5-year survival in patients with NSCLC correlates well with the clinical and pathological stage. Patients with Stage IA disease have a median survival of 58 months whereas patients diagnosed with Stage IV disease have a median survival of only 6 months.

The clear relationship between staging and response to treatment and survival has made proper diagnostic testing and sampling crucial in the diagnosis and treatment of lung cancer. Clinical or noninvasive staging can markedly differ from pathologic staging. It has been shown that up to 24 percent of patients are clinically overstaged and 20 percent are understaged when compared with pathologic data.[24] As a result of these types of discrepancies with their obvious repercussion, the major US and European societies have published guidelines suggesting that all patients should have appropriate pathologic staging prior to undergoing cancer resection with curative intent.

## INVASIVE STAGING FOR NSCLC

Based on the TNM staging system, patients in whom distant metastatic disease has been investigated and found to be absent, the status of nodal metastasis within the mediastinum is the next level of investigation that is needed to accurately stage the patient. To accomplish this, there are several invasive procedures available to the clinician. The primary goal of each procedure is to obtain adequate tissue from within the mediastinal lymph nodes to accurately perform pathologic staging.[25] Regional lymph nodes within the mediastinum are classified by the nodal TNM system (Fig. 3-6). Station 1 nodes or high mediastinal nodes are found lying above a horizontal line at the upper rim of the brachiocephalic (left innominate) vein where it ascends to the left, crossing in front of the trachea at its midline. Station 2 nodes or the upper paratracheal nodes are located lying above a horizontal line drawn tangential to the upper margin of the aortic arch and below the inferior boundary of Station 1 nodes. Station 3 nodes or the prevascular and retrotracheal nodes may be designated 3A (anterior) and 3P (posterior). Station 4 nodes or the lower paratracheal nodes on the right lie to the right of the midline of the trachea between a horizontal line drawn tangential to the upper margin of the aortic arch and a line extending across the right main bronchus at the upper margin of the upper lobe bronchus, and contained within the mediastinal pleural envelope; the lower paratracheal nodes on the left includes nodes to the left of the left lateral border of the trachea, medial to the ligamentum arteriosum. Station 5 nodes (subaortic or aortopulmonary window nodes) are lateral to the ligamentum arteriosum or the aorta or left pulmonary artery and proximal to the first branch of the left pulmonary artery and lie within the mediastinal pleural envelope. Station 6 nodes are lying anterior and lateral to the ascending aorta and the aortic arch or the

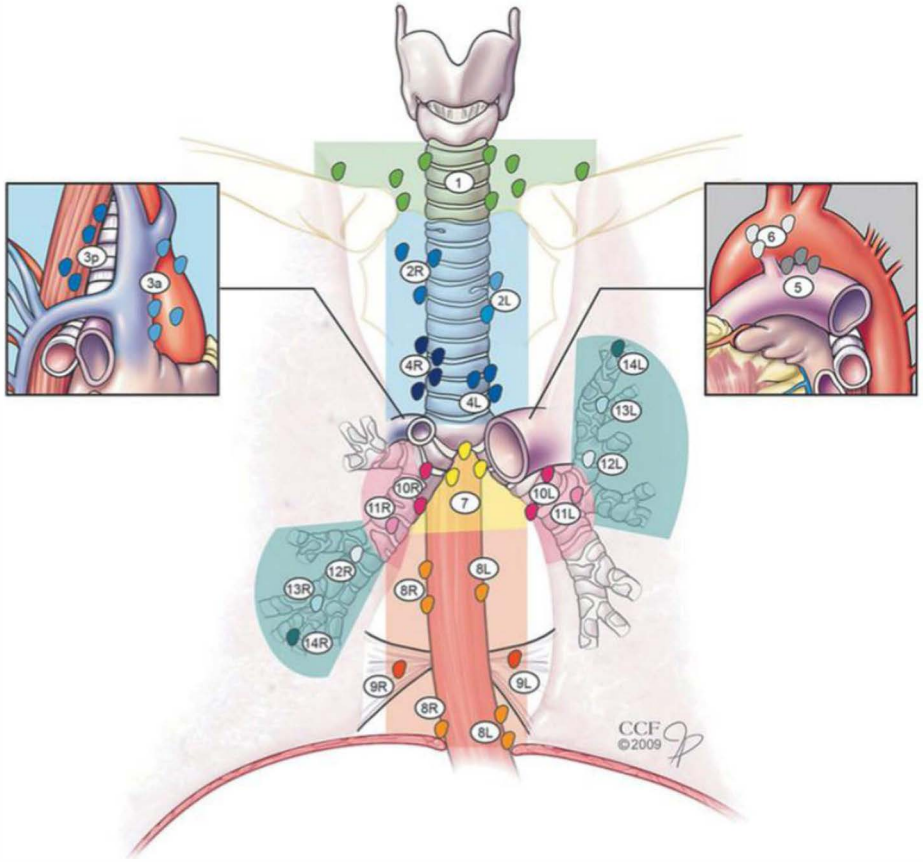

**FIGURE 3-6** Lymph node map: lymph node zones are supraclavicular (green), upper mediastinal (blue), aortopulmonary (gray), subcarinal (yellow), lower mediastinal (orange), hilar/interlobar (pink), and peripheral (aqua). (Reprinted with permission from Cleveland Clinic Center for Medical Art and Photography © 2009–2013. All rights reserved.)

innominate artery, beneath a line tangential to the upper margin of the aortic arch. Station 7 is found caudal to the carina of the trachea, but not associated with the lower lobe bronchi or arteries within the lung. Station 8 nodes lie adjacent to the wall of the esophagus and to the right or left of the midline, excluding subcarinal nodes. Station 9 nodes are located within the pulmonary ligament, including those in the posterior wall and lower part of the inferior pulmonary vein.[26,27]

N1 nodes are defined as peribronchial, intrapulmonary, or hilar nodes located on the ipsilateral side of the primary tumor. N2 nodes are located ipsilateral to the primary tumor within the mediastinal and subcarinal region. N3 nodes are found within the contralateral hilar/mediastinal and ipsilateral or contralateral scalene or supraclavicular regions.

Mediastinoscopy is currently considered the 'gold standard' for mediastinal staging. The procedure allows access to lymph nodes located in nodal Stations 2, 4, and the anterior component of Station 7. The sensitivity of mediastinoscopy ranges between 78 and 98 percent with a specificity of 100 percent. Despite direct visualization of lymphatic tissue and resection there is still a 9 to 11 percent false negative rate.[28] The limits of the procedure are that routine lymph node sampling during a mediastinoscopy does not allow access to Stations 5, 6, posterior 7, 8, and 9.[29] An anterior mediastinoscopy (Chamberlain procedure) can allow sampling of nodal Stations 5 and 6. Although mediastinoscopy is generally a same-day procedure, it is performed in under general anesthesia, has a mortality of 0.2 percent with a morbidity reported up to 2.5 percent, and has considerable cost. It is a surgical procedure performed on a subset of patients who may be deemed nonoperable for eventual surgical resection.[28] Despite current recommendations, mediastinoscopy is performed only in 27 percent of patients undergoing lung cancer surgery. Successful sampling of nodal tissue is variable and nodal tissue is obtained less than 50 percent of the time.[30]

Bronchoscopy provides a minimally invasive approach for the diagnosis of tumors in the central airways. The bronchoscopic evaluation of patients with suspected malignancy is guided by clinical symptoms as well as radiographic findings. Depending upon the history and chest computed tomography (CT)/PET-CT findings, bronchoscopy may be

the diagnostic modality of choice as it can both make the diagnosis and stage the patient at the same sitting. If appropriate staging is to be performed, biopsy of the lesion that will place the patient in the highest stage should occur prior to other biopsies. For example, if a patient presents with a left lower lobe mass, an enlarged subcarinal (Station 7), and right paratracheal (Station 4R) lymph node, the appropriate procedure would be a bronchoscopy with sampling of the 4R node as this would stage the patient with N3 disease, making the patient unresectable. Initial biopsy of the mass could contaminate the working channel and make the sample a false positive, precluding the patient from potentially curative surgery.

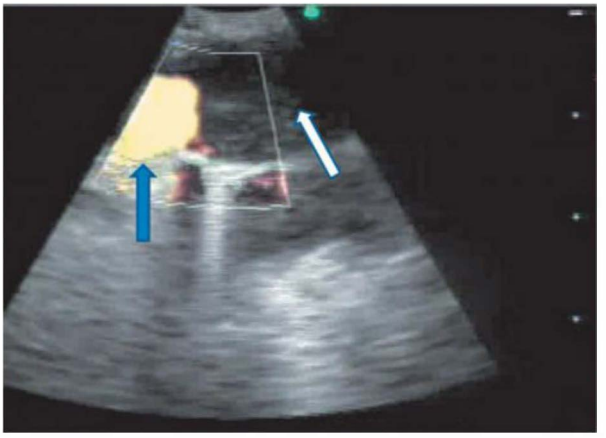

**FIGURE 3-7** EBUS ultrasound image of lymph node (white arrow) and surrounding blood vessel (blue arrow).

## ENDOBRONCHIAL ULTRASOUND-GUIDED TRANSBRONCHIAL NEEDLE ASPIRATION

Transbronchial needle aspiration (TBNA) is a biopsy technique used during bronchoscopy that involves passing a catheter containing a needle through the tracheal or bronchial wall into lymph nodes or masses to obtain samples for cytopathologic assessment. The procedure is performed in the outpatient setting with moderate sedation. TBNA has been shown to be an effective means of both diagnosing and staging lung cancer. Unlike mediastinoscopy, nodal Stations 2, 3, 4, 7, 10, and 11 are generally accessible with TBNA. The procedure is minimally invasive, safe, and less costly than mediastinoscopy and has been shown to preclude surgery in up to 29 percent of patients.[31]

Recent advances in TBNA have integrated ultrasound technology with bronchoscopy allowing direct visualization of mediastinal structures that has greatly improved the yield. In 2005, the convex probe endobronchial ultrasound (EBUS) bronchoscope was first introduced in Japan. The bronchoscope has an ultrasound transducer at the tip as well as a video processor to allow for both a live ultrasound and optical image. This newer technology provides a distinct advantage by allowing for real-time visualization of the targeted lymph node through the airway wall with ultrasound technology. Real-time imaging of the needle sampling of the target lymph node (white arrow) can then be achieved through the working channel of the bronchoscope with a dedicated needle system. Additionally, mediastinal vessels can also be visualized (blue arrow), decreasing the incidence of inadvertent puncture (Fig. 3-7).

Although the convex EBUS system has only been available since 2005, it has made a significant impact on the practice and yield of diagnostic testing for mediastinal staging of lung cancer. In a recent study of 572 lymph nodes in 500 patients, EBUS-TBNA was shown to have a diagnostic yield of 94 percent.[32]

Because of the success and impact of EBUS-TBNA on lung cancer staging, data are now emerging directly comparing the gold standard of mediastinoscopy to EBUS-TBNA for mediastinal staging. A recent prospective, crossover trial with surgical lymph node dissection compared biopsy results of paratracheal and subcarinal lymph nodes in patients undergoing EBUS-TBNA and then mediastinoscopy. In the 66 patients studied, the prevalence of malignancy was 89 percent. EBUS had a higher overall diagnostic yield (91%) compared with mediastinoscopy (78%; $p = 0.007$) in the per lymph node analysis. The sensitivity, specificity, and negative predictive value of EBUS were 87, 100, and 78 percent, respectively. The sensitivity, specificity, and negative predictive value of mediastinoscopy were 68, 100, and 59 percent, respectively. No significant differences were found between EBUS (93%) and mediastinoscopy (82%; $p = 0.083$) in determining true pathologic N stage (per patient analysis).

Although data are favorable, it is important to recognize the limitations of a needle aspirate in that a nondiagnostic test with EBUS-TBNA should not be considered a negative test. If a nondiagnostic result is obtained, confirmatory tissue with mediastinoscopy or by video-assisted thoracic surgery (VATS) is required.[33]

## EBUS FOR RESTAGING THE MEDIASTINUM

Recent data in the oncologic literature have suggested that there may be a role for surgical resection in NSCLC patients who are initially Staged IIIA–N2 and have a favorable response to induction chemotherapy or chemoradiotherapy (neoadjuvant therapy). These patients may be successfully downstaged allowing for resection with curative intent. Accurate restaging of these patients after induction therapy can be challenging. Previously, the standard of care was to attempt restaging with mediastinoscopy. Unfortunately, performing a repeat mediastinoscopy, especially after radiation therapy, can be technically difficult due to scar tissue formation, adhesions, and bleeding.[34,35] It has also been shown that due to these technical challenges the yield of diagnostic tissue sampling during repeat mediastinoscopy decreases.[36]

As a result of the technical challenges associated with repeat mediastinoscopy, some experts currently recommend EBUS-TBNA for initial staging and mediastinoscopy for restaging of the mediastinum, with the understanding that the sensitivity, specificity, and overall accuracy seems to be less for restaging when compared with data on initial staging.[37]

## EBUS AND EUS TBNA: FULL ENDOSCOPIC STAGING

Both EBUS and EUS (esophageal ultrasound) allow for successful sampling of mediastinal lymph nodes but each have certain limitations. EUS fine needle aspiration (FNA), performed with a specialized gastroscope through the GI tract, allows for access to Stations 4R, 4L, 5 (potentially), 7, 8, and 9. In addition, EUS allows access to the left adrenal gland, which could therefore evaluate for Stage 4 disease. By using EBUS-TBNA and EUS-FNA during the same procedure, studies have shown a combined approach yielding a sensitivity of 93 percent and a negative predictive value of 97 percent. In this study, the combined modalities also yielded better results than either procedure alone.[38]

## BRONCHOSCOPIC SAMPLING OF PARENCHYMAL ABNORMALITIES

EBUS can also be used to help improve the accuracy of sampling peripheral nodules. The earliest EBUS system used a radial probe with a 20 MHz transducer that could be inserted via a 2.8 mm working channel. Despite not allowing for real-time guidance, the early studies with radial probe EBUS found significant improvements in the yield of sampling of peripheral nodules. The sonographic characteristics of peripheral nodules have also been shown to correlate well with histology.

There are several available tools by which to obtain specimens during bronchoscopy including forceps biopsy, brushing, bronchial wash/lavage, and TBNA. To perform a bronchoalveolar lavage (BAL), the bronchoscope is wedged in the target segmental or sub-segmental bronchus leading to the lesion. Aliquots of normal saline solution are instilled, and then aspirated. BAL is thought to sample approximately 1 million alveoli, and the cellular and noncellular contents of the lavage fluid have been shown to closely correlate with the inflammatory nature of the entire lower respiratory tract.[39-42] The use of multiple sampling modalities has been shown to improve the yield as compared with using only one method to sample parenchymal nodules/masses.

## ENHANCED NAVIGATION

The use of electromagnetic navigation, especially when used in conjunction with radial probe EBUS, is a novel technology that has been shown to allow accurate sampling of peripheral solitary pulmonary nodules <2 cm in diameter.[43] A virtual bronchoscopy is generated from the patients CT scan. The patient lies in an electromagnetic field and a steerable guide is placed through an extended working channel. A bronchoscopic registration is then performed, which in essence, fuses the CT scan with the patient's anatomy. Navigation to the target then occurs by looking at the CT in the axial, sagittal, and coronal planes. Once found, the guide is removed, and standard bronchoscopic tools such as TBNA needles, forceps, and brushes are placed through the extended working channel.

## RIGID BRONCHOSCOPY AND ADVANCED BRONCHOSCOPIC TECHNIQUES

Although many advanced techniques can be performed with flexible bronchoscopy, the rigid bronchoscope remains the tool of choice for therapeutic interventions.[44,45] The rigid bronchoscope provides an airway in which to oxygenate/ventilate the patient as well as pass multiple devices including large-bore suction catheters, laser/argon plasma coagulation (APC)/electrocautery fibers, the microdebrider blade, and larger biopsy instruments. The rigid bronchoscope itself can also be used to achieve relative lung isolation, dilate stenosis, and "core-out" tumor from the central airways.

### Argon Plasma Coagulation

APC is a noncontact method using ionized argon gas (plasma) to achieve tissue coagulation and hemostasis. As the plasma is directed to the closest grounded source, APC has the ability to treat lesions lateral to the probe. The depth of penetration for APC is approximately 2 to 3 mm; hence, the risk of airway perforation is less when compared with lasers.

### Laser Therapy

The Nd:YAG (neodymium:yttrium aluminum garnet) laser remains the most widely used laser in the lower respiratory system, and has been used for both benign and malignant disease.[46] In addition, newer lasers, the Nd:YAP (yttrium–aluminum–perovskite) and the $CO_2$ laser with a flexible catheter, have been introduced and are available. The primary advantage of laser photoresection is that it provides rapid destruction/vaporization of tissue. Care must be taken however, as the depth of penetration can approach 10 mm, and airway perforation with resultant pneumothorax, pneumomediastinum, and vascular injury has been reported. Despite this, the safety record of laser bronchoscopy is excellent, with an overall complication rate of less than 1 percent.[46] Lesions most amenable to laser therapy are central, intrinsic, and short (<4 cm), with a visible distal endobronchial lumen.[47]

When lesions meet these criteria, patency can be re-established in more than 90 percent of the cases.

## Electrocautery

Electrocautery uses alternating current at high frequency to generate heat, which cuts, vaporizes, or coagulates tissue depending on the power. Electrocautery is a contact mode of tissue destruction and a variety of cautery probes are available including blunt-tip probes, knives, and snares. The snare is an ideal tool for pedunculated lesions as the stalk can be cut and coagulated while preserving the majority of the tissue for pathologic interpretation.[48] The knife is also an excellent tool for producing radial incisions prior to dilation of web-like tracheal stenosis. As with laser therapy, the risks of electrocautery include airway perforation, airway fires, and damage to the bronchoscope.

## Microdebrider

Mechanical debridement of endobronchial tumor and granulation tissue can be accomplished with various modalities. Microdebriders are powered instruments that consist of a hollow shaft with a rapidly rotating blade and suction. The device has been used for many years by the otolaryngology community for sinus surgery and other modalities.[49] More recently, the procedure has been used as an alternative to or in conjunction with other modalities such as laser excision or electrocautery. Airway debulking with the microdebrider is accomplished by shaving and suctioning tissue under direct telescopic guidance through the rigid bronchoscope.[50]

The microdebrider requires a rigid bronchoscope or laryngoscope, and due to its rigid structure, it is not amenable to the flexible bronchoscopic technique. Although the technology appears promising and a useful modality in the management of central airway obstruction (CAO), further studies are required to assess the long-term outcomes of the microdebrider compared with more conventional therapy.

## Airway Stents

Montgomery is credited as initiating the widespread use of airway stents after his development of a silicone T-tube in 1965 for use in patients with tracheal stenosis.[51] Dumon, however, introduced the first completely endoluminal airway stent in 1990.[52] Airway stents are the only technology that can alleviate extrinsic airway compression. They are commonly used in conjunction with the other modalities for patients with intrinsic or mixed disease.

Over the past 15 years, there has been an explosion in both stent design and the number of endoscopists who place airway stents. As with any procedure, it is crucial to understand the indications and contraindications of the procedure as well as be able to anticipate, prevent, and manage the associated complications. Unfortunately, the "ideal stent" has not yet been developed. This stent would be easy to insert and remove, yet not migrate; of sufficient strength to support the airway, yet be flexible enough to mimic normal airway physiology and promote secretion clearance; biologically inert to minimize the formation of granulation tissue; and available in a variety of sizes.

There are currently two main types of stents: metal, generally made of nitinol, and silicone. Although metal stents are easily placed, they can be extremely difficult to extract. They are available in covered (typically with silicone or polyurethane) and uncovered varieties. For malignant airway obstruction, the only appropriate metal stents are covered models, which minimize tumor in growth. Some authors feel that there is no indication for an uncovered metal stent. The over-use of metallic stents in patients with nonmalignant airway obstruction has led to the FDA creating a black-box warning recommending their use as a modality of last resort in these patients.[53] The main advantage of metal stents is their larger internal:external diameter ratio as compared with silicone stents. Although silicone stents require rigid bronchoscopy for placement, they are more easily removed and are significantly less expensive.

## Complications During Bronchoscopy

Bronchoscopy is generally considered a relatively safe procedure.[54] That being said, it is common that patients in whom bronchoscopy is performed can have multiple comorbidities and the bronchoscopist needs to be aware of the patient's medical history including medications and allergies. In addition, the bronchoscopist needs to have a thorough understanding of the effects and side-effects of the medications they will use to achieve adequate topical anesthesia and moderate sedation and be skilled in airway management should the patient experience hypoxemia/hypercapnia. Transient fever is the most common adverse event following BAL, and can be seen in up to one-third of patients. Major adverse events including hypoxemia, pneumothorax, bleeding, and death may also occur, and both patient and procedure-related factors are important determinants. The British Thoracic Society has published its recommendations concerning the performance of diagnostic flexible bronchoscopy and includes steps that should be taken to minimize complications.[54]

## SUMMARY

Cardiothoracic surgery can be associated with a high rate of pulmonary complications due to the high-risk nature of the surgical procedures and also because most of the patients have underlying lung disease. The preoperative evaluation can risk stratify which patients can safely undergo these potentially lifesaving surgical procedures with minimal risk

of morbidity and mortality. By understanding both the preoperative evaluation algorithm and role for bronchoscopy in the preoperative workup, the number of patients who are offered surgery safely can be maximized and the complications limited.

## PULMONARY PHYSIOLOGY, FUNCTION TESTS, AND BRONCHOSCOPIC TECHNIQUES BOARD REVIEW QUESTIONS (CHAPTER 3)

1. Which of the following is the most specific predictor of postoperative complications following lung resection?
   A. $FEV_1$ less than 0.8 L
   B. DLCO less than 40% predicted
   C. Elevated A–a gradient
   D. $P\dot{C}O_2$ greater than 44 mm Hg
   E. $V\dot{O}_{2max}$ less than 10 mL/kg/min
2. Which of the following elevates DLCO?
   A. Emphysema
   B. Pulmonary hypertension
   C. Congestive heart failure
   D. Anemia
   E. Pulmonary fibrosis
3. Which of the following lymph node stations is incorrect?
   A. Station 1: above brachiocephalic vein
   B. Station 9: within pulmonary ligament
   C. Station 6: anterior and lateral to ascending aorta
   D. Station 4L: left of lateral border of trachea
   E. Station 7: cephalad to carina
4. Which of the following nodes is best accessed by a Chamberlain procedure?
   A. Station 2
   B. Station 4
   C. Station 6
   D. Station 8
   E. Station 10
5. Endobronchial ultrasound has been demonstrated to be superior to mediastinoscopy for staging in all of the following except?
   A. Sensitivity
   B. Specificity
   C. Negative predictive value
   D. Overall diagnostic yield

## ANSWERS

1. **Answer: E.** Maximal exercise testing is the most specific predictor of postoperative complications.
2. **Answer: C.** Congestive heart failure elevates DLCO; the other conditions reduce DLCO.
3. **Answer: E.** Station 7 nodes are caudal, not cephalad, to the carina.
4. **Answer: C.** Station 6 nodes (aortopulmonary window) are best accessed via left anterior thoracotomy, or Chamberlain procedure.
5. **Answer: C.** Endobronchial ultrasound has been demonstrated to be superior to mediastinoscopy for staging except in specificity, in which the two modalities are equivalent.

# Congenital Pulmonary Disorders

*Anne C. Fischer*
*Eric Griffiths*

**KEY CONCEPTS**

- Epidemiology
  - Congenital pulmonary anomalies include a multitude of clinical entities linked by a common developmental lineage. The prevalence is dependent upon the particular malformation. These anomalies represent different variations of shared embryologic pathways and therefore possess clinical similarities and occasionally present simultaneously.
- Pathophysiology
  - Physiologically, the impact of these lesions, which can be mild or detrimental, depends largely on two factors—pulmonary hypoplasia and fetal hydrops. The mass effect of fetal intrathoracic lesions can impair lung development and decrease cardiac output secondary to mediastinal shift, causing fetal demise or severe compromise. Lesions that replace functional lung parenchyma can also cause pulmonary insufficiency.
- Clinical features
  - Many congenital pulmonary anomalies present postnatally with frequent pulmonary infections, respiratory distress, and hemoptysis, although others are discovered incidentally on plain chest radiography. Diagnoses of congenital pulmonary malformations are now typically detected with prenatal surveillance imaging.
- Diagnostics
  - Prenatal ultrasound is the primary diagnostic modality whereby congenital pulmonary anomalies are identified in utero and the degree of hydrops is assessed. Postnatally, computed tomography or magnetic resonance imaging can be used to differentiate lesions based on anatomic characteristics; but since surgical resection is the treatment for most mass lesions, additional imaging is of value to ensure the prenatal lesion has not regressed.
- Treatment
  - Resection often is curative for focal lesions, but outcome is ultimately dependent on residual pulmonary function and associated medical conditions. Fetal intervention is being offered as an alternative for some congenital pulmonary anomalies, although outcomes have been mixed.
- Outcomes
  - Outcomes depend on the particular disease process. Generally, excellent survival rates are noted with timely treatment of bronchogenic cysts, pulmonary sequestration, and congenital lobar emphysema. A large percentage of congenital pulmonary adenomatoid malformations postnatally do regress. The prognoses of other entities are adversely affected by the presence of fetal hydrops prenatally or the association of recurrent infections or malignant risk in some of the anomalies.

## INTRODUCTION

Congenital lung malformations represent a diverse spectrum of developmental defects. A high index of suspicion for these relatively rare malformations is essential in evaluating a thoracic lesion in a child. The clinical presentation is variable, presenting as respiratory distress in a newborn or remaining asymptomatic until adolescence or even adulthood. The revolution in prenatal imaging, with the ubiquity of antenatal ultrasound, has enabled earlier and more frequent detection of pulmonary anomalies: The most commonly identified prenatal pulmonary anomaly remains the cystic lung lesion with an estimated incidence of 1 in 8300 to 35,000 births.[1,2] Prenatal characteristics such as

**TABLE 4-1: Characteristics of Congenital Pulmonary Malformations**

| Type | Typical Presentation | Anomaly | Associations |
|---|---|---|---|
| Bronchogenic cyst | Mediastinal location, asymptomatic | Abnormal bronchial budding | – |
| Peripheral pulmonary cyst | Respiratory distress in infants[a] | Abnormal alveolar development | – |
| Congenital lobar emphysema | Acute respiratory distress in neonate (LUL > RML) | Hyperinflation associated with cartilage deficiency | 20% cardiac anomalies |
| Pulmonary sequestration | Antenatally/incidentally detected | – | Anomalous blood supply from aorta; potential GI tract communication |
| Extralobar (25%) | Neonate; dyspnea or difficulty feeding | Separate lobe and pleura | |
| Intralobar (75%) | Later recurrent pneumonias[a] | Intraparenchymal | |
| **CPAM[b] Type (Prevalence)** | **Typical Presentation** | **Cyst size/Epithelium Type** | **Associations** |
| 0 (1–2%) | Acinar dysplasia; fatal at birth | 0.5 cm, tracheal epithelium | – |
| I (>65%) | Macrocystic; often asymptomatic, postnatal dx | 10 cm, bronchiolar epithelium | Risk of malignancy, BAC |
| II (20%) | Small cysts; symptomatic in neonate | 2.5 cm, bronchiolar epithelium | 20% anomalies[c] |
| III (10%) | Microcystic; solid and symptomatic in neonate | 1.5 cm, bronchiolar epithelium | |
| IV (2–4%) | Newborn to 6 years; tension pneumothorax, small cysts on the periphery of lobes | 7.0 cm, distal acinar epithelium | Risk of malignancy, PPB |

BAC, bronchoalveolar carcinoma; LUL, left upper lobe; PPB, pulmonary pleuroblastoma; RML, right middle lobe.

[a]Present later with infection.

[b]Most commonly diagnosed antenatally, characterized by excess bronchiolar proliferation.

[c]Anomalies including extralobar sequestration, diaphragmatic hernia, pulmonary hypoplasia, cardiovascular malformation, hydrocephalus, skeletal malformation, jejunal atresia, Pierre-Robin syndrome, and bilateral renal agenesis/dysgenesis.

the presence and size of cysts, lung echogenicity, anatomic location, vascular supply, and associated pathophysiology including hydrops and mediastinal shift can characterize a lung lesion (see Table 4-1). Since congenital lung lesions vary in behavior from regression to causing fetal demise, the prognosis of a prenatally detected lesion is not always evident. Advances in prenatal imaging have been quintessential in defining the criteria for early therapeutic intervention in lesions adversely affecting fetal development as opposed to expectant management with postnatal resection of symptomatic cases.

A brief highlight of normal lung development is useful in conceptualizing the development of bronchopulmonary foregut malformations. The primitive foregut is the anlage of both pulmonary and gastrointestinal systems, which explains the persistent connection in some anomalies.[3] At 3 weeks, in the *embryonic* stage of gestation, lung development is initiated by the divergence of the tracheal diverticulum from the primitive foregut. Maturation of the conducting airways from the trachea to the terminal bronchioles is completed by the end of the *pseudoglandular* stage (16th week). The development of the highly differentiated respiratory unit for gas exchange occurs in the remaining 24 weeks in utero during the *cannalicular* and *terminal sac* stages wherein the distal respiratory bronchioles and alveoli are added to the pulmonary matrix. In the final 4 weeks in utero up until 8 years of age, the lung's surface area undergoes an exponential increase in alveolar growth.

## BRONCHOGENIC CYSTS

Bronchogenic cysts arise from abnormal budding of the tracheobronchial tree as true foregut anomalies to form a nonfunctioning cystic mass.[4] Two-thirds of these cysts separate early in development and thus are centrally located in the mediastinum, firmly adherent to the carina. These solitary cysts are well-encapsulated spherical lesions, lined with bronchial epithelium and mucous glands. They remain asymptomatic until superimposing infection of the fluid-filled cyst occurs: Less frequently they can be seen in a newborn due to the size of a large lesion compressing surrounding normal lung. Bronchogenic cysts should be excised to avoid further complications of infection, air trapping, and hemoptysis. Otherwise, they present as the most common benign mediastinal cyst in adulthood.

Those that appear later in development as peripheral cysts are less common and are located in the periphery of lower lobes. Since they occur during rapid bronchial division, a bronchial communication is more common. These are lined by ciliated respiratory epithelium resulting from the pseudoglandular stage of development. Respiratory distress is the most common presentation, causing cyanosis, retractions, and grunting from rapid enlargement of the cyst. Air trapping occurs during expiration due to the cyst's lack of cartilaginous support: A ball valve mechanism results in continued cyst expansion. The mass effect of the cyst causes further airway compression and distal

pulmonary hyperinflation, worsening the respiratory compromise. The cyst can be misdiagnosed as a pneumothorax, especially in the setting of a large coexistent bronchial communication; similarly a pneumothorax can be an anticipated complication.

Many of the asymptomatic lesions are discovered incidentally, or when infectious complications intervene with an air fluid level or with recurrent pneumonias localized to the same lobe, pneumothorax, hemoptysis, and upper gastrointestinal bleeding.[5-7] In congenital cystic lung lesions, 3 percent asymptomatic lesions become symptomatic within 10 months[7] and up to 10 percent can become symptomatic in 3 years.[8] Although a chest radiograph is diagnostic in over three-fourth of the cases, thin section computed tomography (CT) scanning with contrast is highly accurate in demonstrating these lesions, particularly in the setting of recurrent respiratory exacerbations.

Regardless of location and presence of symptoms, surgical resection is mandated. Resection of even asymptomatic bronchogenic cysts is advised to precede symptoms to avoid complications. Mediastinal lesions can be enucleated thoroscopically or via a thoracotomy. Segmental or lobar resection is curative for peripheral lesions.

## CONGENITAL PULMONARY ADENOMATOID MALFORMATIONS (CPAM)

CPAM, formerly known as congenital cystic adenomatoid malformations (CCAM), are hamartomatous, multicystic, or mixed adenomatoid intrapulmonary masses, arising from the overgrowth of terminal respiratory bronchioles with suppression of alveolar growth. They are usually localized to one lobe, although they can affect all lobes with equal frequency. These cystic structures may interconnect and communicate with the tracheobronchial tree.

The current classification of CPAMs[9] is a modification of the initial Stocker classification of CCAMs based on cyst size[10] to include the site of origin in the tracheobronchial tree, assuming each type correlates to a perturbation increasingly distal along the airway from trachea/bronchus to acinar/alveolar sac (see Table 4-1). Type 0 malformations are the least common, are composed of multiple, small (<0.5 cm) cysts, and are uniformly fatal at birth (see Table 4-1). Type I malformations, the "large cyst lesion," are the most common (>65%) with a typically dominant large cyst(s) (~10 cm). Type II malformations, "the small cyst lesion," occur 20 to 25 percent of the time, consist of multiple intermediate size (0.5–2.0 cm) cysts, and are associated with the highest incidence of congenital anomalies (20%), including renal dysgenesis, cardiac anomalies, congenital diaphragmatic hernia (CDH), and congenital heart disease. Type III malformations, the only one known as "the adenomatoid lesion," represent 8 percent of CPAMs and are solid appearing with tiny cysts (<1.5 cm) involving typically the entire lobe or lung. Poor prognostic indicators are often associated with Type III cysts since these microcystic lesions tend to be capable of inducing fetal hydrops and pulmonary hypoplasia. Type IV malformations are newly identified large cysts ~7 cm in size usually in one lobe that consists of nonciliated alveolar cells (Type I pneumocytes) in contrast to the ciliated cells in all other types. They often appear in newborns to 6 years of age and have an association with respiratory distress with pneumothorax or infection as well as an association with a risk of malignancy.[11-13]

Prenatally the presentation of a CPAM is highly variable with detection as early as 12 to 14 weeks. For an attempt at a more clinically relevant classification, the ultrasonographic appearance was used as the basis by Adzick et al. using either macrocystic with cysts >5 cm (previously Type I) or microcystic with cysts <5 cm (Type II or III depending on the underlying histology).[14] Macrocystic has a more favorable prognosis and microcystic is more solid with an unfavorable prognosis associated with more anomalies. What has more recently become evident is the recognition of "hybrid" lesions containing features of both CPAMs and bronchopulmonary sequestrations (BPS) indistinguishable until histologic review. Thus, the differential diagnosis of a prenatal cyst can include a variety of lesions, such as CPAM, bronchopulmonary sequestrations, bronchogenic cyst, congenital lobar emphysema (CLE), esophageal duplication cyst, and a CDH (see Fig. 4-1). Thus, further imaging with Doppler ultrasonography can detect the anomalous blood supply to the aorta found with sequestrations. CT imaging can correlate with a pathologic diagnosis of a CPAM with 100 percent concordance.[15] Magnetic resonance imaging (MRI)/fetal MRI can assist in distinguishing whether an echogeneic lung mass is a Type III CPAM or a CDH given the heterogeneity of the mass.

The natural history of these lesions is unpredictable and can range from complete regression in 25 percent to 20 percent that are symptomatic prenatally, and then the ~5 percent category of those with such a rapid growth that mediastinal shift, caval obstruction, impaired cardiac filling, and subsequent nonimmune hydrops and polyhydramnios result.[16] CPAMs without hydrops have a generally favorable survival rate, whereas those 5 percent of CPAMs that develop hydrops and anasarca are associated with a higher mortality rate of up to 100 percent without intervention.[17,18] Large masses causing fetal hydrops in a fetus <32 weeks require in utero intervention to reverse the hydrops and potential fetal demise.[19] In macrocystic lesions, cyst aspiration and thoracoamniotic shunting have been used to alleviate mediastinal compression and hydrops. In contrast, in microcystic lesions, open fetal surgery has been a surgical option to treat those lesions causing hydrops fetalis. CPAMs may grow progressively or regress by unclear mechanisms. Maternal administration of betamethasone has been associated with resolution of hydrops and an increased survival in fetuses with high-risk CPAMs compared with historical controls[20,21]: These findings may be related to a reduction in CPAM growth or improved maturation and need to be

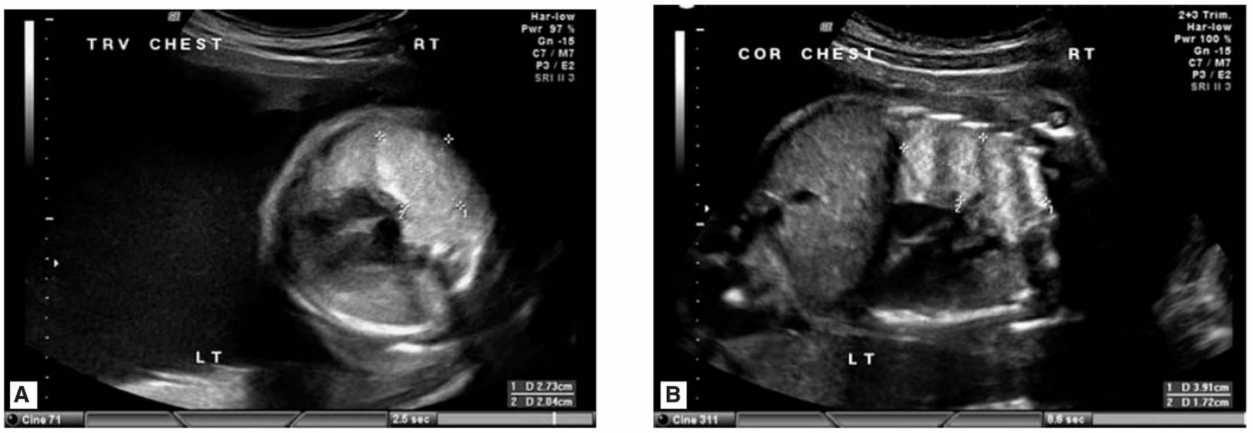

**FIGURE 4-1** Ultrasound of thoracic mass: **A.** Transverse view and **B.** coronal view. This CPAM was demonstrated at 18 weeks filling the thoracic cavity and resolved by 35 weeks of gestation.

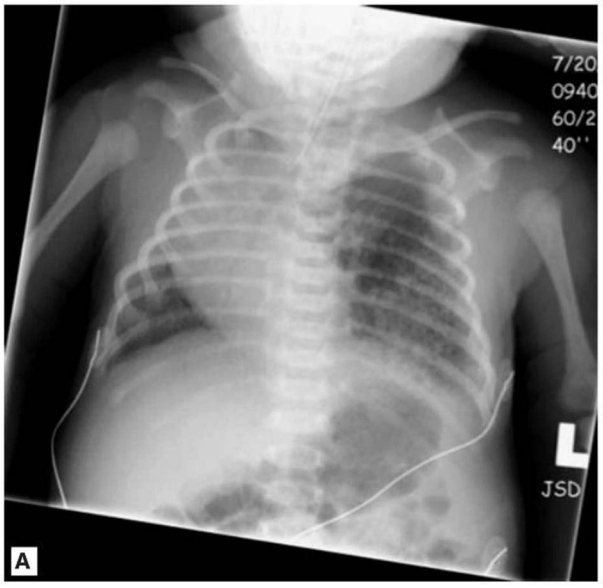
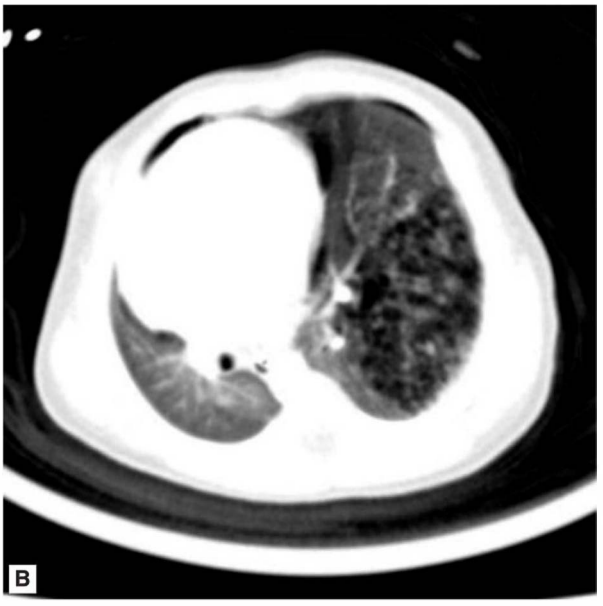
confirmed in a controlled trial as opposed to being compared to historical controls.[22]



Of those who are symptomatic postnatally, 80 percent present with respiratory distress compared to 20 percent who present more subtly with recurrent infections. Symptoms at birth are often due to the mass effect causing mediastinal shift, pneumothorax, or pulmonary hypoplasia.[14,23] The size of the lesion dictates the degree of respiratory distress. Large cysts can produce respiratory distress with such expansion of the cysts from air trapping that the contralateral lung is compressed. Microcystic lesions are also more frequently associated with distress in the newborn period. A radiograph or CT can demonstrate the hyperexpanded lung with contralateral herniation and mediastinal shift (see Fig. 4-2). Those who are symptomatic, with respiratory distress, recurrent infections, or a pneumothorax, require surgical resection and the urgency of resection depends on the symptoms. The majority of children (>60%) remain asymptomatic postnatally[23] and the management remains controversial since the potential to become infected, cause hemoptysis, pneumothorax, or hemothorax, or undergo malignant degeneration persists. At least 8 percent of congenital lung lesions spontaneously regress by 9 months, so the timing of surgery can wait for that period of potential resolution.[24] In a large series, 3 percent of asymptomatic lesions can become symptomatic in that time frame.[8] All lung lesions, even disappearing lung lesions, prenatally need to be reconfirmed by postnatal imaging since CT scans can best identify a detectable malformation unvisualized on plain chest x-ray (CXR)[25] (see Fig. 4-3).



There is a rare association of CPAMs with malignancies, and 8.6 percent of malignant tumors have been shown to be associated with prior cystic malformations,[13] such as bronchioalveolar carcinoma (BAC) in older children and adults, pleuropulmonary blastomas (PPB) in young children, and embryonal rhabdomyosarcomas. PPB are the most common malignancy associated with early childhood cysts (Type IV) with 0.35 to 0.65 PPB cases per 100,000 births.[2] Later in childhood, BAC occurs and can be associated with Type I cysts, and cystic synovial sarcoma appears de novo. Despite the confusion in the literature, PPB is not a premalignant CPAM, since cytogenetic abnormalities (Trisomy 8) are distinctly found in PPB suggesting that the earliest presentation of a low-grade cystic malignancy that can convert into a sarcomatous disease over 12 to 72 months.[26,27] Malignancies have been reported later even after resection of the CPAM. So not only does elective resection for pathologic certainty require close surveillance postresection, but also prophylactic resection of a lung cyst will not prevent the later development of PPB.[28]

Definitive therapy is surgical resection. An elective anatomic lobectomy, either via an open or a thoracoscopic approach, remains the procedure of choice to avoid incomplete resection, persistent pneumothorax, and potential recurrence. Multilobar involvement is best treated by a lobectomy with a segmental resection for a parenchymal-sparing procedure.[29] Postoperatively, respiratory compromise may acutely worsen in neonates with coincident pulmonary hypoplasia and pulmonary hypertension, requiring extracorporeal membrane oxygenation.

## PULMONARY SEQUESTRATION

A pulmonary sequestration is an ectopic mass of nonfunctioning lung tissue with an anomalous systemic artery and without a bronchial connection to the tracheobronchial tree. Sequestrations are classified as either intralobar or extralobar.[4,30] The majority are intralobar, as an anomalous intraparenchymal lesion without investing pleura. Extralobar sequestrations are separate from the normal lobe and contained within a distinct visceral pleura. The typical blood supply is from the systemic circulation arising from the descending or abdominal aorta (75%) or other thoracic vessels (25%): This systemic blood supply is characteristically

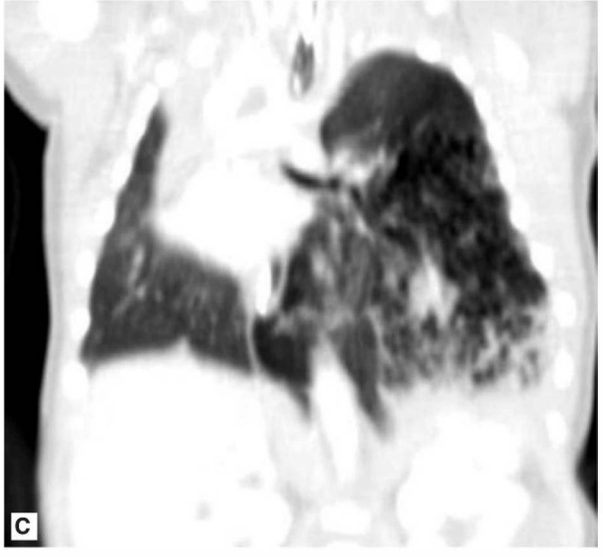


**FIGURE 4-2** **A.** CXR of left CPAM in a newborn in respiratory distress. **B.** Thoracic CT of left CPAM in newborn (sagittal cuts). **C.** Thoracic CT with coronal reconstructions of thoracic mass in newborn—left lower lobe identified. Note mediastinal shift and apparent compression of left upper lobe consistent with presentation of respiratory distress. (CPAM, congenital pulmonary airway malformation; CLE, congenital lobar emphysema).

identified upon imaging. The systemic feeding arteries often are multiple and branch off the aorta, and up to 15 percent are infradiaphragmatic. Multiple theories attempt to postulate the derivation of sequestrations, assumed to develop as accessory lung buds off an anomalous aortic branch that separates due to traction upon further growth.

Most sequestrations are in the left lower lobes. The most common type is the "Rokitansky lobe," which occurs on the left with a feeding vessel from the aorta. However, 15 percent of sequestrations are located below the diaphragm as a retroperitoneal mass, called an "abdominal accessory lobe."[31] Sequestrations often have a patent communication with the gastrointestinal tract, and extralobar types are associated with congenital anomalies (50–65%) such as congenital diaphragmatic hernia,[31] bronchial atresia, colonic duplication, pulmonary hypoplasia, absent pulmonary artery, vertebral anomalies, and esophageal communication.[4,32] Because of the associated diaphragmatic defects, radioisotope scanning of right lower lobe lesions can distinguish a herniated liver from a right lower lobe sequestration.

Typically the extralobar sequestration is asymptomatic and found incidentally prenatally or due to the associated congenital anomalies. Despite no connection to the tracheobronchial tree, the sequestration may become infected by hematogenous spread causing respiratory distress from recurrent pneumonia. Symptoms may also reflect the

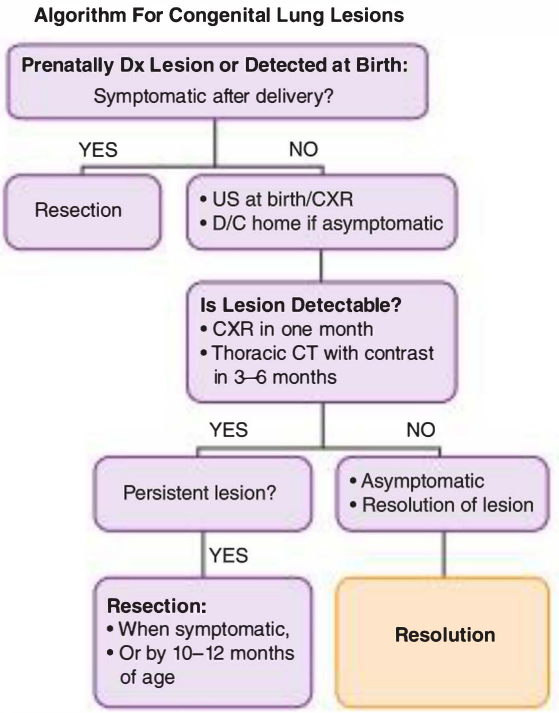

**FIGURE 4-3** Algorithm for congenital lung lesions.

secondary cardiac manifestations from the coincident large venous shunts to the systemic circulation. Typical venous drainage is to the systemic circulation (inferior vena cava, azygous vein, or portal vein) creating a left-to-right shunt; thus, large shunts are at risk for potentially creating high-output cardiac failure. The scimitar syndrome is due to anomalous venous return to the vena cava creating a left-to-right shunt, and the venous drainage appears as a sickle-shaped shadow in the right lower lobe.[31]

Intralobar lesions remain asymptomatic until recurrent infections or hemoptysis occurs. A cystic or atelectatic mass is present on plain radiographs but definitive diagnosis requires documenting a systemic arterial supply by Doppler ultrasonography or nuclear magnetic resonance angiography: Both techniques are more frequently used than angiography, the prior gold standard. All sequestrations should be excised to avoid future complications with infection and fatal hemoptysis. Intralobar lesions may require a lobectomy, and extrapulmonary lesions require an excision that can be accomplished by standard thoracotomy or more recently by thoracoscopic resection.[33,34]

## CONGENITAL LOBAR EMPHYSEMA

CLE is a rare cause of respiratory distress in the newborn and is characterized by overexpansion of a pulmonary lobe and alveolar overdistension. A variant of bronchomalacia can cause CLE with focal cartilaginous deficiency of the tracheobronchial tree, resulting in regional airway collapse with expiration and then air trapping leading to emphysematous changes. Over one-half are diagnosed by 1 month of age and presentation after 6 months is unusual. A chest radiograph is sufficient to diagnose a large emphysematous lobe with atelectasis in the ipsilateral lobe. The upper lobes are most commonly involved with the following incidence—left upper lobe (42%), right middle lobe (35%), right upper lobe (21%), and bilaterally (20%).[30] The etiology is not clear in the majority of cases; however, both bronchial cartilaginous dysplasia and polyalveolar lobes are the pathologies present in a quarter of cases each. Extrinsic compression can occur from an intrathoracic mass such as a vascular or cardiac anomaly, teratoma, vascular ring, or patent ductus arteriosus. Even the end stage of respiratory distress syndrome in a neonate with chronic pulmonary interstitial emphysema (PIE) can evolve into CLE. Alveolar cells make up the emphysematous tissue seen in both CLE and CPAM Type IV that are pathologically similar. Twenty percent of associated malformations are cardiac anomalies (PDA, ventricular septal defect [VSD], and tetralogy of Fallot). Moderate distress presents initially until the lobe gradually enlarges causing cyanosis by continued compression of the uninvolved lung due to continued expansion. Severe life-threatening distress is rare but may require immediate surgical intervention, a thoracotomy, to allow the overinflated lobe to decompress upon herniation and to prevent the intrathoracic compression by a lobectomy. Bronchoscopy and positive pressure ventilation can exacerbate the underlying pathophysiology of CLE creating a life-threatening situation, which can only be relieved by rapid thoracotomy to decompress the hyperventilated lobe. Many lesions can resolve spontaneously but surgical intervention, a lobectomy, is indicated in those lesions that are symptomatic from compression of the normal lung and mediastinum.[35]

These varied congenital lung malformations are relatively unusual individually. Early diagnosis requires a high index of suspicion and familiarity with their presentation since they are difficult to detect. Whereas early diagnosis is amenable to an uncomplicated surgical resection, a delay in diagnosis can be associated with substantial morbidity.

## CONGENITAL PULMONARY DISORDERS BOARD REVIEW QUESTIONS (CHAPTER 4)

1. Which of the following is correct regarding bronchogenic cysts?
   A. One-third of cysts develop early and are centrally located.
   B. Bronchogenic cysts are usually spherical and lined with intestinal epithelium.
   C. Thirty percent of clinically silent cysts will become symptomatic within 10 months of age.
   D. Segmental resection is appropriate for peripheral lesions.
   E. Up to 25 percent of congenital cysts will spontaneously regress by 9 months of age.

2. Which is correct regarding congenital pulmonary adenomatoid malformation (CPAM)?
   A. This lesion is a result of terminal respiratory bronchiole undergrowth.
   B. It is usually localized to one lobe.
   C. Type 0 malformations are the most common.
   D. Type 1 malformations are associated with the highest incidence of congenital anomalies.
   E. Type 3 malformations are generally larger than 7 cm.

3. Which is true for congenital pulmonary adenomatoid malformation (CPAM)?
   A. CPAM may grow or regress by unclear mechanisms.
   B. Twenty percent present with respiratory distress.
   C. Microcystic lesions are less frequently associated with respiratory distress.
   D. CPAM is classified as a premalignant pleuropulmonary blastoma.
   E. Thoracoscopic wedge resection is the preferred surgical option.

4. Which is true regarding pulmonary sequestration?
   A. The majority are extralobar.
   B. Up to 75 percent of systemic feeding arteries are infradiaphragmatic.
   C. Most sequestrations occur in the left lower lobe.
   D. Sequestrations rarely have a patent communication with the gastrointestinal tract.
   E. The intralobar form is associated with congenital anomalies in 40 percent of patients.

5. Which is true regarding congenital lobar emphysema (CLE)?
   A. It is characterized by underexpansion of a lobe due to alveolar underdistension.
   B. Presentation after 6 months is unusual.
   C. The most commonly involved lobe is the right upper lobe.
   D. Fifty percent of associated anomalies are cardiac.
   E. Bronchoscopy and positive pressure ventilation is the treatment of choice.

## ANSWERS

1. **Answer: D.** Segmentectomy or lobectomy is appropriate therapy for peripheral cysts. Two-thirds of cysts develop early and are centrally located. Bronchogenic cysts are usually spherical and lined with bronchial epithelium. Only 3 percent of clinically silent cysts will become symptomatic within 10 months of age. Up to 8 percent of cysts will spontaneously regress by age 9 months.
2. **Answer: B.** CPAM is usually localized to one lobe. It is the result of terminal respiratory bronchiole overgrowth. Type 1 malformations are the most common. Type 2 malformations have the highest association with congenital anomalies. Type 3 malformations have multiple cysts <1.5 cm.
3. **Answer: A.** CPAM may grow or regress spontaneously by unclear mechanisms. Eighty percent present with respiratory distress, which most frequently is associated with microcystic lesions in the newborn. CPAM is not a premalignant lesion. Anatomic lobectomy is the procedure of choice.
4. **Answer: C.** Most sequestrations occur in the left lower lobe. The majority are intralobar and often have a patent communication with the gastrointestinal tract. About 15 percent of systemic feeding arteries arise below the diaphragm. The extralobar form is associated with congenital anomalies in 40 percent of cases.
5. **Answer: B.** Presentation is most common during the first month of life. CLE is characterized by alveolar overdistension with subsequent overexpansion of the lobe. The most commonly involved lobe is the left upper lobe. Twenty percent of associated anomalies are cardiac. Bronchoscopy and positive pressure ventilation can worsen the pathophysiology and create a life-threatening situation.

# 5 Benign Diffuse Pulmonary Disorders

*Christian A. Merlo*

**KEY CONCEPTS**

- Epidemiology
  - Diffuse benign pulmonary disorders cover a broad range of primary lung diseases and can be associated with systemic disorders.
- Pathophysiology
  - Most benign pulmonary disorders are derived from intrinsic or extrinsic injury. Such injury can take the form of cellular and/or humoral immunologic injury triggered by inhaled antigens, infectious agents, or autoimmune processes. Chemical injury from smoking or certain drugs has also been implicated.
- Clinical features
  - Most presenting symptoms include progressive dyspnea and cough. Other symptoms include chest pain, wheezing, and hemoptysis. Physical signs include heavy use of accessory muscles of breathing, cyanosis, and clubbing. Systemic signs of illness seen with some illnesses include fatigue, weight loss, and malaise.
- Diagnostics
  - Most diffuse benign disorders are characterized by plain chest radiography, computed tomography, and open or video-assisted thoracoscopic lung biopsy. Most of these disorders have characteristic radiologic pulmonary parenchymal patterns, adenopathy (e.g., sarcoidosis), and histologic characteristics. Bronchoscopy with transbronchial biopsies/bronchoalveolar lavage, fine-needle aspiration biopsies, and sputum cultures and/or cytologies is also helpful in many cases. Finally, a complete blood count with differential (e.g., eosinophilic processes) and serum chemistries are helpful in some cases.
- Treatment
  - Although treatment recommendations vary with the particular pulmonary process, many are corticosteroid based while others are predicated on removal of an inciting agent (e.g., drug, tobacco smoke).
- Outcomes
  - Clinical outcomes vary widely according to the particular process.

## INTRODUCTION

Diffuse benign pulmonary disorders cover a broad range of primary lung diseases but may also be associated with systemic disorders. These range from chronic conditions such as idiopathic pulmonary fibrosis (IPF) associated with poor survival to acute disease of hypersensitivity pneumonitis (HP) with usually a good response to treatment. Some of these diseases have unique clinical characteristics while others share similar radiographic changes, symptoms, or pulmonary function abnormalities. Therapy differs for many of the diffuse benign pulmonary diseases, making accurate diagnosis paramount.

Each of these disorders may occur due to intrinsic or extrinsic injury. For instance, the pneumoconioses are due to the inhalation of damaging foreign material into the lung, while HP is due to an allergic response to foreign material or medications. On the other hand, interstitial lung diseases such as IPF, sarcoidosis, lymphangioleiomyomatosis (LAM), eosinophilic granulomatosis (EG), and the pulmonary disorders associated with collagen vascular disease are believed to be due to intrinsic lung inflammation and injury.

The benign diffuse lung diseases may also be categorized based on physiologic presentation, particularly the type of change seen by pulmonary function studies. Some of the disorders are associated with an obstructive ventilatory defect (LAM, EG) or restrictive ventilatory defect [IPF, nonspecific interstitial pneumonitis (NSIP), asbestosis], while others may present with combined obstruction and restriction

[sarcoid, bronchiolitis obliterans with organizing pneumonia (BOOP)].

Finally, these diseases may be categorized based on radiographic findings (i.e., diffuse interstitial infiltrates, alveolar infiltrates, cystic lesions, or honeycombing). This chapter reviews the most common benign pulmonary diseases including clinical presentation, diagnosis, and treatment.

## IDIOPATHIC PULMONARY FIBROSIS (IPF)/USUAL INTERSTITIAL PNEUMONITIS (UIP)

IPF is a progressive, fatal disease with no known cause. It is manifest by diffuse interstitial lung scarring with a predominance of fibrosis in the subpleural and lower lung zones.[1] This disease has several different names, including cryptogenic fibrosing alveolitis, usual interstitial pneumonitis, and IPF. IPF is progressive, refractory to therapy, and ultimately leads to respiratory compromise and death, usually within 5 years of diagnosis.[2–5] The typical patient presents in the seventh decade of life with gradual onset of shortness of breath and a dry, nonproductive cough. Young patients can be affected, however, particularly in familial forms of the disease. IPF is frequently misdiagnosed as "pneumonia" because common symptoms of cough and dyspnea are associated with pulmonary infiltrates; however, the protracted course and lack of fever and purulent sputum make pneumonia less likely. Physical examination typically demonstrates bilateral "Velcro-like" crackles, predominantly in the lung bases. Resting or exercise-induced hypoxemia is often present. Chest radiographs show small lung volumes with interstitial infiltrates predominantly in the lower and peripheral lung zones (Fig. 5-1). High-resolution computed tomography (HRCT) of the chest can help distinguish the diagnosis of IPF from other interstitial lung disorders. Typical findings include peripheral and lower lung zone interstitial thickening with honeycombing and traction bronchiectasis[6,7] (Fig. 5-2A and B). The fibrosis and honeycombing may be interspersed with relatively normal-appearing lung parenchyma. Pulmonary function studies show a restrictive ventilatory defect with a low diffusing capacity for carbon monoxide (DLCO).[7] As the disease progresses, the total lung capacity, vital capacity, and DLCO fall, indicating worsening fibrosis. In the early stages of the disease, oxygen desaturation may occur only with exercise; but as the disease progresses, severe resting hypoxemia is a common finding.[7]

**FIGURE 5-1** PA chest x-ray of a patient with IPF. Note small lung volumes and lower lobe interstitial infiltrates.

The diagnosis of IPF is established by open lung biopsy together with appropriate clinical and radiographic findings.[1,7] Transbronchial bronchoscopic biopsies are frequently performed by many practitioners for interstitial lung disease and may be useful to exclude other diagnoses such as

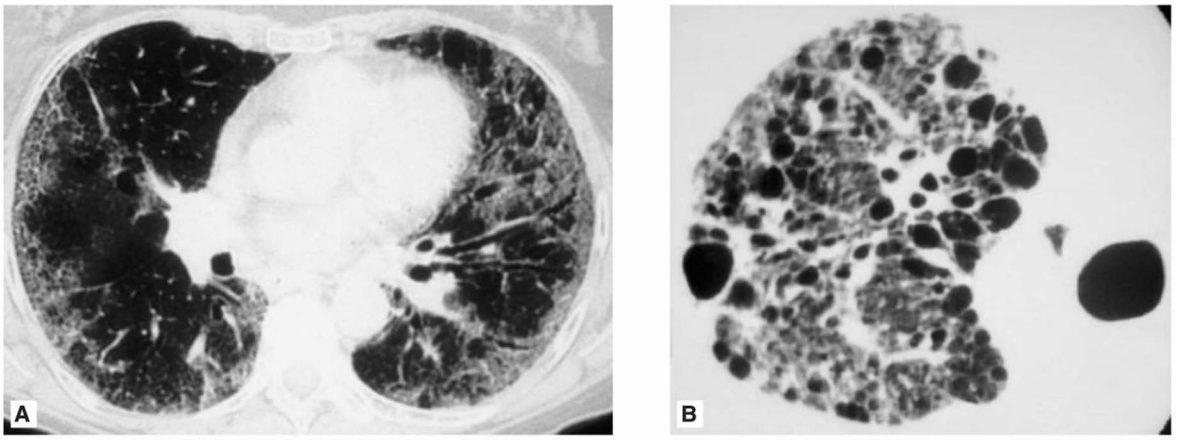

**FIGURE 5-2** **A.** High-resolution chest CT of IPF showing peripheral interstitial fibrotic infiltrates with areas of traction bronchiectasis interspersed with areas of normal lung parenchyma. (Courtesy of Stanley Siegelman, MD.) **B.** Close-up view of HRCT showing marked honeycombing and interstitial fibrotic changes in a patient with IPF.

sarcoidosis, BOOP, eosinophilic pneumonia, or extrinsic allergic alveolitis. However, transbronchial biopsies are inadequate to establish the diagnosis of IPF because a larger tissue sample is necessary to visualize the geographic changes seen in this condition. These include areas of fibrosis and honeycombing interposed between areas of normal-appearing lung[1,7] (Fig. 5-3). Thus, video-assisted thoracic surgical (VATS) biopsy has become the standard approach if a tissue diagnosis is warranted. It is important to note that there is controversy regarding the need to establish a tissue diagnosis when all clinical and radiographic findings suggest the diagnosis of IPF.[8] This is particularly true for older patients and those with far advanced disease. For those patients who are younger with atypical findings, open biopsy should be considered.

There is no known effective medical treatment for IPF. High-dose corticosteroids (1 mg/kg methylprednisolone) given for several weeks and followed by a gradual taper has been the mainstay of therapy for many years, with few patients improving.[7] One study showed minimal improvement with a combination of prednisone and azathioprine,[9] but widespread success with this approach has not been reported. Other potent agents such as cyclophosphamide have been used, also with limited success.[7] Gamma interferon has also been studied but has little clinical benefit.[10,11] For patients below 65 years of age who are otherwise healthy, lung transplantation remains the only viable treatment option for IPF.

## NONSPECIFIC INTERSTITIAL PNEUMONITIS

After Liebow and Carrington proposed the first major classification scheme for the idiopathic interstitial pneumonias (IIP),[12] several investigators found that a significant number of biopsies did not fit into the described subtypes.[13,14] The term *nonspecific interstitial pneumonitis* (NSIP), first used by Katzenstein, represents a distinct histologic type of interstitial *pneumonitis* with clinical characteristics that differ from UIP/IPF.

Although NSIP and IPF may be clinically indistinguishable, there are some differences that may help to differentiate these two diagnoses. Patients with NSIP typically present with subacute symptoms rather than the insidious onset characteristic of IPF.[15] Fever is also a common complaint among patients with NSIP and is rare in IPF.

Radiographically, NSIP typically has diffuse bilateral ground-glass opacities on HRCT.[16] Honeycombing is a hallmark feature of IPF but is not present in NSIP. Alveolar infiltrates and occasionally nodules have been described in NSIP, but these are not common.

The diagnosis of NSIP is made by open or VATS lung biopsy (Fig. 5-4). Katzenstein originally divided biopsies among three groups based on the amount of fibrosis present.[14] Group I consisted of interstitial infiltrates with predominant lymphocytes, occasional plasma cells, and minimal fibrosis. The infiltrates were noted to be temporally uniform, in contrast to the lesion of UIP, which is temporally heterogeneous. Group II contained the interstitial infiltrates but had marked amounts of associated fibrosis. Group III included marked distortion of the lung architecture from collagen deposition, scarring, and occasional honeycombing.

The prognosis for NSIP is much better than that for IPF. The majority of patients will improve or recover (74% in one series).[15] However, the likelihood of improvement depends on the severity of fibrosis. Patients with Katzenstein Group III NSIP (severe fibrosis) have the least favorable prognosis. Corticosteroids with or without other immunosuppressive agents are the mainstay of therapy. However, it is important to note that there are no randomized controlled trials proving benefit for any form of therapy, and a number of patients have improved without specific treatment.

## CRYPTOGENIC ORGANIZING PNEUMONIA/BRONCHIOLITIS OBLITERANS ORGANIZING PNEUMONIA

First described in 1983[17] and then again in 1985[18] under the name BOOP, cryptogenic organizing pneumonia (COP) is an increasingly recognized cause of pulmonary disease. Disagreement continues to exist regarding the name for this process; thus, both names are used interchangeably.[19] Although the term BOOP is more commonly used in the United States, COP is preferred, as designated by the American Thoracic Society and European Respiratory Society. COP specifically refers to the idiopathic form of the disease. However, organizing pneumonia, the histologic correlate, has been identified in association with a variety of diseases as well as drug and inhalational exposures.

COP can present in a variety of forms.[20–23] The most common is a nonresolving pneumonia.[18,20–23] Patients typically complain of fevers, cough, and malaise. Myalgias have been described in a number of patients. Symptoms usually are present for several months, and patients may have been treated with one or multiple courses of antibiotics without significant improvement. Inspiratory squeaks are often present on physical examination.

Mild leukocytosis is common, as well as an elevated erythrocyte sedimentation rate, which may sometimes be over 100. Pulmonary function testing can show a combination of restriction and obstruction as well as a reduced diffusion capacity. Frank hypoxemia is rare.[18]

Chest radiography typically shows multiple areas of patchy alveolar infiltrates bilaterally.[18] CT scans most commonly show areas of consolidation with air bronchograms; however, a variety of other patterns have also been described (Fig. 5-5).[18,21] These range from a diffuse nodular pattern to band-like areas of consolidation. Pleural effusions are uncommon.

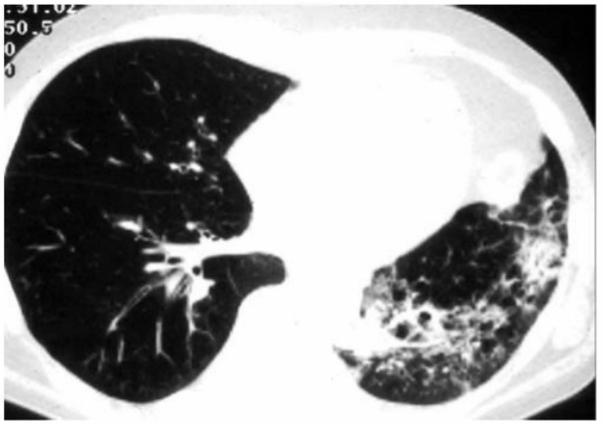

**FIGURE 5-5** Chest CT scan showing the patchy infiltrates characteristic of BOOP.

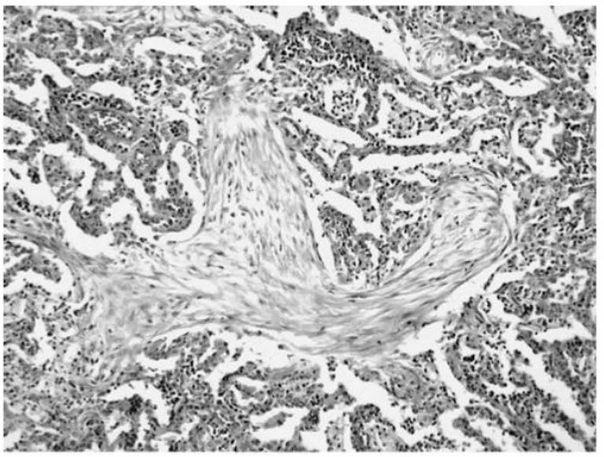

**FIGURE 5-6** Histopathologic specimen from a patient with BOOP. Note tufts of loose collagen plugging the airway.

The diagnosis of COP is made by lung biopsy, which shows the histologic features of organizing pneumonia (Fig. 5-6).[18,20–24] Although transbronchial biopsies are mostly sufficient, the small biopsies obtained by this procedure may be insufficient to completely distinguish the process from other underlying pathology.[19,23,24] It is important to exclude other processes, since organizing pneumonia can sometimes be found in association with other entities, such as fibrotic disease. VATS or open lung biopsy may be necessary in some circumstances to establish a firm diagnosis.

Treatment consists of glucocorticoids for 6 to 12 months.[18,20–24] Patients typically have a good response, with close to two-thirds having clinical remission within a short time. However, relapses while tapering steroids are common. Relapses typically respond to reinstitution of higher doses of glucocorticoids and do not appear to affect the long-term course of the disease.

COP has had other notable presentations.[18,20–24] Focal lesions resembling solitary lung nodules have been described by a number of authors. The diagnosis was typically found after surgical resection, which stemmed from the concern that the nodules were a malignant process. The patients tended to do well without any further treatment. A rapidly progressive form of COP has also been described.[25] This form advances much more rapidly, with a fulminant course and high mortality.

## OTHER IDIOPATHIC INTERSTITIAL PNEUMONIAS

IPF, NSIP, and COP make up the majority of the IIP encountered in clinical practice. There are other forms of IIP that are less common and are dealt with briefly below.

### Acute Interstitial Pneumonia (AIP)

AIP is a rapidly progressive interstitial disease with typically a fulminant course.[19] It typically presents with a viral-like prodrome of myalgias, fever, chills, and malaise. Patients usually present within 3 weeks of onset of the illness and most require mechanical ventilation. CT reveals diffuse ground-glass opacification and, to a lesser extent, basilar airspace consolidation. The histologic lesion is that of diffuse alveolar damage. Mortality is high, well over 50 percent, and there is no effective therapy.

### Respiratory Bronchiolitis-Associated Interstitial Lung Disease (RB-ILD) and Desquamative Interstitial Pneumonia (DIP)

Respiratory bronchiolitis is a pathologic lesion found in cigarette smokers; it is characterized by pigmented macrophages in the lumens of the first- and second-order respiratory bronchioles.[19] These lesions are most often seen incidentally on biopsies done for unrelated reasons and rarely cause symptoms. However, a small percentage of patients do present with clinically significant interstitial disease with this lesion on biopsy; the clinical condition is then termed RB-ILD.

The clinical spectrum ranges from minimal complaints to severe dyspnea.[19] The most common symptoms are gradually progressive dyspnea and new or worsening cough. Males are more likely to be affected than females. CT typically reveals centrilobular nodules, thickened airways, and sometimes ground-glass opacification. Patients almost universally improve with cessation of smoking.

The pathologic lesion of DIP is an accumulation of macrophages in the alveolar spaces.[19] Because of its similar male predominance, association with cigarette smoking, and the presence of macrophages, DIP is thought to represent one end of a spectrum of disease, where the other end would be RB-ILD. However, there are some differences, such as the uniform presence of ground-glass opacification seen in DIP. Honeycombing can be seen in DIP, but only in a minority of patients, and it tends to be very limited in extent. As with RB-ILD, the prognosis is good, with smoking cessation thought to be important. Patients with DIP are commonly treated with corticosteroids, but there have been no treatment trials proving benefit.

### Lymphoid Interstitial Pneumonia (LIP)

LIP is the last of the IIP included in the recent consensus classification.[19] This disease is most often seen in combination with other diseases such as Sjögren syndrome, acquired immunodeficiency syndrome, various autoimmune diseases, and Castleman disease.[19,26,27] The disease tends to affect women more than men. Initial presentations include slowly progressive shortness of breath, cough, and weight loss. CT typically reveals a pattern of bilateral diffuse or patchy ground-glass opacification, with poorly defined centrilobular nodules.[27] Thickening of the peribronchiovascular bundles and irregular septal thickening are also common.[27] Cystic changes are noted in a majority of patients, but honeycombing is less common.

The histology of LIP is marked by a dense infiltration with lymphocytes and plasma cells.[19,26] The infiltration is especially marked in the alveolar septum. Lymphoid follicles and germinal centers are commonly seen.

The prognosis is highly variable, with the majority of patients remaining stable or improving; however, over one-third of patients may have progressive disease.[19,26,27] Treatment usually consists of corticosteroids with or without other immunosuppressive agents.

## INTERSTITIAL LUNG DISEASE ASSOCIATED WITH COLLAGEN VASCULAR DISEASE

The collagen vascular diseases present with a wide range of symptoms and findings, and they have variable courses. Given the systemic nature of the diseases, it is not unexpected to find that patients commonly develop pulmonary pathology. The full range of known complications is beyond the scope of this chapter and have been described in detail elsewhere.[28] The complications are not limited to the lung parenchyma but rather include all aspects of the respiratory system as well as the respiratory muscles, pleural space, upper airway, and pulmonary vasculature. The complications also do not always represent a direct injury caused by the underlying collagen vascular disease. Some of the therapies for these diseases have pulmonary side effects, such as methotrexate-induced lung injury in patients being treated for rheumatoid arthritis or pulmonary infections from immunosuppression. Bibasilar fibrosis from repeated aspirations due to esophageal dysmotility from scleroderma has been well described.

Histologically, the types of interstitial disease found include those that have been previously mentioned. These comprise nonspecific interstitial pneumonia, UIP, and BOOP.[28,29] Other forms of interstitial disease have also been described, including lymphocytic interstitial pneumonia and diffuse alveolar damage.[28,29] Prognosis depends on the histologic type of interstitial disease and is largely similar to that seen in patients without underlying collagen vascular disease.

## SARCOIDOSIS

Sarcoidosis is a multiorgan disease with almost all cases having pulmonary manifestations at some point during its course.[30] Pulmonary manifestations range from asymptomatic hilar adenopathy, to endobronchial involvement with airflow limitation to diffuse nodules to end-stage lung fibrosis.

Sarcoidosis has a worldwide distribution and affects different racial and ethnic groups variably. In the United States, annual incidence estimates are 10.9 cases per 100,000 Whites and 35.5 cases per 100,000 Blacks.[31] The etiology remains unknown, but some epidemiologic research supports an infectious etiology whereas other evidence suggests an environmental exposure.[30]

The clinical presentation of pulmonary sarcoidosis is highly variable. Probably the most common is asymptomatic hilar adenopathy found on chest radiography done for an unrelated reason.[30,32] Common pulmonary symptoms include cough, dyspnea, and retrosternal chest pain. Systemic symptoms include fatigue, weight loss, and malaise.[30,32] Löfgren syndrome is a notable acute presentation of sarcoidosis characterized by the triad of hilar lymphadenopathy, polyarthralgias, and erythema nodosum.

Sarcoidosis is staged by chest radiograph.[33] Stage I disease is defined as the presence of hilar lymphadenopathy without other parenchymal infiltrates (Fig. 5-7), whereas stage II includes hilar lymphadenopathy with infiltrates. In stage III disease, there are infiltrates without hilar lymphadenopathy, and stage IV disease is defined by the presence of end-stage fibrosis (Fig. 5-8). Classically, sarcoidosis affects the upper and midlung zones. Small nodules ranging in size from 2 mm to 1 cm in diameter are the most common finding.[33] The nodules are typically found around the bronchovascular bundles. Patchy areas of airspace consolidation can also be seen, leading to the term *alveolar sarcoidosis*.[33] Mediastinal adenopathy is very common on CT, with calcification present in approximately 50 percent of patients, typically in a focal or "eggshell" pattern.[33]

**FIGURE 5-7** Chest x-ray showing bilateral hilar adenopathy without pulmonary infiltrates, depicting stage I pulmonary sarcoidosis.

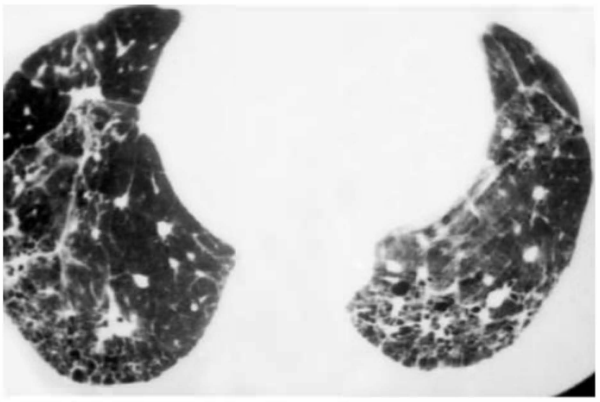

**FIGURE 5-8** Bilateral fibrotic changes as seen in stage IV pulmonary sarcoidosis.

Histologically, the lesion of sarcoidosis is the noncaseating granuloma. Granulomas are tightly packed and composed of epithelioid cells, including multinucleated giant cells and lymphocytes[30–32,34] (Fig. 5-9). These lesions can be found in lymph nodes, the lung parenchyma, and airway mucosa. However, noncaseating granulomas are not unique to sarcoidosis and other etiologies must be excluded clinically and pathologically, including fungal and mycobacterial disease, HP, pneumoconiosis such as beryllium-induced lung disease, and drug reactions.[34]

No treatment is needed for asymptomatic patients with hilar adenopathy. The majority of these patients and patients with Löfgren syndrome will have complete spontaneous remissions.[32] Corticosteroids are the mainstay of treatment for symptomatic sarcoidosis. Other immunosuppressive

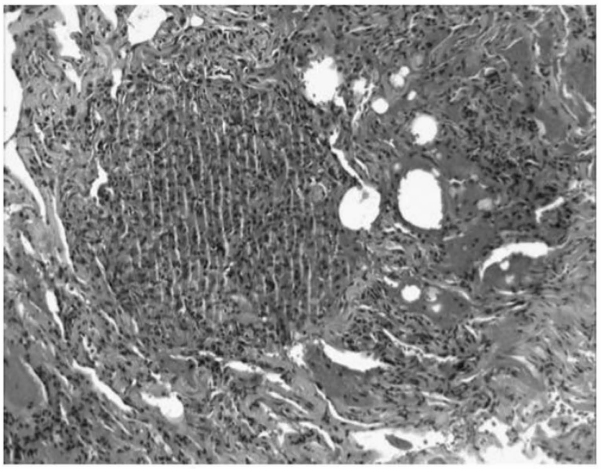

**FIGURE 5-9** Transbronchial lung biopsy showing typical noncaseating granuloma from a patient with pulmonary sarcoidosis. (Courtesy of Rubin Tuder, MD.)

agents such as cyclophosphamide, methotrexate, and azathioprine are reserved for patients with chronic nonsteroid-responsive disease, although there is little literature to fully support their use.[32]

## PULMONARY ALVEOLAR PROTEINOSIS

PAP is a rare disease first described by Rosen and colleagues in 1958.[35] The hallmark of this disorder is the thick, proteinaceous material that fills the alveolar spaces and impairs gas exchange. The disease is now recognized to exist in three forms: acquired, congenital, and secondary.[36] The acquired form represents over 90 percent of all reported cases[36] and is the type mainly discussed here.

Acquired PAP typically affects men in the fifth decade of life.[35,36] Symptoms tend to be gradual in onset, with a median of 7 months before diagnosis.[36] Common complaints include progressive dyspnea, cough, and fatigue.[37] Low-grade fevers have been reported, but higher temperatures suggest a superimposed infection.[37] Physical examination findings are nonspecific and frequently normal despite significant hypoxemia.[36] The radiographic appearance is nonspecific, with typically a bilateral alveolar filling process, but interstitial patterns can coexist or predominate.[36] HRCT scans show ground-glass opacification in a geographic pattern.[36] CT may also show interlobular thickening of the septa, producing a "crazy paving" pattern[36] (Fig. 5-10).

Historically, open lung biopsy was required for diagnosis.[36] However, more recent experience has shown that bronchoscopic techniques can reliably diagnose the majority of patients.[36,37] BAL produces a characteristic "milky" return, which represents the proteinaceous material that accumulates in the alveolar spaces.[36,37] Transbronchial biopsies have a high diagnostic yield as well.[37]

Treatment of PAP has been with whole-lung lavage under general anesthesia with a double-lumen endotracheal tube.[36,37] This procedure produces significant and durable improvements in clinical, physiologic, and radiographic parameters. However, the majority of patients will need repeated lavages over time.

Recent studies have found a link between granulocyte-macrophage colony-stimulating factor (GM-CSF) and PAP.[36] Initial studies found that GM-CSF "knockout" mice develop a lung disease similar to PAP. Further studies have found that most patients with acquired PAP have blocking antibodies to GM-CSF in lavage fluid and serum. These findings have led to the novel approach of using exogenous GM-CSF as treatment, with some success in small case series.

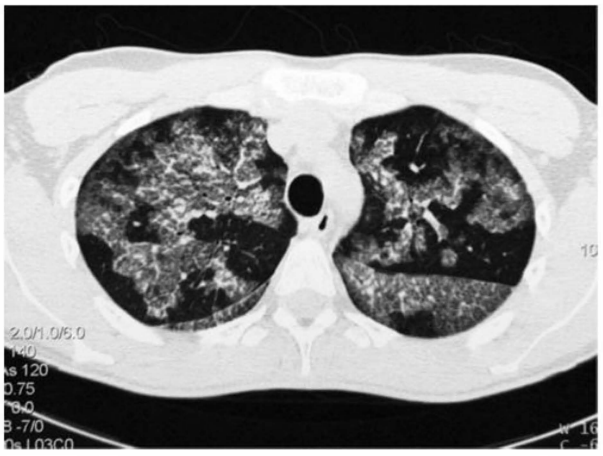

**FIGURE 5-10** Pulmonary alveolar proteinosis. Note bilateral infiltrates with a distinct appearance that has been described as "crazy paving."

## EOSINOPHILIC LUNG DISEASES

The eosinophilic lung diseases constitute a wide range of processes with a common finding of eosinophils in serum, lavage fluid, and/or on histology.[38] Early classifications included the syndrome of pulmonary infiltrates with eosinophilia (PIE); however, peripheral eosinophilia is variable in some processes and thus is not inclusive of the full range of diseases. The most current terminology is used here as a review of the important processes likely to be encountered. These include acute and chronic eosinophilic pneumonia (CEP), Churg–Strauss syndrome, and allergic bronchopulmonary aspergillosis (ABPA). A discussion of all the other diseases included in this category is beyond the scope of this chapter.

### Simple Eosinophilic Pneumonia (Löffler Syndrome)

Löffler syndrome was first described in 1932.[39] It consists of migratory pulmonary infiltrates and blood eosinophilia. Patients are typically asymptomatic or have only minimal symptoms.[39] Chest radiographs are usually described as a combination of interstitial and alveolar patterns that are migratory and peripherally located and often based in the pleura.[40] Infiltrates can be unilateral or bilateral.[40]

The underlying etiology, when found, has usually been linked to a parasitic infection.[38] *Ascaris* infection has classically been described. Drug reactions have also been found.

Patients typically have full resolution of radiographic and blood abnormalities within 1 month.[38] This resolution is usually spontaneous and rarely requires treatment with corticosteroids. Pathologic specimens are seldom required to confirm the diagnosis.

### Idiopathic Acute Eosinophilic Pneumonia

IAEP is a rare disease that has typically been reported in otherwise young, healthy individuals. Since the first reports in 1989, around 100 cases have been described.[41–43] This is a

diagnosis of exclusion with a characteristic presentation that includes an acute febrile illness (usually of less than 5 days' duration), bilateral infiltrates, hypoxemic respiratory failure, and significant BAL eosinophilia (>25 percent).[38,41–43] IAEP can easily mimic atypical pneumonia and acute respiratory distress syndrome (ARDS).

The typical presentation is that of a febrile illness with dyspnea, cough, myalgias, pleuritic chest pain, and respiratory distress.[38,41–43] Mechanical ventilation is frequently required. Chest x-rays invariably show bilateral infiltrates, which are usually diffuse and can be alveolar, interstitial, or a mixture of both. Only a minority of patients present with peripheral eosinophilia. However, the subsequent development of eosinophilia has been reported in as many as 68 percent of patients in one series.[43]

BAL is recommended in suspected cases to demonstrate the characteristic eosinophilia in the lavage fluid.[38,41–43] Eosinophil counts representing 40 to 50 percent of the differential is typical. When done, transbronchial biopsies and open lung biopsies have found varying stages of diffuse alveolar damage, including with marked interstitial and alveolar infiltration with eosinophils.[44] Because IAEP is a diagnosis of exclusion, the second role for lavage and/or biopsy is to rule out the presence of an underlying infectious etiology.

Treatment generally consists of corticosteroids with a relatively short duration. Patients will generally have a rapid response, with improvement within 1 to 2 days.[38] Relapse after discontinuation of steroids is not characteristic, and the absence of relapse has been suggested as a diagnostic criterion.[38] In one series, almost 25 percent of patients improved spontaneously without the use of corticosteroids.[43]

## Chronic Eosinophilic Pneumonia

Although this process was originally described by Christoforidis and Molnar in 1960,[45] most authors give the credit to Carrington and coworkers, who published the first large series in 1969.[46] As compared with acute eosinophilic pneumonia, CEP has a more subacute presentation and causes milder symptoms.

In one series of 107 patients, the average duration of symptoms before diagnosis was 7.7 months.[47] Patients tend to be in their fourth or fifth decade at presentation. A 2:1 female-to-male ratio has been noted.[47,48] A history of atopy occurs in one-half of patients, with asthma being the most common form.[47,48] Presenting complaints have included cough, fever, dyspnea, and weight loss.[47] Other notable symptoms seen in approximately one-third of patients include sputum production, wheezing, and night sweats.[47]

Diagnostic tests can be very helpful in the diagnosis of CEP. Peripheral eosinophilia is very common, occurring in 88 to 95 percent of patients, with a mean value of 26 to 32 percent.[47,48] Other laboratory values are also elevated, including erythrocyte sedimentation rates and serum IgE levels.[47,48] BAL contains very high levels of eosinophils, representing 25 percent to over 40 percent of the total cells.[38,48]

Chest radiography has classically been reported as showing the "photographic negative of pulmonary edema"[46] (Fig. 5-11A). However, a more recent series of patients have shown that only 25 percent have this finding.[47] The most common findings are peripheral bilateral infiltrates that were described as consolidated, ground-glass, or a mixture of both.[38,47,48] Upper lobe predominance is more common than lower lobe.[48] Migratory opacities, pleural effusions, and cavitation are uncommon.[38,47,48] CT sometimes helps to show the peripheral nature of the infiltrates.[38] Mediastinal adenopathy has been shown in 3 of 6 patients in one series[49] and 7 of 40 patients in another.[48]

Biopsy typically reveals intra-alveolar exudates rich with eosinophils and histiocytes.[38,46–48] The surrounding interstitium is frequently also infiltrated with eosinophils and histiocytes (Fig. 5-11B).[38,46–48] Approximately 50 percent of patients may also have interstitial fibrosis.[38,46–48] At times, mild vasculitis is seen.[38,46–48] Coexisting BOOP is also a frequent finding.[46–48]

Some authors suggest that patients with a typical clinical presentation and typical radiographic findings can be treated empirically.[47] Others would favor the addition of bronchoscopy with lavage to confirm the presence of increased eosinophils.[38] However, most favor empiric trials of corticosteroids. Patients typically show rapid improvement in symptoms, usually within 24 to 48 h, followed in time by radiographic resolution.[46–48] This rapid response is felt to be characteristic and confirms the diagnosis. The lack of a prompt response should suggest an alternative diagnosis and consideration of a biopsy.

Unlike acute eosinophilic pneumonia, CEP is characterized by a high rate of relapse when patients are weaned off of steroids.[46–48] Most authors have recommended prolonged courses of steroids, on the order of 6 months to 1 year. Although relapses are common, they respond well to increased doses of steroids.

## Pulmonary Langerhans Cell Histiocytosis (Eosinophilic *Granuloma*)

PLCH, also known as eosinophilic *granuloma* (EG), is a rare form of diffuse lung disease. Although most commonly found affecting the lungs solely, Langerhans cell histiocytosis can involve multiple organs including the bone, skin, pituitary gland, and other organs.[50] Langerhans cells are normally found in small numbers in the lung, where they function as antigen-presenting cells. In PLCH, the population of Langerhans cells is expanded, with destructive consequences for the parenchyma. The etiology for the expansion of this cell population is unknown.

Affected individuals tend to be in their third or fourth decade at the time of diagnosis.[51,52] The vast majority of patients diagnosed with PLCH are current smokers.[50–52]

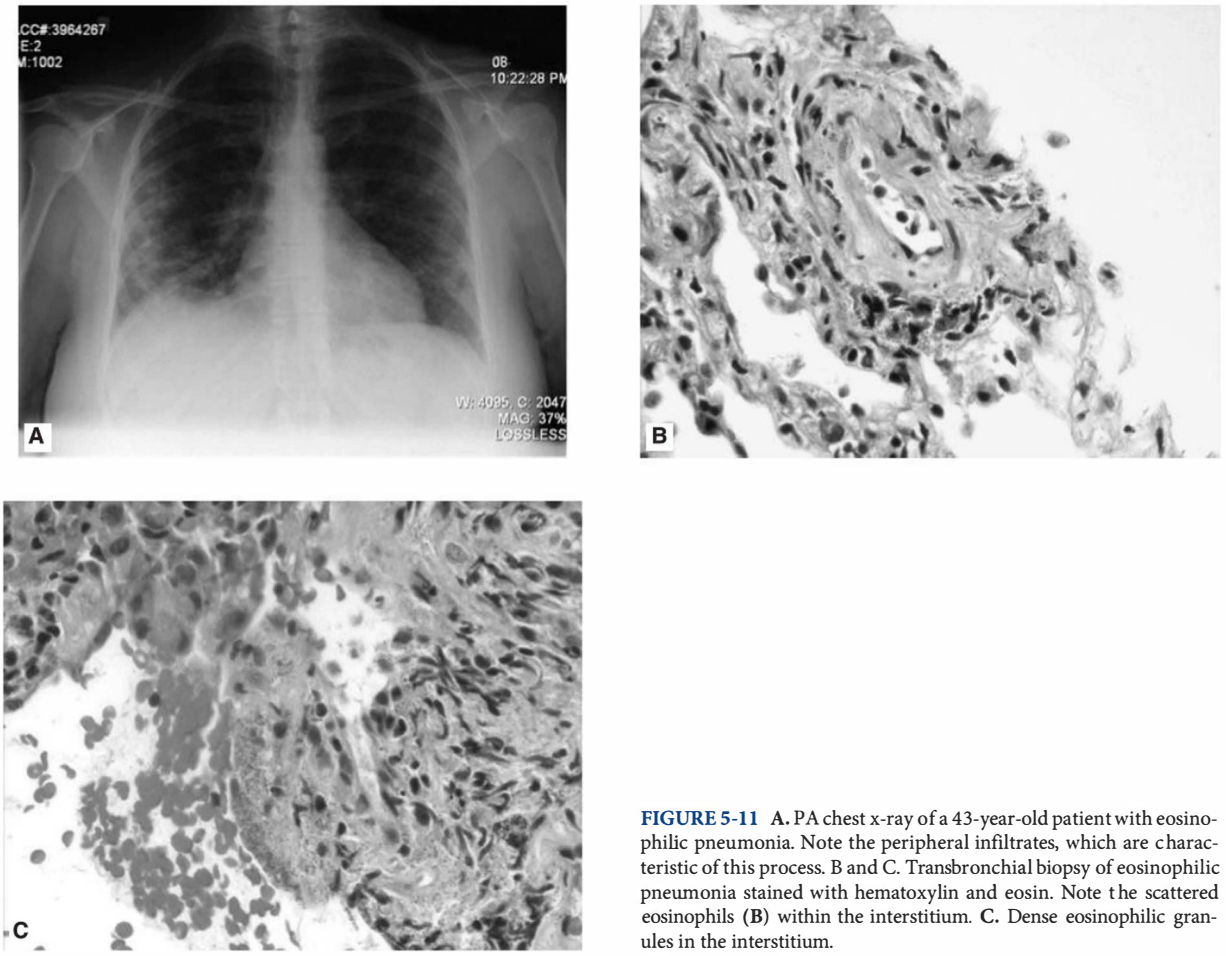

**FIGURE 5-11** **A.** PA chest x-ray of a 43-year-old patient with eosinophilic pneumonia. Note the peripheral infiltrates, which are characteristic of this process. B and C. Transbronchial biopsy of eosinophilic pneumonia stained with hematoxylin and eosin. Note the scattered eosinophils **(B)** within the interstitium. **C.** Dense eosinophilic granules in the interstitium.

At presentation, approximately one-fourth of patients will be asymptomatic.[50,51] Common symptoms include nonproductive cough, dyspnea with exertion, and pleuritic chest pain.[51] In one series, 11 percent of patients had experienced spontaneous pneumothorax.[51] Chest radiography typically reveals bilateral reticulonodular and interstitial infiltration with upper- and middle-lobe predominance.[50] Cystic changes are common and may be the predominant lesion in later stages of the disease.[50] Similar findings on CT, in the proper clinical context, are felt to be diagnostic, thus obviating the need for open lung biopsy.[50,53]

The course of the illness is highly variable. Most patients will have resolution of symptoms and radiographic abnormalities with smoking cessation, but a small percentage will go on to end-stage lung disease.[50,51] Corticosteroids have been variably used, but there is no consensus as to their utility. Lung transplantation has been advocated for patients with end-stage disease; however, there are reports of recurrence in the transplanted lung.[54]

## ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

ABPA occurs in up to 28 percent of patients with steroid dependent asthma and 15 percent of patients with cystic fibrosis.[55–57] The disease occurs when patients have a complex immune response to antigens expressed by *Aspergillus* that is colonizing the bronchial mucosa. Although most commonly associated with the fungus *Aspergillus fumigatus*, this allergic process has been described with other fungi including *Candida, Penicillium*, and other species of *Aspergillus*, including *A. flavus*.[55] The diagnosis of ABPA is based on a variety of clinical, radiographic, and laboratory findings. Suggested criteria include a history of asthma or cystic fibrosis, immediate cutaneous reactivity to *Aspergillus* species, an elevated total IgE (>1000 ng/mL), elevated serum IgE antibodies to *A. fumigatus*, precipitating antibodies to *A. fumigatus*, central bronchiectasis, and chest x-ray infiltrates. Striking peripheral blood eosinophilia is common as well as sputum cultures that grow *Aspergillus* species.

Symptoms commonly include wheeze, cough, fever, and anorexia.[55,57] Sputum production is also common with "dirty green" plugs. During an exacerbation chest radiography may reveal fleeting pulmonary infiltrates as well as dense infiltrates in central bronchioles giving rise to a "gloved finger" appearance.

Corticosteroids are the cornerstone of therapy to treat and reduce the frequency of exacerbations.[55–57] Most authorities recommend initial treatment for several months followed by a slow taper. Some patients will go into clinical remission but the majority will require continued long-term therapy for intermittent exacerbations. Recently several studies have suggested a role for the oral antifungal itraconazole as a steroid sparing agent.[58,59]

## HYPERSENSITIVITY PNEUMONITIS

HP is a clinically diverse disease process that results from the inhalation of a variety of antigens.[60–62] Farmer's lung is the classic example but numerous other examples of HP, also known as extrinsic allergic alveolitis, have been described.[60–62] The hallmark of this disease is an individual's immunologic response to an inhaled antigen. In order for HP to develop, first, the patient must be exposed to a potential antigen; second, the antigen must be of sufficiently small size (usually <3 μm) to travel through the respiratory tract and be deposited in an alveolus and distal bronchial tree; and third, there must be an immune response resulting in an inflammatory reaction.[60–62]

A multitude of exposures to a variety of antigens have been documented and described. Most forms of HP have been associated with antigens from fungi and bacteria such as *Mucor stolonifer,* which causes paprika slicer's lung in people who work with moldy paprika pods, and *Thermoactinomyces vulgaris,* which causes bagassosis in people who work with moldy sugarcane.[60] Pigeon breeder's lung is caused by exposure to animal proteins found in bird droppings, feathers, and serum.[60] A variety of chemicals have been implicated in HP, including hydrophthalic anhydride, which causes epoxy resin lung in people who work with heated epoxy resin.[60]

Although many people may be exposed to an antigen through occupation or hobbies, only a small percentage will go on to develop HP.[60–62] For example, in one study, only 8 percent of pigeon breeders in the Canary Islands were found to meet the criteria for pigeon breeders' lung.[63] In most studies, only 5 to 15 percent of exposed people go on to develop features of HP.[61] The host factors that determine whether an individual will develop an inflammatory reaction have yet to be determined.

HP has classically been subdivided into three forms: acute, subacute, and chronic.

### Acute Hypersensitivity Pneumonitis

The acute form of HP is thought to occur after a large inhalational exposure to an antigen. Characteristic symptoms include fever, chills, dyspnea, chest tightness, cough, and malaise.[60–62] Symptoms usually begin within 4 to 8 h of exposure and resolve 24 to 48 h later.[60–62] Patients typically describe similar symptoms after repeated exposures. Chest radiography can show diffuse ground-glass opacification or reticulonodular infiltrates[62] (Fig. 5-12). A lower-lobe predominance is common.[62] Lung function tests can reveal a restrictive defect as well as impaired diffusion.[61]

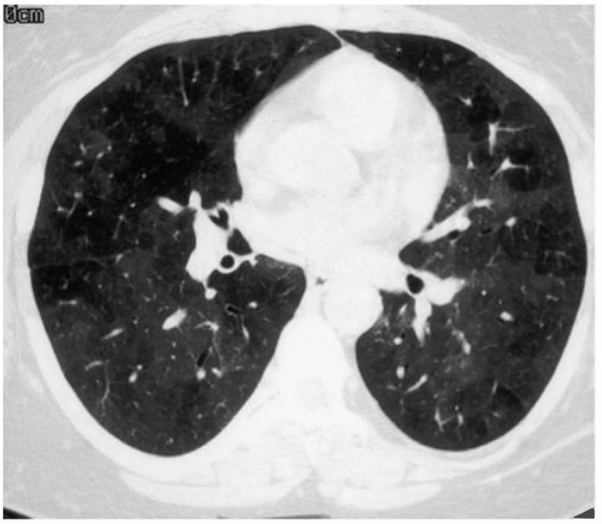

**FIGURE 5-12** Chest CT of a 45-year-old woman with acute hypersensitivity pneumonitis from exposure to a pet bird. Note bilateral "ground-glass" opacifications.

### Subacute and Chronic Hypersensitivity Pneumonitis

Unlike acute HP, subacute and chronic forms have an insidious onset of cough and dyspnea.[60–62] Other common symptoms include fatigue, malaise, and weight loss. Few authors make a distinction between subacute and chronic forms other than to suggest that patients with subacute HP can experience episodes of symptoms similar to acute HP.[61] A major difference between acute HP is the tendency to develop parenchymal fibrosis in some cases leading to end-stage lung disease. These patients can also develop right heart failure and digital clubbing.[60] Chest x-rays and CT in chronic forms have marked fibrosis and ground-glass attenuation[60–62] (Fig. 5-13). Centrilobular poorly defined micronodules are very suggestive of HP in both the acute and chronic forms.[60] Pulmonary function testing usually reveals restriction and decreased diffusion but a small percentage of patients have also been shown to develop an obstructive defect regardless of a smoking history.[60–62,64]

As there are no definitive tests, the diagnosis of HP is largely based on clinical presentation and history.[60–62,65] Suggested diagnostic criteria typically include (1) a history

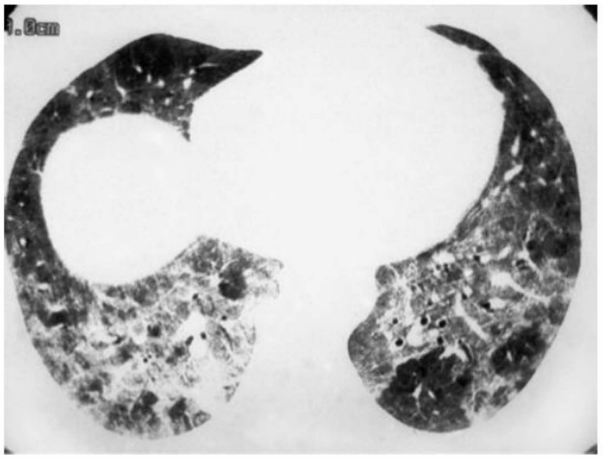

**FIGURE 5-13** Chest CT scan showing bilateral diffuse interstitial fibrosis with interspersed ground-glass opacifications from a patient with chronic hypersensitivity pneumonitis.

of exposure to a known antigen, (2) serum precipitating antibodies to the suspected antigen, (3) a history of common symptoms temporally related to antigen exposure, (4) an appropriate response to an inhalation challenge, (5) compatible results from radiographic and pulmonary function tests, and (6) granulomatous interstitial pneumonitis.[60–62,65] With this framework, several key points need further discussion.

A thorough history of possible exposures, occupational and domestic, is important to discern possible antigens. However, in regard to subacute and chronic forms, the insidious nature of the disease may prevent the identification of likely antigen.

Although supportive, the finding of precipitating antibodies is not diagnostic as a high number of exposed people will develop antibody responses but will not have detectable disease.[60–62] Alternatively, the absence of antibodies does not rule out HP owing to the lack of standardized antigen testing in laboratories.

Inhalational challenges, exposing the patient to the suspected antigen in either the natural environment or in a hospital setting and monitoring for a clinical response, have been used mainly in the research setting.[60]

Invasive diagnostic testing, including BAL and lung biopsy, is typically used in cases where the diagnosis is less apparent. BAL usually reveals a marked lymphocytosis with an inversion of the CD4 to CD8 ratio; however, this is variable and may depend on the type of HP and host factors.[60,62] The histology of HP can also be variable. Findings of cellular bronchiolitis, lymphoplasmacytic interstitial infiltrates, and poorly formed granulomas are considered typical.[62] However, multiple other patterns including UIP and NSIP have also been described.[60,62]

Most experts agree that the first goal of treatment is eliminating exposure to the inciting antigen.[60–62] However, repeated exposure to inhaled antigens does not necessarily lead to a chronic form with fibrosis but currently there is no way to predict that patients will have a progressive form of the disease.[60–62] There is no consensus for the use of corticosteroids.[60–62] A randomized controlled trial using corticosteroids in farmer's lung showed that corticosteroids lead to a more rapid improvement in pulmonary function, but there was no difference in outcomes at 5 years.[66] Interestingly, patients who were treated with corticosteroids tended to have more frequent episodes.[66]

## DRUG-INDUCED LUNG DISEASE

The true incidence of drug-induced lung injury is unknown, owing to the absence of definitive diagnostic studies and the high rate of underlying pulmonary diseases among patients, making it difficult to establish definitive causal relationships. Histologically, the majority of the injury patterns resemble those of disorders already discussed.[67–69] These include nonspecific interstitial pneumonia, organizing pneumonia, eosinophilic pneumonia, and HP. Other patterns of injury include diffuse alveolar damage, pulmonary hemorrhage, and edema. Two of the more common clinically encountered drug toxicities are discussed below.

### Methotrexate-Induced Lung Injury

The spectrum of methotrexate pulmonary toxicity is wide, including interstitial disease, pleural effusions, fibrosis, and noncardiogenic pulmonary edema.[67,70] The most commonly reported toxicity is an interstitial pneumonitis, which has been variably termed methotrexate pneumonitis, acute interstitial pneumonitis, and HP. The true frequency is unknown, with reports ranging from 2 to 10 percent of patients. It usually presents with subacute symptoms of cough, dyspnea, and low-grade fevers. Peripheral eosinophilia has been reported in up to 40 percent of patients. Pulmonary function tests typically reveal a restrictive pattern with a reduced diffusion capacity. Chest radiographs have usually shown a bilateral, predominantly basilar interstitial pattern. Alveolar and nodular patterns as well as pleural effusions and adenopathy have also been reported (Fig. 5-14). Lung biopsy reveals lymphocytic infiltration of the interstitium; granulomas and eosinophilia are seen in some cases (Fig. 5-15).

Methotrexate pneumonitis can occur at any time during therapy, and dose and route of therapy do not appear to predict its occurrence.[67,70] Most people will recover completely after cessation of the methotrexate. Corticosteroids are generally recommended for patients with significant impairment.

### Amiodarone Pulmonary Toxicity

Four clinical presentations of amiodarone pulmonary toxicity have been described: interstitial pneumonitis, ARDS, BOOP, and pulmonary nodules.[68,71] The most common is

**FIGURE 5-14** Methotrexate-induced lung injury showing bilateral pulmonary infiltrates with areas of consolidation on a background of increased interstitial markings.

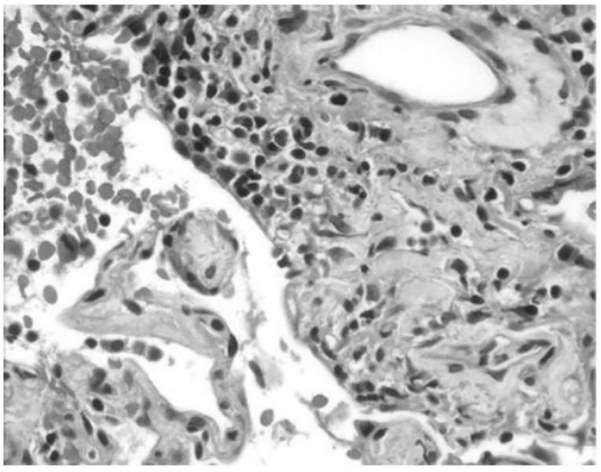

**FIGURE 5-15** Biopsy specimen of methotrexate-induced lung injury showing lymphocytic interstitial infiltrates with occasional eosinophils.

interstitial pneumonitis. The presentation is typically subacute, and it tends to occur after several months of therapy. Although it can occur at any dose, it does so usually in the context of a higher daily dosage (>400 mg/day). Patients' complaints frequently include cough, dyspnea, fever, and pleuritic chest pain.

There are no diagnostic studies for amiodarone pulmonary toxicity.[68,71] Laboratory studies are nonspecific but can show leukocytosis and elevated erythrocyte sedimentation rates. Pulmonary function studies reveal decreased diffusion capacity. Chest radiographs reveal patchy bilateral interstitial infiltrates. Lung biopsy is of limited value, as the findings are nonspecific. Alveolar accumulation of foamy macrophages occurs in people taking amiodarone with or without clinical disease. Other findings include type II pneumocyte hyperplasia and alveolar septal thickening.

Treatment consists of discontinuing amiodarone.[68,71] The majority of cases slowly resolve due in part to the prolonged half-life of the agent. Corticosteroids have had anecdotal success in some cases. For some patients in whom the use of alternative antiarrhythmic agents was not possible, a strategy of low-dose corticosteroids while continuing amiodarone has had some success.

## BENIGN DIFFUSE PULMONARY DISORDERS BOARD REVIEW QUESTIONS (CHAPTER 5)

1. Which of the following is correct regarding idiopathic pulmonary fibrosis?
   A. There is a predominance of fibrosis in the subpleural and upper lung zones.
   B. It typically presents in the fifth decade of life with shortness of breath and a productive cough.
   C. Classic CT findings include traction bronchiectasis and honeycombing.
   D. Pulmonary function studies show an obstructive pattern with low DLCO.
   E. Transbronchial biopsies are usually adequate to establish the diagnosis.

2. Which is true regarding cryptogenic organizing pneumonia?
   A. The least common presentation is a nonresolving pneumonia.
   B. Significant leukocytosis is common.
   C. Frank hypoxemia is almost universal.
   D. Transbronchial biopsy is often insufficient to make the diagnosis.
   E. Treatment consists of steroid therapy over 2 to 3 months.

3. Which is correct regarding sarcoidosis?
   A. About 50 percent of cases will have pulmonary manifestations.
   B. The least common presentation is asymptomatic hilar adenopathy.
   C. Löfgren syndrome is an acute presentation characterized by erythema nodosum, polyarthralgias, and hilar adenopathy.
   D. The disease classically affects the lower and midlung zones.
   E. The histologic lesion is the caseating granuloma.

4. Which of the following is true regarding allergic bronchopulmonary aspergillosis?
   A. It occurs in nearly 30 percent of steroid-dependent asthmatics.
   B. The diagnosis is based on chest x-ray findings.
   C. IgA levels are elevated above 1000 ng/mL.
   D. Elevated peripheral blood eosinophilia is rare.
   E. Antifungals are the cornerstone of therapy.

5. Which is the most common presentation of amiodarone pulmonary toxicitiy?
   A. Pulmonary nodules
   B. BOOP
   C. ARDS
   D. Interstitial pneumonitis
   E. Pleural effusion

## ANSWERS

1. **Answer: C.** Classic CT findings of IPF include traction bronchiectasis and honeycombing. There is a predominance of fibrosis in the subpleural and lower lung fields. It typically presents in the seventh decade of life with shortness of breath and a dry, nonproductive cough. PFTs show a restrictive pattern with low DLCO. Transbronchial biopsies are usually inadequate because a larger tissue sample is necessary.
2. **Answer: D.** As a large tissue sample is necessary to make the diagnosis of COP/BOOP, transbronchial biopsy is often insufficiency. A nonresolving pneumonia is the most common presentation with only mild leukocytosis. Frank hypoxemia is rare. An extended period of steroid therapy over 6 to 12 months is the standard treatment.
3. **Answer: C.** Löfgren syndrome is an acute presentation of sarcoidosis characterized by erythema nodosum, polyarthralgias, and hilar adenopathy. Almost all cases will have pulmonary manifestations during some point of the disease process. The most common presentation is asymptomatic hilar adenopathy. Sarcoidosis classically affects the upper and midlung zones. The histologic lesion is the noncaseating granuloma.
4. **Answer: A.** Nearly 30 percent of steroid-dependent asthmatics will develop ABPA. The diagnosis is based on a combination of radiographs, clinical findings, and laboratory tests, including elevation of IgE levels above 1000 ng/mL. Striking peripheral blood eosinophilia is common. Corticosteroids are the cornerstone of therapy to treat and reduce the frequency of exacerbations.
5. **Answer: D.** Interstitial pneumonitis is the most common presentation of amiodarone pulmonary toxicity and tends to occur after several month of therapy in a subacute fashion.

# Thoracic Infections

*Kaushik Mandal*

6

**KEY CONCEPTS**

- The etiology and clinical manifestations of pneumonia depend on the environment where the disease is acquired and the host characteristics.
- Treatment of pneumonia is based on an assessment of place of therapy (outpatient, hospital ward, or ICU), the presence of coexisting cardiopulmonary diseases, and the presence of modifying factors.
- Although prompt initiation of antibiotics is critical in patients with nosocomial pneumonia, all patients with suspected pneumonia should have a sampling done of lower respiratory tract secretions to better guide the therapy.
- Lung abscess should be managed initially with appropriate medical therapy and/or percutaneous drainage.
- Owing to the presence of branching hyphae, infections due to actinomycosis and nocardiosis may be mistaken for fungal infections. It is important to make the distinction because actinomycotic infections do not respond to antifungal therapy but rather to antibiotics.
- Surgical consultation is regularly requested for the diagnosis and treatment of pulmonary complications of the endemic mycoses: *Histoplasma capsulatum, Blastomyces dermatitidis* and *Coccidioidomycosis immitis,* and the yeast *Cryptococcus neoformans*. All resemble pulmonary malignancies.
- Histoplasmosis causes pericarditis, mediastinal fibrosis, and mediastinal granuloma, which can cause entrapment of vascular structures, the esophagus, and the trachea.
- Coccidioidomycosis can cause both spontaneous pneumothorax associated with effusion and thin-walled cavities that can become superinfected with tuberculosis and aspergillosis.
- Cryptococcosis can result in organ damage from tissue distortion secondary to an expanding fungal burden.
- Most patients with pulmonary aspergillosis have either impaired immunity or underlying preexisting chronic lung disease. Aspergillomas may develop in preexisting cavities. Surgery is indicated for complications of the disease, such as massive hemoptysis.
- Surgery has largely been supplanted by multiple-regimen medical therapy for tuberculous and nontuberculous mycobacterial infections. There is still a role for pulmonary resection in multidrug-resistant infection, cavitary lesions, and lung destruction.

## PNEUMONIA AND LUNG ABSCESS

Lower respiratory tract infections are important in the practice of the thoracic surgeon because their complications may require surgical intervention and they may complicate thoracic surgical procedures.

### Pneumonia

Pneumonia is an infection of the lower respiratory tract that involves the terminal airways: respiratory bronchioles, alveolar ducts, and alveoli. The infection develops when the sterility of the tracheobronchial tree is breached by the introduction of a virulent pathogen or a defect in the host immunologic defense. Symptoms of acute lower respiratory infection may include fever or hypothermia, rigors, sweats, new cough with or without sputum production or change in color of respiratory secretions in a patient with chronic cough, chest discomfort, or shortness of breath. Most patients also have nonspecific symptoms, such as fatigue, myalgias, abdominal pain, anorexia, and headache.

Despite advancements in the diagnosis and treatment of pneumonia in the past century, it is listed by the Centers for Disease Control and Prevention as the sixth leading cause of death in the United States and the leading cause of death from infectious diseases.[1] Contemporary management of pneumonia is based on whether the infection was acquired in the community versus in the hospital, including any care

facility, the severity of illness, and the patient's comorbid conditions, including immune status.

## COMMUNITY-ACQUIRED PNEUMONIA

Community-acquired pneumonia (CAP) is commonly defined as an acute infection of the pulmonary parenchyma in a patient not hospitalized or residing in a long-term-care facility for ≥14 days before the onset of symptoms. CAP is among the leading causes of death in the United States, accounting for some 65,000 deaths in 2002[2]; it is responsible for more than 10 million physician visits a year and some 1.4 million hospital discharges. The most common etiologic agent of CAP is *Streptococcus pneumoniae,* which accounts for about two-thirds of all cases of bacteremic pneumonia.[2] Other pathogens include *Haemophilus influenzae, Mycoplasma pneumoniae, Chlamydia pneumoniae, Staphylococcus aureus, Streptococcus pyogenes, Neisseria meningitidis, Moraxella catarrhalis, Klebsiella pneumoniae* and other gram-negative rods, *Legionella* species, influenza virus (depending on the season), respiratory syncytial virus, adenovirus, and parainfluenza virus. Gram-negative bacilli (Enterobacteriaceae and *Pseudomonas*) are the cause of CAP in some patients (those who have had previous antimicrobial treatment or who have pulmonary comorbidities). The frequency of other causes, such as *Mycobacterium tuberculosis, Chlamydophila psittaci* (psittacosis), *Coxiella burnetii* (Q fever), *Francisella tularensis* (tularemia), and endemic fungi (*Histoplasma, Coccidioides, Blastomyces*) vary between epidemiologic settings.[3] Certain pathogens cause pneumonia more commonly among persons with specific risk factors. For instance, pneumococcal pneumonia is especially likely to occur in the elderly and in patients with a variety of medical conditions, including alcoholism, chronic obstructive airway disease, immune-deficiency, etc. *Legionella* is an opportunistic pathogen that is rarely recognized in healthy young children and young adults. *It is an important cause of pneumonia in organ transplant recipients* and in patients with renal failure.

All patients suspected to have pneumonia should undergo chest radiography for the following reasons: to confirm the diagnosis, to provide information on the location and extent of the disease, to explore the possibility of complications such as pleural effusion, multilobar disease, and cavitation; to detect underlying pulmonary disease or alternative diagnoses; and to monitor the progression or resolution of the disease.[4] Other appropriate tests for hospitalized patients with CAP include a complete blood cell count and differential, serum creatinine, blood urea nitrogen, glucose, electrolytes, and liver function tests. Oxygen saturation should be assessed by pulse oximetry in all admitted patients and arterial blood gas in sicker patients. There should be two pretreatment blood cultures as well as Gram's staining and culture of expectorated sputum.[4,5]

Other tests that should not be performed routinely but might be useful in some patients admitted to the hospital include the urinary antigen assays for *Legionella* species and *Strep. pneumoniae* and a direct stain (i.e., acid-fast) for the detection of mycobacterial infections in patients who are in high-risk categories for tuberculosis.[3,5] HIV serology with informed consent should also be considered, especially for persons aged 15 to 54 years.[3] Serologic testing may also include tests for viral agents, endemic fungi, and other unusual pathogens in appropriate clinical settings. Invasive diagnostic techniques (transtracheal aspiration, bronchoscopy with a protected brush catheter, bronchoalveolar lavage [BAL], and direct percutaneous fine-needle aspiration of the lung) are used to obtain lower airway specimens uncontaminated by oropharyngeal flora. These procedures may help to obtain early accurate diagnosis and are reserved for occasional patients who are severely ill.[1,5] Potentially infected body fluids from other anatomic sites—including pleural fluid, joint fluid, and cerebrospinal fluid (CSF)—should be obtained for chemistry, Gram's staining, and culture if warranted by the clinical presentation.

Pathogen-directed antimicrobial therapy is ideal, but this is usually not feasible because no etiology can be identified in more than 50 percent of cases. Empiric antibiotic regimens should include coverage of "atypical pathogens" and should be changed when results of culture and *in vitro* sensitivity tests become available.[3] All admitted patients should receive their first dose of antibiotic therapy within 8 h of arrival at the hospital. This has been shown to reduce mortality at 30 days.[6] The American Thoracic Society (ATS) currently makes recommendations based on an assessment of place of therapy (outpatient, hospital ward, or ICU), the presence of coexisting cardiopulmonary disease (chronic obstructive pulmonary disease [COPD], congestive heart failure), and the presence of modifying factors such as age, immune status, other comorbid factors, etc. Most patients can be treated using monotherapy with antipneumococcal fluoroquinolone except for ICU-admitted patients who should receive β-lactam plus either a macrolide or a quinolone. Appropriate at-risk patients should receive a regimen with two antipseudomonal agents.

## HOSPITAL-ACQUIRED (NOSOCOMIAL) PNEUMONIA

Hospital-acquired pneumonia (HAP) is defined as pneumonia that occurs 48 h or more after admission and that was not incubating at the time of admission. According to the report from the National Center for Infectious Diseases, nosocomial pneumonia is the most frequent hospital-acquired infection in the combined medical and surgical ICUs, which accounts for 31 percent of all infections in the ICU.[7] Risk factors for HAP include mechanical ventilation for >48 h, residence in an ICU, duration of ICU or hospital stay, severity of underlying illness, and presence of comorbidities. Generally, loss of mechanical host defense and suppression of normal flora probably explain a major component of the increased risk of pneumonia in hospitalized patients. The most obvious compromise of normal host immunity in hospitalized patients is alteration of the mechanical components of lung defenses.

Nearly half of the HAP cases are polymicrobial. Early-onset HAP (occurring in the first 4 days of hospitalization) is often caused by community-acquired pathogens such as *H. influenzae, Strep. pneumoniae*, or methicillin-susceptible *Staph. aureus* (MSSA). HAP developing ≥5 days after hospitalization ("late onset") is often caused by aerobic gram-negative bacilli (e.g., *Pseudomonas aeruginosa*, Enterobacteriaceae, or *Acinetobacter*) or methicillin-resistant *Staph. aureus* (MRSA).[8] In patients receiving mechanical ventilation, these antibiotic-resistant pathogens assume increasing importance. Other gram-negative rods, such as *Escherichia coli* and *Klebsiella* species, are also common pathogens. Nosocomial viral and fungal infections are uncommon causes of HAP in immunocompetent patients.

Ventilator-associated pneumonia (VAP) is a pneumonia that arises more than 48 to 72 h after endotracheal intubation. VAP accounts for as much as 83 percent of nosocomial pneumonia and carries a particularly poor prognosis, with a reported mortality rate of up to 50 percent. Aspiration of oropharyngeal or gastric contents contaminated with colonizing flora is important in the pathogenesis of VAP. Several factors that lead to impairments in level of consciousness and/or swallowing and cough reflexes (e.g., related to cerebrovascular disease) increase the risk for the development of aspiration pneumonia. The oropharynx appears to be the most important source of microorganisms. Continuous aspiration of subglottic secretions has been associated with significant reductions in the incidence of VAP in two randomized trials.[9] Supine patient positioning may also facilitate aspiration, which may be decreased by a semirecumbent positioning.[10] Enteral nutrition has been considered a risk factor for the development of pneumonia mainly because of an increased risk of aspiration of gastric contents. However, its alternative, parenteral nutrition, is associated with higher risks for infections associated with intravascular devices, complications of line insertions, higher costs, and loss of intestinal villous architecture, which may facilitate enteral microbial translocation. Nasogastric intubation and gastroparesis are other known risk factors for aspiration.

The diagnosis of HAP is suspected if the hospitalized patient has a radiographic infiltrate that is new or progressive along with clinical findings suggesting infection, which include the new onset of fever, purulent sputum, leukocytosis, and decline in oxygenation. Most studies of nonintubated patients have involved clinical diagnosis with sputum culture. A recent meta-analysis showed that the most acceptable standards for the diagnosis of VAP require quantitative cultures of BAL fluid or protected specimen brush samples. BAL is also recommended if the patient is already receiving antibiotics.

Initial inadequate antimicrobial therapy for HAP is an independent risk factor for increased mortality. Initial therapy (while awaiting results of cultures) must be empiric and cover a broad spectrum of possible pathogens. Demographics, host factors (e.g., severity and acuity of illness, comorbidities), duration of hospitalization, prior antibiotic use, and antimicrobial resistance patterns within the hospital or ICU must be taken into account in selecting antibiotics for empiric treatment. Rates of resistance are influenced by type and size of hospital, ICU or non-ICU setting, anatomic site of isolation, and patterns of prior antibiotic use within individual patients or institutions. Empiric treatment for pneumonia occurring within the first 4 days of hospitalization in patients without severe comorbidities or exposure to antibiotics need not encompass *P. aeruginosa* or potentially resistant pathogens. However, broader-spectrum coverage (to include these pathogens) is advised for critically ill ICU patients requiring prolonged mechanical ventilation or those who have received prior antibiotics. In this context, a combination of antipseudomonal β-lactam (e.g., cefotetan) plus an aminoglycoside (if no contraindications to aminoglycoside use exist) can be used. Alternatively, a fluoroquinolone can be substituted for the aminoglycoside. Linezolid is an alternative to vancomycin for the treatment of MRSA. The Study Group on Aspiration Pneumonia found that ampicillin plus the β-lactamase inhibitor sulbactam, when compared with clindamycin with the optional addition of a second- or third-generation cephalosporin, was equally effective in terms of clinical response.[10] Antibiotic therapy should be tailored appropriately when culture results become available.

## Lung Abscesses

### ETIOLOGY AND PATHOLOGY

Lung abscess is defined as necrosis of the pulmonary tissue caused by microbial infection and the formation of cavities containing necrotic debris or fluid. The process usually begins as a localized pneumonitis. Liquefaction necrosis of the lung tissue eventually communicates with the bronchial tree. This partial internal drainage results in the classic cavity with an air-fluid level. The formation of multiple small (<2 cm) abscesses is occasionally referred to as necrotizing pneumonia or lung gangrene. Both lung abscess and necrotizing pneumonia are manifestations of a similar pathologic process.

Aspiration of infectious material is the most frequent etiologic mechanism in the development of primary lung abscess. Poor oral hygiene, dental infections, and gingival disease are common in these patients. Some of the factors that predispose to aspiration include states of compromised consciousness (e.g., cerebrovascular accident, seizure, alcoholism, anesthesia, head trauma, and coma) and esophageal disease (e.g., achalasia, reflux disease, and various causes of esophageal obstruction). Immunocompromised hosts—including patients on various chemotherapies, malnourished patients, and those with multiple trauma—are also at risk. Secondary lung abscess can occur from a hematogenous source; bronchial obstruction by tumor, stricture, or foreign body; or extension from an extrapulmonary site, such as mediastinal, subdiaphragmatic, or hepatic abscesses.[11]

The posterior segment of the right upper lobe and the superior segment of the right lower lobe are the most

common locations for lung abscess. This is due to gravitation of the infectious material from the oropharynx into these dependent areas of the lung. Lung abscesses have numerous infectious causes. The dominant pathogens are *Peptostreptococcus, Bacteroides, Prevotella,* and *Fusobacterium* species.[12] A primary lung abscess may be caused by *Strep. pneumoniae, Strep. viridans, K. pneumoniae,* and *H. influenzae.* Selected nonbacterial pathogens that can produce lung abscess include parasites (e.g., *Entamoeba histolytica*), many fungi (e.g., *Aspergillus* species, *Histoplasma capsulatum*), and mycobacteria. A number of opportunistic infections, such as nocardiosis and aspergillosis, can dominate in lung abscess in immunocompromised hosts.

One unique mechanism for the development of lung abscesses occurs in Lemierre syndrome, or jugular vein suppurative thrombophlebitis.[13] This infection begins in the pharynx (sometimes with an overt tonsillar or peritonsillar abscess) but spreads to involve spaces in the neck and the carotid sheath, which contains the internal jugular vein. Bacteremia, due to *Fusobacterium necrophorum*, and septic emboli to the lungs, which subsequently cavitate, are all characteristic complications of this process once the vessels are involved. Tricuspid valve endocarditis, usually due to *Staph. aureus*, also typically causes septic emboli that are widely distributed in both lungs. This is a common feature of endocarditis complicating injection drug use and an infrequent complication of septic venous thrombosis in other settings.

## CLINICAL PRESENTATION

Most of these patients present with a subacute onset of illness and do not seek medical attention for 2 weeks or more after the onset of illness. Early symptoms are often those of pneumonia—that is, malaise, anorexia, sputum-producing cough, sweats, and fever. Initially, foul sputum is not observed in the course of the infection; however, after cavitation occurs, putrid expectorations are quite prevalent. The odor of breath and sputum of a patient with an anaerobic lung abscess is often quite pronounced and noxious and may provide a clue to the diagnosis. Hemoptysis may occasionally follow the expectoration of the putrid sputum. The sputum may contain gangrenous lung tissue. Chest pain, if present, usually indicates pleural involvement.

On physical examination, a small area of dullness, indicating localized pneumonic consolidation, is found, and usually suppressed (rather than bronchial) breath sounds. Fine or medium moist crackles may be present. If the cavity is large, there may be tympany and amphoric breath sounds. Signs of pulmonary suppuration generally disappear with appropriate antibiotic therapy, but this disappearance does not necessarily denote cure. If the abscess becomes chronic, weight loss, anemia, and hypertrophic pulmonary osteoarthropathy may occur. Physical examination of the chest may be negative in the chronic phase, but rales and rhonchi are usually present.

## DIAGNOSIS

Chest x-rays early in the course may show a segmental or lobar consolidation, which sometimes becomes globular as pus distends it. The distinctive characteristic of lung abscess, the air-fluid level, can be observed only on a chest x-ray film taken with the patient upright or in the lateral decubitus position (Fig. 6-1). In the presence of associated pleural thickening, atelectasis, or pneumothorax, the air-fluid level may be obscured. A computed tomography (CT) scan of the chest is valuable for better anatomic interpretation. It can demonstrate cavitation within an area of consolidation, the thickness and regularity of the abscess wall, and the exact position of the abscess with regard to the chest wall and bronchus.

The indications and comparative benefits of invasive procedures such as transtracheal aspirates, transthoracic aspirates, and fiberoptic bronchoscopy are controversial and depend to a great extent on operator ability. The use of these methods to obtain appropriate culture specimens should be strongly considered in patients who do not respond to medical therapy within 2 weeks. However, dependable microbiologic data can be obtained only if these procedures are performed prior to the institution of antibiotic therapy. Most pulmonologists believe that these diagnostic procedures should not be performed routinely in all patients but should be reserved for patients with atypical presentations or unclear diagnoses. Bronchoscopy may also be used to exclude the presence of a foreign body or neoplasm and can provide drainage. These invasive procedures should be avoided in patients with coagulation disorders or bleeding tendencies and in those for whom it is difficult to provide adequate oxygenation.

Lesions that simulate bacterial lung abscess include cavitating bronchogenic carcinoma, bronchiectasis, empyema secondary to a bronchopleural fistula, tuberculosis, coccidioidomycosis and other mycotic lung infections, infected pulmonary bullae or air cysts, pulmonary sequestration, silicotic nodules with central necrosis, subphrenic or hepatic (amebic or hydatid) abscesses with perforation into a bronchus, and Wegener's granulomatosis. Detailed history, repeated clinical evaluation, and the procedures described above can usually differentiate these disorders from simple lung abscess.

## MEDICAL TREATMENT

Appropriate use of antibiotics determines morbidity and mortality in patients with lung abscess. Clindamycin is currently the first choice for the treatment of anaerobic infections; penicillin is a less-favored alternative. The Study Group on Aspiration Pneumonia[14] also included patients with primary abscesses and found that ampicillin plus the β-lactamase inhibitor sulbactam, as opposed to clindamycin, with the optional addition of a second- or third-generation cephalosporin, was equally effective in terms of clinical response. For gram-negative organisms as well as *Pseudomonas*, aminoglycosides and quinolones or cephalosporins can be used. Nafcillin or oxacillin or cephalexin

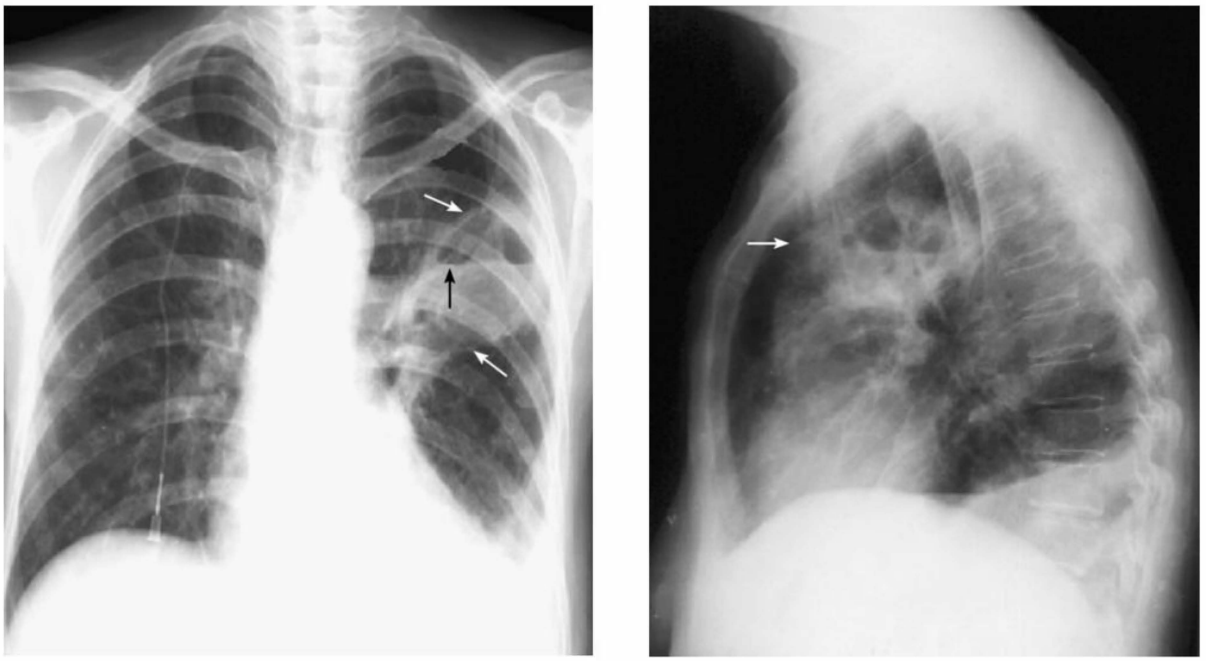

**FIGURE 6-1** Posteroanterior and lateral chest x-ray views of a patient with lung abscess. A well-defined area of increased transparency can be seen in the left upper lobe (white arrow). More than half of the cavity is filled with fluid and air (black arrow).

is recommended as a first-line agent for gram-positive organisms. The supportive treatment should include chest physiotherapy with postural drainage as well as nutritional support. Serial radiographs have limited use in the evaluation of response to therapy.

## SURGICAL TREATMENT

The availability of effective antibiotic therapy for primary lung abscess has drastically modified the natural history of the disease and diminished the role of surgery. Operative indications are less frequent in current practice, and these procedures are undertaken electively for chronic illnesses only after medical therapy has been unsuccessful. Prior to any surgical intervention, major considerations in patients with a delayed medical response include:

- An associated condition that precludes response, such as obstruction with a foreign body or neoplasm
- Erroneous microbial diagnosis with infection due to bacteria, mycobacteria, or fungi that have not been suspected and are not being treated
- Large cavity size (usually >6 cm in diameter) that may require prolonged therapy or empyema, which necessitates drainage
- An alternative, nonbacterial cause of cavitary lung disease, such as cavitating neoplasm, vasculitis, or pulmonary sequestration
- Other causes of persistent fever, such as drug fever or *Clostridium difficile*–associated colitis

***External Drainage.*** Indications for drainage include ongoing sepsis despite adequate antimicrobial therapy, progressively enlarging lung abscess in imminent danger of rupture, failure to wean from mechanical ventilation, and contamination of the opposite lung. In current practice, due to advances in interventional radiology, most of these lung abscesses are drained percutaneously under CT, ultrasound, or fluoroscopic guidance with acceptable success rates and morbidity.[15] This approach may be problematic in patients with coagulopathies if a significant amount of lung tissue must be traversed and other anatomic structures do not allow for unimpeded access to the cavity; another difficulty is posed by the presence of material within the abscess that cannot be effectively evacuated through a drainage tube. In addition, there is always a concern for soiling the pleural space with abscess contents. Direct tube drainage may be indicated in severely ill patients with large abscesses. Safe and effective pneumonostomy or cavernostomy with direct drainage (Monaldi procedure) depends on accurate topical localization of the abscess and a high degree of certainty that the underlying lung is firmly adherent to the overlying parietal pleura.

Endoscopic drainage of lung abscesses has also been reported with acceptable outcomes.[16] The procedure is performed by placing a pigtail catheter into the abscess cavity under bronchoscopic visualization and leaving the catheter in place until the cavity has drained. It can be considered in selected patients who have an airway connection to the abscess or in whom an endobronchial obstruction that prevents drainage is present.

***Surgical Resection.*** Surgical resection is now required in less than 10 percent of the cases of lung abscess. Indications for surgical intervention include unsuccessful medical management over a period of 8 weeks; complications such as bronchopleural fistula, empyema, massive or significant recurrent hemoptysis, and the persistence of a cavity larger than 6 cm after 8 weeks of treatment; necrotizing infection associated with multiple abscesses; and rupture into the pleural cavity with pyopneumothorax. Surgical intervention may also be indicated when there is a strong suspicion of carcinoma present. Intraoperatively, the patient will require double-lumen intubation or a bronchial blocker to help prevent spillage of pus into the contralateral lung, and rigid bronchoscopy may be indicated. Careful dissection and meticulous hemostasis are very important because of the adhesions and distorted anatomy caused by the abscess. Suction decompression of large cavities prior to dissection is usually helpful. Lobectomy is typically required, as segmentectomy may be inadequate and pneumonectomy is rarely necessary. Complete resection of involved areas as well as placement of two large-caliber tubes will help to speed recovery, prevent recurrence, and avoid the development of empyema.

## ACTINOMYCOTIC INFECTIONS

Owing to the presence of branching hyphae, infections due to actinomycosis and nocardiosis may be mistaken for fungal infections. It is important to make the distinction because actinomycotic infections do not respond to antifungal therapy but rather antibiotics.

### Actinomycosis

#### ETIOLOGY AND PATHOLOGY

Actinomycosis is a relatively uncommon subacute-to-chronic disease characterized by the production of suppurative abscesses or granulomas that eventually develop draining sinuses and dense scarring. These lesions discharge pus containing the organisms, which are filamentous, gram-positive, anaerobic-to-microaerophilic bacteria that are not acid fast. The branching form of the bacterium allows it to be recognized by the presence of "sulfur granules," or masses of hyphae, in the pus. In humans, actinomycosis is usually caused by *Actinomyces israelii,* which is a commensal in the normal human oropharyngeal flora. Areas of clinical manifestations of actinomycosis include cervicofacial, thoracic, and abdominal sites. Cervicofacial is the most common, comprising up to 50 percent of reported cases. Infections in the soft tissues of the mouth and throat can manifest themselves as submandibular masses with chronic draining sinuses. The infection can spread by direct extension from the neck across fascial planes into the mediastinum. Interestingly, there does not seem to be any greater incidence of the disease in patients who are immunocompromised, including those with HIV, patients who have undergone organ transplantation, or those on steroids.[17] Lung infection can result from dental surgery or aspiration and after trauma, including introduction of the organism from esophageal perforation. Hematogenous spread from distant lesions is also possible and can infect preexisting cavitary disease in the lung.

#### CLINICAL PRESENTATION

Thoracic actinomycosis commonly presents as a pulmonary infiltrate or mass that, if left untreated, can spread to involve the pleura, pericardium, and chest wall with rib osteomyelitis. The patient may have any combination of the nonspecific symptoms, such as fever, dry or productive cough, blood-streaked sputum, shortness of breath, chest pain, weight loss, fatigue, and anorexia. Physical examination may reveal abnormal breath sounds. The presence of sinus tracts with drainage from the chest wall (i.e., pleurocutaneous fistula) should raise very high clinical suspicion.

#### DIAGNOSIS

Definite diagnosis can be made by histopathologic examination and anaerobic culture of material from draining sinuses and abscesses. The "sulfur granules" are practically pathognomonic; they are approximately 1 mm in diameter and can be seen by the naked eye as yellowish particles. Microscopically, they are composed of branching filamentous rods that stain positive on Gram's stain (Fig. 6-2). On chest x-ray, the presence of a mass-like lesion that extends across fissures or pleura, invades into the adjacent chest wall or thoracic vertebrae, or causes local destruction of the ribs or sternum suggests thoracic actinomycosis. CT scans usually reveal an infiltrative mass with focal areas of decreased

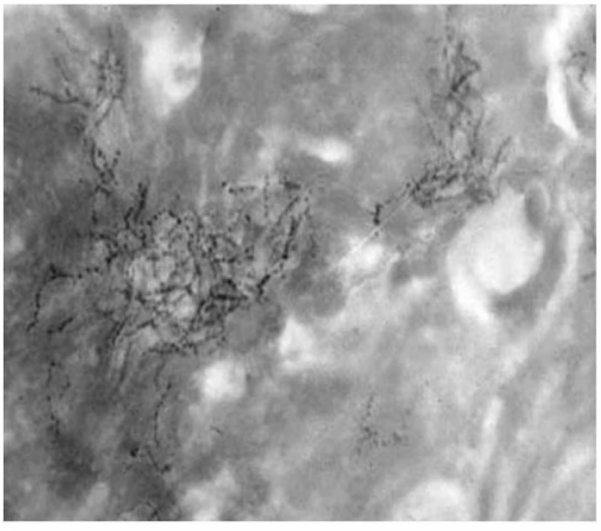

**FIGURE 6-2** Characteristic actinomycetic granules.

attenuation that enhance with contrast. This infiltrative mass has a tendency to invade surrounding tissues, and lymphadenopathy is uncommon.

### MEDICAL TREATMENT

High-dose penicillin, administered over a prolonged period, is the cornerstone of therapy for actinomycosis. Prolonged treatment is necessary owing to the presence of surrounding dense fibrous tissues. Lack of a clinical response from a patient receiving penicillin therapy may also indicate the presence of resistant companion bacteria, which may require modification of the antibiotic regimen.

### SURGICAL TREATMENT

Surgical intervention may be implemented for drainage of an abscess or empyema and for radical excision of sinus tracts when feasible. The most common indication for surgery is exploratory thoracotomy to rule out carcinoma.[18] Rarely, actinomycosis may be complicated by an unusual but significant hemoptysis—another indication for surgery—although selective bronchial artery embolization is a viable option in this setting. Even if histology suggests complete resection, it must still be followed by prolonged antibiotic therapy, as surgery alone is usually not curative. Inadequate antibiotic therapy postoperatively may result in complications such as bronchopleural fistulas and empyema.

## Nocardiosis

### ETIOLOGY AND PATHOLOGY

Nocardiosis is an acute, subacute, or chronic suppurative infection caused by weakly gram-positive, filamentous bacteria found worldwide in soils. *Nocardia asteroides* (80 percent) and *Nocardia brasiliensis* are the principal causes of human disease. *Nocardia farcinica* is being recognized with increasing frequency. The disease has a pronounced tendency toward remission and exacerbation, and infections are localized or disseminated. Localized infection usually manifests itself as primary cutaneous or, rarely, lymphocutaneous disease. Nocardiosis is an opportunistic infection, and disseminated or fulminant disease mainly occurs in immunocompromised hosts with underlying illnesses such as chronic granulomatous disease and HIV infection as well as patients on immunosuppressive therapy.[19] Lung transplant recipients have a particularly high incidence. Inhalation of the free-living organism is the likely route of infection. Introduction of *N. asteroides* via the respiratory tract results in pulmonary lesions, most often manifest as multiple abscesses. *Nocardia* abscesses are characteristically confluent, with little evidence of encapsulation, which probably accounts for the ready dissemination from the initial pulmonary focus. This organism also evades the host's bactericidal mechanisms. The primary disease, which occurs in the pulmonary system, may mimic tuberculous, staphylococcal, or mycotic infection. Hematogenous dissemination to the brain, kidneys, and liver are the most common metastatic sites.

### CLINICAL PRESENTATION

Symptoms in patients with nocardiosis are indistinguishable from those in patients with similar pulmonary infections of other microbial etiology. Cough with sputum production and fever are the dominant symptoms. Subcutaneous abscesses and draining sinuses near the chest wall that contain sulfur granules, similar to those observed in actinomycosis, are characteristic. Lung examination may reveal diffuse or localized abnormal breath sounds.

### DIAGNOSIS

The diagnosis of nocardiosis is established by aerobic culture of the causative organism from the site(s) of infection. Because *Nocardia* organisms grow more slowly than common bacteria, the microbiology laboratory should always be notified when nocardiosis is clinically suspected, especially if sputum is submitted. Bronchial brushings or percutaneous transthoracic needle aspiration biopsy of the lung may help to obtain appropriate samples and avoid the need for thoracotomy. *Nocardia* organisms are not demonstrated with routine hematoxylin and eosin (H&E) stain and may be seen only by a careful search of sections stained with Gram's, *Gomori methenamine silver* (GMS), or acid-fast bacillus stain.

Possible findings on chest x-ray and/or CT scan include irregular nodules (which may cavitate), reticulonodular or diffuse alveolar pulmonary infiltrates, lung abscess formation, and pleural effusion. All patients with pulmonary nocardiosis should have brain imaging by either CT scan or magnetic resonance imaging (MRI).[20]

### MEDICAL TREATMENT

Sulfonamides are first-line antimicrobial therapy and sulfadiazine is generally preferred because of its central nervous system (CNS) and CSF penetration. The combination of trimethoprim/sulfamethoxazole (TMP/SMX) or minocycline in high doses is an acceptable alternative. Treatment for a minimum of 2 to 3 months is recommended; treatment for as long as 12 months may be necessary, especially for systemic disease. Prophylactic TMP/SMX should be considered in transplant centers with excess rates of nocardial infection.[21]

### SURGICAL TREATMENT

Surgical intervention may be required for the drainage of lung abscess or empyema or when the diagnosis of a lung lesion is unclear. Pulmonary resection for previously diagnosed *Nocardia* infection is rarely indicated.

# MYCOTIC THORACIC INFECTIONS

## Histoplasmosis

### ETIOLOGY AND PATHOLOGY

Pulmonary manifestations are the hallmark of histoplasmosis, as this, also known as Darling disease, is probably the most common of all fungal infections of the lungs. Clinical syndromes range from asymptomatic infection to diffuse alveolar disease causing respiratory difficulty and occasionally death. *H. capsulatum* is a dimorphic fungus that remains in a mycelial form at ambient temperatures and grows as yeast at body temperature in mammals. Although the fungus can be found in temperate climates throughout the world, it is endemic to the Ohio, Missouri, and Mississippi River valleys in the United States. Farmers, construction workers, and people who enjoy outdoor activities are the most at risk. The disease results from aerosolization of conidial and mycelial fragments from contaminated soil due to the excreta of chickens, pigeons, and bats, which are then deposited in the alveoli. Conversion from the mycelial to the pathogenic yeast form occurs intracellularly. The host defense includes the fungistatic properties of neutrophils and macrophages. T-lymphocytes are crucial in limiting the extent of infection. Susceptibility to dissemination is increased markedly with impaired cellular host defenses.

### CLINICAL PRESENTATION

There is a wide spectrum of pulmonary histoplasmosis syndromes. The extent of disease and mode of presentation following initial exposure correlate with the size of the inoculum that was inhaled and the *Histoplasma*-specific immunity of the exposed subject. Pulmonary auscultation reveals nonspecific rales, wheezes, or findings consistent with the extent of underlying pneumonitis, consolidation, or cavitation.

***Asymptomatic Infection.*** Approximately 85 to 90 percent of infected immunocompetent individuals are asymptomatic. As the cell-mediated host immunity matures, delayed-type hypersensitivity to histoplasmal antigens occurs (3 to 6 weeks after exposure). The skin antigen test for *Histoplasma* species turns positive. Over weeks to months, the inflammatory response produces calcified fibrinous granulomas with areas of caseous necrosis. Most asymptomatic cases are now identified by the incidental finding of enlarged mediastinal or hilar lymph nodes or pulmonary nodules seen on radiographs or CT scans obtained for the evaluation of other conditions. Perhaps the main significance of such findings is the need to differentiate them from malignancy (Fig. 6-3).

***Acute and Subacute Pulmonary Histoplasmosis.*** Inhalation of a large amount of inoculums results in an inflammatory response in the lung and adjacent lymph nodes, similar to the Ghon complex of pulmonary tuberculosis.[22] This can be due to primary infection or reinfection. Nonimmune subjects usually present within 2 weeks with respiratory symptoms and diffuse pulmonary involvement radiographically. Fever, headache, malaise, myalgia, abdominal pain, and chills are common symptoms. Enlarged hilar and mediastinal lymph nodes (mediastinal lymphadenitis) are present in 5 to 10 percent of patients. Mediastinal histoplasmosis results in fibrosing mediastinitis, which can cause symptoms of compression and is the most frequent benign etiology of superior vena cava (SVC) obstruction. Cough, hemoptysis, dyspnea, and/or chest pain may be present; these are related to the degree of compression imposed on the pulmonary airway and circulation. Rarely, compression of the esophagus occurs, which causes dysphagia.

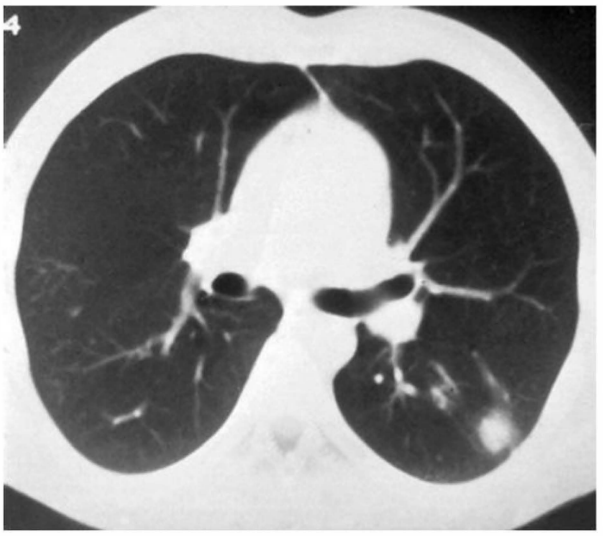

**FIGURE 6-3** Single pulmonary nodule in a patient with histoplasmosis.

***Chronic Pulmonary Histoplasmosis.*** This form occurs mostly in middle-aged men with underlying pulmonary disease (e.g., COPD); it is rare in children and represents 10 percent of symptomatic cases. Chronic pulmonary histoplasmosis (CPH) resembles reactivation tuberculosis, which is a common misdiagnosis. It is associated with cough, dyspnea, chest pain, weight loss, fevers, malaise, and night sweats. The clinical course of untreated CPH is progressive, with spread to contiguous lung. Complications, such as hemoptysis and bronchopleural fistulas, may ensue. Other infections can coexist, such as mycobacterial and other fungal infections (e.g., aspergillosis). Concurrent neoplasia is not uncommon.

Radiographs typically show changes of emphysema. Airspace opacities are present and may surround preexisting bullae, producing the appearance of cavitation with air-fluid levels. In severe cases the lung disease may progress and produce diffuse confluent airspace disease. As the patient recovers, the opacities on chest x-ray become more defined and nodular in appearance. The disease is almost always in the upper lobes and may be bilateral or unilateral in distribution. The inflammatory process progressively destroys lung tissue

and retracts the hilar structures upward as a consequence of the loss of lung volume. Pleural thickening adjacent to the lung disease is often present. Untreated cases may lead to progressive pulmonary fibrosis, which may result in respiratory and cardiac failure and recurrent infections.

***Progressive Disseminated Histoplasmosis.*** This form occurs mostly in hosts who are immunocompromised and probably results from a failure to develop protective cellular immunity following the acute infection. Symptoms vary depending on the duration of illness. Evidence for dissemination includes hepatosplenomegaly, extrapulmonary lymphadenopathy, mucosal or skin lesions, anemia, leukopenia, thrombocytopenia, or hepatic enzyme elevation. Furthermore, gastrointestinal involvement may produce diarrhea and abdominal pain. Cardiac involvement resulting in valvular disease, cardiac insufficiency, or vegetations may cause dyspnea, peripheral edema, angina, and fever. CNS involvement may produce headache, visual and gait disturbances, confusion, seizures, altered consciousness, and neck stiffness or pain. Note that subacute progressive disseminated histoplasmosis results in adrenal infection in 80 percent of patients. Radiographically, localized, cavitary, or miliary infiltrates as well as mediastinal lymphadenopathy may be present. The presence of calcified lymph nodes and lung granulomas suggests that disseminated disease has resulted from reinfection. Diffuse nodular opacities can be seen on CT scan (Fig. 6-4).

## DIAGNOSIS

Histoplasmin skin testing is not recommended for diagnostic purposes because of the high rate of positive reactions in endemic areas and the wide variability of response. *H. capsulatum* can be recovered from sputum, BAL fluid, lesions, blood, or bone marrow on routine fungal cultures; but the organism grows slowly and plates must be kept up to 12 weeks. The combination of blood and bone marrow cultures increases the likelihood of positive results. In chronic or severe acute pulmonary disease, organisms can be cultured from sputum or bronchial washings. Multiple specimens increase yield. Antibody testing can be performed using immunodiffusion, complement fixation, and radioimmunoassay in increasing order of sensitivity.

Antibody levels peak 6 weeks following exposure and decline over a 2- to 5-year period. Antigen detection in serum and urine is useful in immunocompromised individuals, whose ability to produce antibodies may be impaired. Cross-reactivity with antigens from *Blastomyces dermatitidis* and *Coccidioides immitis* may cause a false-positive test result. Urine specimens have higher sensitivity, up to 90 percent for disseminated disease. Paired urine and serum specimens have the highest yield. Note that some patients with acute histoplasmosis may have high serum levels of angiotensin-converting enzyme. This may cause a diagnostic confusion with sarcoidosis, especially if the patient also has hilar adenopathy.

Tissue may have to be obtained from pulmonary lesions and lymph nodes by bronchoscopy, percutaneous needle biopsies, or rarely, thoracoscopy in order to make the diagnosis. Histologic findings in pulmonary histoplasmosis demonstrate a predominantly mononuclear infiltrate. Multiple caseating granulomas are characteristic, with multinucleated giant cells and possible peripheral fibrosis and central calcification. On H&E staining, the yeast form of *H. capsulatum* has a false capsule. Special stains, such as GMS or periodic acid-Schiff (PAS), may reveal budding yeast, but the organisms can be mistaken for *Pneumocystis carinii* and other fungal organisms. In chronic pulmonary forms—in addition to underlying lung disease—vascular involvement, tissue necrosis, and scarring are present. Extensive fibrosis with collagen deposition is observed in fibrosing mediastinitis.

Echocardiography, CT scan of the abdomen, as well as CT scan and MRI of the brain should be performed when involvement of these areas is suspected. Lumbar puncture (LP) in CNS histoplasmosis demonstrates a lymphocytic pleocytosis, with elevated protein and normal or low glucose.

**FIGURE 6-4** Chest CT in progressive histoplasmosis, showing diffuse pulmonary nodules.

## MEDICAL TREATMENT

No treatment is needed for asymptomatic immunocompetent individuals without serious underlying disease. The antifungal therapy of choice is amphotericin B or its liposomal formulation for disseminated disease. The recommended duration of therapy is 12 weeks for acute and subacute histoplasmosis, 12 to 24 months for chronic disease, and 6 to 18 months for disseminated progressive disease. Patients with disseminated disease and HIV should be on treatment for life. Itraconazole can be used for those with moderate illness and for completion of therapy after response to amphotericin. In those who are hypoxic corticosteroids should be added. Mediastinal and hilar lymphadenopathies usually resolve. Granulomatous inflammation causes extensive enlargement with caseating necrosis, which may fibrose

with progressive healing. Occasionally, the lymph nodes may remain enlarged, compressing surrounding structures and distorting anatomic architecture.

### SURGICAL TREATMENT

Indications for surgery include:

- The presence of persistent or progressive cavitations with repeated relapses despite multiple courses of intensive medical treatment
- Medical therapy is insufficient to alleviate the compressive effects of progressive fibrosis, calcification, and scarring:
  - Life-threatening tracheobronchial and esophageal obstruction and bronchoesophageal fistula
  - SVC syndrome, pulmonary vascular obstruction, or middle-lobe syndrome associated with fibrosing mediastinitis
- Severe valvular insufficiency due to involvement in disseminated histoplasmosis
- Symptomatic broncholithiasis (which occurs when a calcified node erodes into a bronchus) if bronchoscopic extraction was unsuccessful

During surgery, care should be taken to avoid spilling necrotic material into the mediastinum and initiating a further fibrotic reaction.

## Aspergillosis

### ETIOLOGY AND PATHOLOGY

Pulmonary aspergillosis comprises a spectrum of mycotic diseases caused by *Aspergillus* species. Human illness is usually caused by *Aspergillus fumigatus* and Aspergillus niger and, less frequently, by Aspergillus flavus and Aspergillus clavatus. The transmission of fungal spores to the human host is via inhalation. *A. fumigatus* exists in two forms: (1) conidiophores, the reproductive forms that produce and release thousands of spores and (2) hyphae, which represent mature spores characterized by a 45-degree dichotomous branching pattern. The fungus grows widely in soil, water, and decaying vegetable or animal material. The spores are readily inhaled, and the fungus is commonly found in the sputum of healthy individuals.[23] Most patients with pulmonary aspergillosis have either impaired immunity or underlying preexisting chronic lung disease such as bronchiectasis, COPD, or tuberculosis. Impaired immunity may be secondary to alcoholism, advanced age, poorly controlled diabetes mellitus, underlying malignancy, cirrhosis, malnutrition, sepsis, AIDS, or organ transplantation.

### CLINICAL PRESENTATION

Pulmonary aspergillosis may present as any of three distinctive clinical syndromes: allergic bronchopulmonary aspergillosis, aspergilloma, and invasive aspergillosis.

***Allergic Bronchopulmonary Aspergillosis.*** Allergic bronchopulmonary aspergillosis (ABPA) represents a hypersensitivity reaction to *A. fumigatus* in patients with poorly controlled asthma or cystic fibrosis. It is associated with a type I, III, or IV allergic response to *Aspergillus* antigens. Excessive mucus production in association with impaired ciliary function leads to mucoid impaction of the airways. The plugs of inspissated mucus contain hyphal elements of *A. fumigatus* and eosinophils, but the organisms remain within the bronchial lumen; this feature differentiates ABPA from invasive aspergillosis. The inflammatory response results in damage to the bronchial wall with airway destruction and the subsequent development of bronchiectasis. ABPA was initially described as a disease characterized by episodic wheezing, pulmonary infiltrates, pyrexia, sputum and blood eosinophilia, and sputum containing brown flecks or plugs. Almost all ABPA patients have clinical asthma. The disease may progress through various stages based on clinical, serologic, and radiographic findings. These stages need not occur in order. The first four stages—which are acute, remission, recurrent exacerbation, and corticosteroid-dependent asthma—are potentially reversible with no long-term sequelae. However, the fifth stage, fibrotic lung disease, in which bronchiectasis or fibrosis develops, is irreversible.[24]

***Aspergilloma or Saprophytic Aspergillosis.*** Aspergilloma is the most common form of pulmonary aspergillosis. It is noninvasive, involves the colonization of a preexisting pulmonary cavity or ectatic bronchus secondary to a wide variety of underlying pulmonary conditions, and occurs most often in the upper lobe. Simple aspergilloma develops in isolated thin-walled cysts lined by ciliated epithelium while the surrounding lung is normal. Complex aspergilloma develops in cavities formed by gross disease in the surrounding lung tissue. The most common underlying conditions are tuberculosis, sarcoidosis, and bronchiectasis. Histologically, the aspergilloma represents a fungal ball, or mycetoma, which consists of a mass-like conglomerate of intertwined hyphae intermingled with fibrin, cellular debris, mucus, and other blood products. This mycetoma may calcify in an amorphous or ring-like fashion. A pulmonary aspergilloma does not initiate the destructive pulmonary process, as is seen in ABPA and invasive aspergillosis. Most cases of aspergilloma are thought to arise from colonization and proliferation of the fungus in areas of devitalized lung with a poor blood supply. Most patients with pulmonary aspergilloma are asymptomatic. The most common presenting symptom, hemoptysis, has been reported in 50 to 80 percent of patients. Hemoptysis is usually intermittent and scanty but may be life-threatening. When symptoms such as cough, dyspnea, malaise, and weight loss are present, they are varied and are often difficult to ascribe to the aspergilloma in the presence of underlying pulmonary disease. Fever is an unusual finding in aspergilloma and suggests an alternate cause or concurrent bacterial infection.[25] Physical examination is generally nonspecific, although localizing signs such

as decreased air movement, bronchial breath sounds, and adventitial sounds may be heard.

***Invasive Pulmonary Aspergillosis.*** Invasive pulmonary aspergillosis (IPA) is now the most common fungal pulmonary infection in severely immunocompromised patients such as hematopoietic stem cell—or organ-transplant patients with hematologic malignancies undergoing intensive chemotherapy.[26] This infectious process is characterized by the invasion of blood vessels, resulting in multifocal infiltrates. Dissemination to other organs, particularly the CNS, may occur. Invasive aspergillosis typically manifests itself with fever, cough, sputum production, dyspnea, pleuritic chest pain, and sometimes hemoptysis in patients with prolonged neutropenia or immunosuppression. Fever that persists despite the administration of broad-spectrum antibiotics is present in a majority of patients except in corticosteroid-treated patients and is often the first clinical sign. Hypoxemia is present in diffuse disease. Among patients who have undergone organ transplantation, bone marrow recipients are most at risk for *Aspergillus* infection. In patients with leukemia and lymphoma, aspergillosis may occur after chemotherapy-induced bone marrow suppression, with resultant prolonged neutropenia.

## DIAGNOSIS

Several sets of diagnostic criteria incorporating the clinical, immunologic, and radiographic features of the disease have been proposed for the diagnosis of ABPA, since no single test is sufficiently discriminating. ABPA is defined by the following abnormalities: asthma, eosinophilia, a positive skin test result for *A. fumigatus*, marked elevation of the serum immunoglobulin E (IgE) level to greater than 1000 IU/dL, and positive test results for *Aspergillus* precipitins (primarily IgG, but also IgA and IgM antibodies). Chest x-ray characteristics include fleeting pulmonary infiltrates, central bronchiectasis, and mucoid impaction, which can result in lobulated masses or atelectasis. CT scanning is helpful in better defining bronchiectasis; images may show that the apparent lobulated masses are mucus-filled dilated bronchi. Minor criteria for diagnosis include positive *Aspergillus* radioallergosorbent assay test results, expectoration of brown plugs, and culture findings for *Aspergillus* in sputum. Histopathology and GMS staining may demonstrate degenerating eosinophils and typical fungal hyphae.

Aspergilloma does not cause many characteristic laboratory abnormalities. The diagnosis is usually made based on clinical and chest radiographic features coupled with serologic evidence of *Aspergillus* species. Results of the *Aspergillus* precipitin antibody test (i.e., for IgG) are usually positive. Chest radiography reveals a mass in a preexisting cavity, usually in an upper lobe, manifest by a crescent of air partially outlining a solid mass. Associated pleural thickening adjacent to the cavity is characteristic and may predate the development of an aspergilloma. CT scan images provide a better definition of the mass within a cavity and may demonstrate multiple aspergillomas in areas of extensive cavitary disease. Imaging can be performed with the patient in the supine and prone positions to demonstrate movement of the mass within the cavity.

Currently available antibody testing is not helpful for the diagnosis of invasive aspergillosis. In the appropriate clinical setting of pulmonary infiltrates in a patient who is neutropenic or immunosuppressed, visualization of the characteristic fungi, using silver stain or Calcofluor, or a positive culture result from sputum, needle biopsy, or BAL fluid should result in the prompt institution of therapy. Invasive aspergillosis demonstrates the characteristic septate hyphae, branching at acute angles, and acute inflammatory infiltrate and tissue necrosis with occasional granulomata and blood vessel invasion. A halo sign (i.e., an area of ground-glass infiltrate surrounding nodular densities on CT scan images) may be very helpful in the early diagnosis of aspergillosis. Later disease may show a crescent of air surrounding nodules, indicative of cavitation. Because *Aspergillus* is angioinvasive, infiltrates may be wedge-shaped, pleura-based, and cavitary, which is consistent with pulmonary infarction.

## MEDICAL TREATMENT

The goals of therapy for APBA are to treat acute exacerbations of disease and prevent the development of the fibrotic stage and bronchiectasis; therefore, early diagnosis is crucial. ABPA requires treatment with oral corticosteroids as a hypersensitivity reaction. Inhaled steroids are not effective. A recent double-blind, placebo-control trial has also demonstrated a potential benefit from the addition of oral itraconazole 200 mg twice daily to steroids. This may allow more rapid resolution of infiltrates and symptoms, facilitating steroid tapering or lowering the needed maintenance corticosteroid dosage. Bronchodilators such as β-agonists, anticholinergics, and leukotriene antagonists are also used for the treatment of asthma symptoms in ABPA.

Medical therapy is usually not effective for the treatment of aspergilloma because amphotericin B penetrates *Aspergillus* cavities poorly. Most patients are asymptomatic and treatment is not required unless significant hemoptysis occurs, in which case surgical intervention is indicated. Invasive aspergillosis is often rapidly progressive and has a high mortality rate; therefore, preventive therapy and rapid institution of therapy in patients in whom the diagnosis is suspected may be lifesaving. Prophylactic antifungal therapy with amphotericin B in high-risk patients may prevent invasive aspergillosis. The largest therapeutic experience is also with amphotericin B. Lipid formulations of amphotericin are indicated for the patient who has impaired renal function or who develops nephrotoxicity while receiving amphotericin. Oral itraconazole is an alternative for patients who can reliably take oral medication, especially those who respond to initial intravenous therapy.[27] Combination antifungal therapy sometimes may be used, or newer antifungal agents, such as caspofungin, may be instituted as monotherapy in patients in whom initial therapy with amphotericin B has failed.

Voriconazole is a new broad-spectrum triazole active in vitro against various yeasts and molds including *Aspergillus* species. A recent randomized trial showed that in patients with invasive aspergillosis, initial therapy with voriconazole led to better responses and improved survival and resulted in fewer severe side effects than the standard approach of initial therapy with amphotericin B.[28] For transplant patients, the level of immunosuppression should be decreased if possible.

### SURGICAL TREATMENT

Areas of mucoid impaction due to ABPA may have a mass-like appearance and are sometimes resected as an undiagnosed lung mass. Surgical removal of aspergilloma is definitive treatment; it has been advocated to be reserved for high-risk patients such as those with episodes of recurrent or life-threatening hemoptysis and patients who are immunocompromised. Aspergillomas tend to develop in clinically ill individuals with poor pulmonary function, and operations are often technically challenging because of the dense fibrosis around the cavity, the obliteration of pleural space and fissures, the enlarged and tortuous bronchial arteries, and the diseased pulmonary parenchyma surrounding the lesion. Inflammatory fibrosis of the pulmonary parenchyma and pleura may prevent the remaining lung from expanding fully so that it fills the pleural space after resection. For patients with life-threatening symptoms whose condition is unfit for pulmonary resection, cavernostomy and myoplasty may be considered.[29] Careful long-term follow-up is necessary in all patients because of the risk of recurrence. Overall, the morbidity of surgical treatment must be weighed against the clinical benefit for each patient. Bronchial artery embolization rarely produces a permanent success due to systemic collateral supply, but it may be useful as a temporizing procedure in patients with life-threatening hemoptysis. Other modalities that have been used include radiation therapy and endobronchial or percutaneous intracavitary instillation of amphotericin B under fluoroscopic or CT guidance. For invasive aspergillosis, the marginal response rates to antifungals, combined with the aggressive nature of the disease, lead to mortality rates that approach 90 percent with medical therapy alone, especially in immunocompromised patients. Aggressive surgical resection is therefore recommended for localized disease that has failed to respond to prolonged antifungal therapy.[30] A thoracoscopic approach has been reported that may result in a less-complicated postoperative course.[31]

## Coccidioidomycosis

### ETIOLOGY AND PATHOLOGY

Coccidioidomycosis is the infection caused by the dimorphic fungi of the genus *Coccidioides* (*C. immitis* and *C. posadasii*). These fungi are endemic to certain lower deserts of the southwestern United States. Infection is acquired by inhalation of a single arthroconidium, usually dust from uncultivated soil in the endemic areas. Within the lung, an arthroconidium changes from a barrel-shaped cell to a spherical structure and then greatly enlarges. Enlarging spherules produce internal septations; within each of the resulting subcompartments, individual cells (endospores) evolve. After several days, mature spherules rupture, releasing endospores into the infected tissue. If the infecting dose is huge or the person's immune status is impaired, overwhelming pulmonary disease and acute respiratory distress syndrome (ARDS) can occur. More often, localized pulmonary infection is the result. Coccidioidal pneumonia may clear, spread locally, or disseminate.

### CLINICAL PRESENTATION

Approximately two-thirds of infected persons experience few or no symptoms. The initial, or primary, infection is called valley fever when the disease is mild. Although the symptoms of coccidioidomycosis closely resemble those of other common respiratory infections, a respiratory illness with an accompanying rash in a patient with recent exposure to an endemic area is suggestive of a coccidioidal infection. Other systemic symptoms include fever, sore throat, malaise, and headache. Acute coccidioidal pneumonia may be self-limited or seems to respond to treatment with antibiotics. In certain situations, acute coccidioidal pneumonia may progress to involve the pleura, the formation of a mass-like lesion, necrosis, and cavity formation (coccidioidal cavities). In approximately 5 percent of patients, pneumonia can become chronic and cavities and nodules can persist as residual pulmonary nodules and chronic fibrocavitary pneumonia. The latter is characterized by night sweats, fatigue, weight loss, chronic cough, hemoptysis, and dyspnea. If necrosis involves the pleura, rupture with contamination of the pleura and extensive bronchopleural disease can ensue. When rupture does occur, a bronchopleural fistula is formed. Dyspnea and chest pain are the most common resulting symptoms, typical of a pneumothorax. Multiple areas of the lung may be involved due to seeding of several areas or airway spread of the infection.

Diffuse pulmonary or miliary coccidioidomycosis is the pulmonary manifestation of widespread dissemination in an individual with a very poor host response or if the fungal inoculum is large. The patient may manifest ARDS with hypoxia; in some cases, hypercapnea may also occur. *Coccidioides* may invade the vasculature, and spherules can be carried hematogenously to the entire pulmonary vasculature and many other organs. Extrapulmonary coccidioidomycosis can involve any organ; however, disseminated lesions are most commonly seen in the skin, lymph nodes, bones, and joints. Coccidioidal meningitis is also a manifestation of dissemination. Fortunately, disseminated disease occurs in only 0.5 to 1 percent of cases.[32]

### DIAGNOSIS

The clinical presentations of coccidioidomycosis are protean, necessitating a high index of suspicion for the disease.

A definitive diagnosis is established by the recovery of *Coccidioides* from respiratory secretions, tissues, or body fluids. Microscopic examination of sputum is positive in only 10 percent of cases. Bronchoscopy increases the yield dramatically, particularly if there is a lesion in the airways or parenchyma that can be biopsied. Alternatively, BAL is often useful. Respiratory samples should always be examined by cytology. Fine-needle aspiration of the lung often yields the organism, but more than one attempt is often necessary. Skin tests are not helpful in making the diagnosis. If skin lesions are present, a punch biopsy is quick and often positive. Pathologic examination using a silver stain shows granulomatous inflammation with the classic double-walled spherules with endospores. Serologic testing is one of the mainstays of diagnosis. The precipitin test, which measures IgM antibody, will be positive in 1 to 2 weeks and will remain positive for up to 6 months. Serology for the slower but more persistent IgG response is also tested using complement fixation or immunodiffusion assays and, more recently, enzyme immunoassay. Coccidioides will grow in nearly all laboratory media and often within the first week. The organism grows best at room temperature. A positive identification of the mold can be quickly made by a commercially available deoxyribonucleic acid (DNA) probe.

Radiographic manifestations vary depending on the clinical presentation. Residual coccidioidal cavities are commonly solitary and peripheral in location on a radiograph. Their walls are often strikingly thin with little or no discernible surrounding infiltrate. In ruptured cavities, an effusion coexists with the pneumothorax on chest x-ray, resulting in an air-fluid level. Since a spontaneous pneumothorax does not normally produce an effusion, this finding is of diagnostic significance. Chronic fibrocavitary pneumonia shows complex mixtures of infiltrate and cavitation. Hilar adenopathy is also common. A diffuse miliary or reticulonodular pattern on chest radiograph or CT scan (Fig. 6-5) is strongly associated with disseminated disease.[33] When disseminated disease is suspected, other diagnostic modalities include CT of the abdomen and pelvis and a bone scan to identify occult bony lesions. If the patient has even minimal CNS symptoms, an LP should be performed to rule out coccidioidal meningitis.

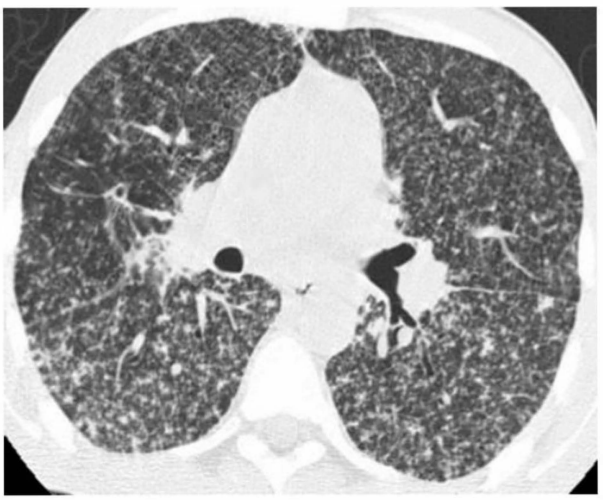

**FIGURE 6-5** Chest CT of a patient with miliary coccidioidomycosis.

## MEDICAL TREATMENT

In the absence of symptoms, treatment is not recommended. Since it is possible for coccidioidal cavities to change appearance, repeat chest radiographs at intervals ranging from 6 months to 2 years, depending on their apparent stability, are helpful in determining whether the lesion is enlarging or disappearing. Treatment is recommended if symptoms such as local pleural discomfort and hemoptysis occur. Such symptoms often improve after treatment with oral antifungal agents (ketoconazole, fluconazole, or itraconazole), but they may return if treatment is discontinued. The duration of treatment is typically 1 year or longer. A clinical response to treatment is usually evident by improvement in respiratory symptoms and periodic radiographs. Amphotericin B can be used for refractory infections unresponsive to oral therapy and is also the initial therapy of choice for rapidly progressive diffuse reticulonodular pneumonia and disseminated disease. As the patient's pulmonary status improves, treatment can be switched to an oral azole for at least 1 year. Patients with an underlying immunodeficiency state may have to be treated indefinitely.[34] A few case reports suggest that the new antifungal voriconazole is effective in disseminated disease refractory to other antifungals.[35]

## SURGICAL TREATMENT

Surgery is never the mainstay of treatment, although it may be critical for making the correct diagnosis. Cavities are considered candidates for resection if they are visible for longer than 2 to 4 years in association with symptoms, adjacent to pleura, rapidly enlarging, or thick walled or if they contain a fungus ball. Severe or recurrent hemoptysis is a strong indication for surgery. Surgical resection has also been recommended when the cavities occur in diabetic or pregnant patients and when they coexist with pulmonary tuberculosis.

In pyopneumothorax associated with a ruptured coccidioidal cavity, surgical resection of the cavity is the preferred approach if the condition is diagnosed promptly. If the diagnosis is delayed a week or more, a conservative approach with chest tube placement and oral antifungal treatment can be attempted. Persistent bronchopleural fistulas or lungs that are restricted by residual disease are other indications for surgery. In the case of ruptured cavities, the extent of surgical resection may have to be limited because of the extensive contamination of the pleural space. Lobectomy may not necessarily be indicated, since lesser resections are associated with equally low recurrence and complications rates.[36]

## Blastomycosis

### ETIOLOGY AND PATHOLOGY

North American blastomycosis is an endemic fungal infection predominantly seen in the south central and midwestern United States and portions of Canada. The disorder is the systemic pyogranulomatous disease caused by *B. dermatitidis*, a dimorphic organism usually acquired through inhalation of aerosolized conidia. At body temperature, these conidia transform to the yeast phase and a self-limited infection develops in the majority of persons. Rarely, blastomycosis may occur in accidental percutaneous exposure or following dog bites. Conjugal and perinatal transmissions have been reported, but person-to-person transmission is extremely rare. Most individuals who develop blastomycosis report occupations or hobbies—specifically hunting and fishing, camping, cutting timber, and operating heavy equipment—that likely enhance exposure to *B. dermatitidis*. The fungus has been identified in pigeon manure and soil. The major acquired host defense against *B. dermatitidis* is cellular immunity, which is mediated by antigen-specific T lymphocytes and lymphokine-activated macrophages. Chronic infection limited to the lungs or disseminated infection involving extrapulmonary sites develops in the minority of cases.

### CLINICAL PRESENTATION

Blastomycosis is a systemic disease that can involve virtually any organ. Acute blastomycosis is a condition that occurs with unknown frequency among patients exposed to *B. dermatitidis* through inhalation.[37] Most of the data from outbreaks suggest that the vast majority of patients exposed to *B. dermatitidis* develop a self-limited nonspecific flu-like illness that does not progress to chronic disease.

Chronic pulmonary blastomycosis is a disease usually manifest by symptoms of chronic pneumonia, which may progress to a pyogranulomatous process. Common symptoms include weight loss, fever, night sweats, and a cough productive of purulent sputum. Hemoptysis is uncommon. The disease is difficult to distinguish clinically from other fungal pulmonary diseases, tuberculosis, nocardiosis, chronic necrotizing bacterial pneumonia, and neoplastic disease. In fewer than 10 percent of cases, pulmonary blastomycosis presents with severe clinical manifestations, ARDS, and respiratory failure. This severe and unusual manifestation occurs in both immunocompromised and otherwise normal patients and is associated with an extremely high mortality. There are also several reports of so-called miliary blastomycosis associated with disseminated disease but not necessarily with frank respiratory failure. Many of these patients are severely immunosuppressed, but if a diagnosis is established early, there is often a favorable outcome with appropriate systemic antifungal therapy.

Extrapulmonary involvement with *B. dermatitidis* occurs in over 50 percent of patients with chronic blastomycosis. The skin and subcutaneous tissue are the most common sites. Typical lesions are verrucous (wart-like) plaques or cutaneous ulcers, frequently with a distinctive purplish hue surrounding the skin lesions. Subcutaneous disease is usually manifest as subcutaneous nodules that may suppurate and spontaneously drain, forming deep cutaneous ulcers. These lesions can easily be mistaken for pyoderma gangrenosum, squamous cell carcinoma, and other chronic cutaneous infections. Other sites that can be potentially involved include the genitourinary tract, bones, CNS, and the nasal and oral mucosa. Less common sites include the larynx, thyroid, sinuses, and eyes.

### DIAGNOSIS

The diagnosis of blastomycosis is established when *B. dermatitidis* is isolated from any clinical specimen. Transbronchial, transthoracic, or open-lung biopsy may be necessary. The organism grows well in the mycelial phase at 25°C to 30°C on routine fungal media. Conversion to the yeast phase at 37°C and demonstration of morphologically typical yeast forms confirms the identity of the organism. Commercial test kits are available that allow early identification of mycelial cultures by recognition of unique DNA sequences or fungus-specific exoantigens.[38] In culture-negative cases or before the culture becomes positive, the finding of broad-based budding yeast with a doubly refractile cell wall (Fig. 6-6) on histologic or cytologic specimens is strongly suggestive of *B. dermatitidis*. At present, there is no reliable, sensitive, and specific serologic methodology in use for routine diagnostic purposes.

Radiographically, chronic pulmonary blastomycosis does not have a typical appearance. Parenchymal abnormalities may occur in the upper lobes and may appear as unilateral or bilateral lobar or segmental abnormalities. Pulmonary nodules with or without cavitation and mass-like lesions are

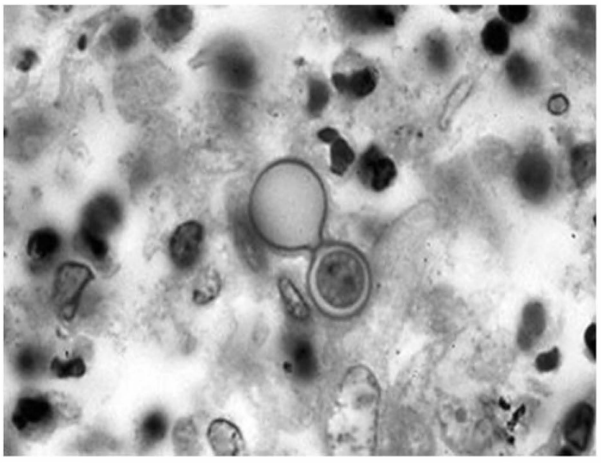

**FIGURE 6-6** Broad-based budding yeasts typical for *Blastomyces dermatitidis*.

frequently noted. The mass lesion of pulmonary blastomycosis may mimic carcinoma of the lungs. Pleural effusion and mediastinal lymphadenopathy may be seen in very few cases.

### MEDICAL TREATMENT

There is controversy as to whether patients with acute self-limited blastomycosis should be treated with antifungal therapy. Chronic blastomycosis, however, requires antifungal therapy because the disease rarely resolves spontaneously. Untreated, chronic blastomycosis can be associated with mortality rates approaching 60 percent. Most experts recommend a minimum of 6 months of oral azole (typically, itraconazole) therapy for mild-to-moderate pulmonary or nonmeningeal disseminated blastomycosis. The role of the amphotericin B formulations in the treatment of blastomycosis is probably limited to patients with severe or life-threatening disease, including all patients with CNS involvement, most immunocompromised patients (including transplant recipients and HIV-infected patients), and other iatrogenically immunosuppressed patients.[39] Amphotericin B is given as "induction therapy" to gain control of the disease, and an azole is given as "consolidation therapy" to complete at least 6 months of therapy. Long-term suppressive therapy may be needed in immunocompromised patients.

### SURGICAL TREATMENT

The main indication for surgery is usually to rule out malignancy. Surgical intervention is also necessary for drainage of large cavitary abscesses. Known blastomycotic cavitary lesions should be resected if they persist after adequate drug treatment. If the diagnosis is made only at the time of thoracotomy, drug treatment should follow operation.

## Cryptococcosis

*Cryptococcus neoformans* is an encapsulated yeast. The species has four serotypes based on antigenic specificity of the capsular polysaccharide; these include serotypes A and D (*C. neoformans var neoformans*) and serotypes B and C (*C. neoformans var gattii*). The *C. neoformans var neoformans* is the most common variety in the United States and other temperate climates throughout the world; it is found in aged pigeon droppings.[40] Naturally occurring cryptococcosis occurs in both animals and humans, but animal-to-human or person-to-person transmission via the pulmonary route has not been documented. Transmission via organ transplantation has been reported when infected donor organs were used. The lungs are thought to be the initial site of almost all infections due to *C. neoformans* and, after the CNS, they are the second-most clinically relevant site of infection. It is postulated that humans become infected with *C. neoformans* by inhaling the basidiospore form of this fungus. Basidiospores are smaller than the yeast forms obtained from clinical samples and have much smaller polysaccharide capsules, thus facilitating deposition in the alveoli and terminal bronchioles after inhalation. The alveolar macrophages ingest the yeast. Phagocytosis and destruction of the unencapsulated yeast cells readily occur, whereas encapsulated organisms are more resistant to phagocytosis. A cryptococcal polysaccharide capsule has antiphagocytic properties and may be immunosuppressive. Host response to cryptococcal infection includes both cellular and humoral components.

### CLINICAL PRESENTATION

The pattern of cryptococcal pulmonary disease is extremely variable, ranging from asymptomatic saprophytic airway colonization to ARDS, which is observed in hosts who are immunocompromised (e.g., patients with AIDS, organ transplant recipients). Subclinical primary infections are common and the vast majority of infected patients are asymptomatic. Symptoms may include cough with scant sputum, pleuritic chest pain, fever, weight loss, malaise, and rarely hemoptysis. Night sweats, as observed in tuberculosis, are uncommon in cryptococcal pulmonary disease but may occur with disseminated or CNS disease. On occasion, cryptococcal pulmonary disease may even manifest as a slowly progressive mass that can compress thoracic structures such as the vena cava. Although chronic infection can occur, patients who are immunocompetent normally have spontaneous regression of both clinical and radiologic manifestations. The presentation of pulmonary cryptococcosis in HIV-infected persons appears to be more acute and severe than in other patient groups. The severity of symptoms and extent of dissemination are inversely proportional to the CD4 lymphocyte count, with most symptomatic cases occurring in patients with counts less than 100/μL.[40]

*C. neoformans* infection is usually characterized by little or no necrosis or organ dysfunction until late in the disease. Organ damage may accelerate in persons with heavy infections. Organ damage stems primarily from tissue distortion secondary to the expanding fungal burden. Extensive inflammation or fibrosis is rare. The characteristic lesion consists of a cystic cluster of yeast with no well-defined inflammatory response. Well-formed granulomas generally are not present. After lung and CNS infection, the next most commonly involved organs in disseminated cryptococcosis are the skin, prostate, and medullary cavity of the bones.

### DIAGNOSIS

The diagnosis of active cryptococcal pulmonary infection can be suggested by the appearance of the characteristically encapsulated yeast forms in specimens of sputum, BAL fluid, or tissue. Culture of the organism from these same specimens can establish the diagnosis. *C. neoformans* is readily cultured in routine fungal medium that does not contain cycloheximide. In cases of clinically silent cryptococcal nodules that are sampled to rule out the possibility of malignancy, cultures of tissue can be negative despite the presence of yeast

on histopathologic inspection. Cultures of associated pleural effusion should be performed, as they are usually positive.

The use of the serum cryptococcal antigen as a screening test for pulmonary cryptococcosis is less likely to be positive in the immunocompetent population than in the immunocompromised. In fact, the test is positive in virtually all patients with HIV infection and pulmonary cryptococcosis. The presence of a positive serum cryptococcal antigen titer implies deep tissue invasion and a high likelihood of disseminated disease.[41] The testing of pleural fluid for the presence of the polysaccharide antigen can be very useful in suspected cases in which cultures are negative.

Radiographic manifestation features of pulmonary cryptococcosis in patients with pulmonary cryptococcosis vary widely. Well-defined, noncalcified nodules, either solitary or a few, are the most common radiographic findings. Cavitation in cryptococcal nodules is rare. Other possible findings in the chest include lobar infiltrates, masses, hilar and mediastinal adenopathy, and pleural effusions. An LP to obtain CSF for cryptococcal antigen testing and culture is indicated if the patient has neurologic symptoms or an underlying condition that predisposes to dissemination. An LP should also be strongly considered if the patient's serum cryptococcal antigen titer is very high (>1:250). CSF should also be tested if *Cryptococcus* is diagnosed from surgical specimen.

### MEDICAL TREATMENT

Patients with asymptomatic pulmonary cryptococcosis with a negative serum cryptococcal antigen may not require any systemic therapy. Patients presenting with symptomatic pulmonary infection should be treated with either fluconazole or amphotericin B. Fluconazole is preferred for most patients, since it can be administered orally and is less toxic than amphotericin B. Treatment with fluconazole should be continued for 36 months in immunocompetent patients. For those individuals who are unable to tolerate fluconazole, itraconazole for 6 to 12 months is an acceptable alternative. In the presence of more severe disease, treatment with amphotericin B may be necessary for 6 to 10 weeks. In immunocompromised patients, combination therapy with the amphotericin B and flucytosine is recommended, followed by high-dose fluconazole for a total of 10 weeks. After 10 weeks of therapy, the fluconazole dosage may be reduced, depending on the patient's clinical status.[41] It is recommended that all HIV-infected individuals continue maintenance therapy for life.

### SURGICAL TREATMENT

Surgical excision of infected pulmonary tissue is indicated only in cases of pseudotumor-like masses that impinge on adjacent structures. However, the diagnosis is often not clear until the time of surgical resection. Once the diagnosis is established, the lesion should not be resected unless it can easily be removed by wedge resection.[42] Pleural effusions can be treated with systemic therapy alone and rarely require drainage.

## Mucormycosis (Zygomycosis)

### ETIOLOGY AND PATHOLOGY

Mucormycosis refers to rare, severe infections with fungi of the order Mucorales. *Rhizopus* species are the most common causative organisms. They are saprophytic fungi that are ubiquitous in soil or decaying organic material. Spores produced by the fungi become airborne and are inhaled into the respiratory tract, which is the most common route of inoculation in a susceptible host. Humans with intact immunity are generally unaffected, but those with impairments of immunity due to cancer and its therapy, metabolic dysfunction (e.g., diabetes or ketoacidosis), or iatrogenic causes of immune suppression (e.g., steroids or cytotoxic chemotherapy) are at greatest risk for infection. Pulmonary and rhinocerebral infections predominate as a consequence of the frequency of airborne inoculation. Inhalation of spores in sawmill dust is also the source of allergic interstitial pneumonitis or alveolitis syndromes, which have been described in healthy lumber workers.

Direct contamination of skin or wounds by traumatic implantation of spores from soil and other environmental sources may occur, even in the hospital setting. Ingestion of spores with subsequent invasion of the gastrointestinal tract occurs rarely. Once spores reach tissue compartments, they germinate and hyphal elements develop and proliferate. The hyphal structures of the Zygomycetes are nonseptate or have rare septa, with broad, nonparallel walls. The hyphae are highly angioinvasive. Invasion of blood vessels by hyphae characteristically results in hemorrhage, thrombosis, infarction, and tissue necrosis. Death can result from progressive tissue destruction, uncontrolled hemorrhage, or both.

Pulmonary mucormycosis is a rapidly progressive infection that occurs when the spores settle in the bronchioles and alveoli. A diffuse pneumonia with infarction and necrosis results, and the infection can spread to contiguous structures such as the mediastinum and heart. Apparent hematogenous dissemination to the brain has also been described.

### CLINICAL PRESENTATION

Mucormycosis has a very high mortality rate of at least 50 percent. Due to the similarity in clinical features between mucormycosis and other more common filamentous fungal diseases and the difficulty in making a specific diagnosis, many cases of pulmonary mucormycosis are not suspected on the basis of clinical presentation. Neutropenic patients may present with fever refractory to broad-spectrum antibiotics, a cough that is typically nonproductive, severe or subtle pleuritic chest pain, and rapidly progressive dyspnea. Hemoptysis is a late sign indicating fungal erosion into blood vessels. Fatal hemoptysis due to fungal invasion of the pulmonary artery or aorta has occasionally been reported. If unchecked, the infection has a propensity to invade relentlessly through multiple tissue planes and erode into the chest wall, pericardium, myocardium, SVC, and diaphragm.

Obstruction of major airways by endobronchial masses due to fungi has been described in diabetic patients. Pulmonary involvement is often seen as a prelude to or in concert with disseminated zygomycosis. Once the disease has disseminated to other sites, including brain, skin, liver, or kidneys, the prognosis is poor. In patients with a mild degree of immune impairment, the pace of the disease is frequently less rapid. These patients may present with the slow development of cavitary lesions or pulmonary infiltrates or nodules in conjunction with fever and dry cough.

### DIAGNOSIS

The diagnosis of pulmonary mucormycosis can be difficult, since the presentation does not differ from that of diffuse pneumonias due to other microbial agents. There is a striking similarity to invasive aspergillosis. Sputum or BAL specimens can show the characteristic hyphae, which is usually the first clue to the presence of the disease. The hyphae can also be demonstrated on lung biopsy. A recent report of mucormycosis in cancer patients noted that about 80 percent with definite or probable pulmonary zygomycosis had a concomitant pneumonia due to another pathogen, either a mold (e.g., *Aspergillus* or *Fusarium*) or a bacterial species. Thus the presence of dual infection may obscure the diagnosis of mucormycosis. Accordingly, the detection of a Mucorales fungus in a respiratory sample should not be ignored, even if concomitant pathogens are also isolated in an immunosuppressed patient. Unfortunately, even when the correct diagnosis is made in a timely manner, the time between diagnosis and death is typically only a few days.

Radiographically, pulmonary mucormycosis may present as segmental or lobar infiltrates, isolated nodules, cavitary lesions, hemorrhage or infarction, or disseminated disease. A predilection for upper lobe involvement exists. Consolidation may be multilobar. Cavitation producing an air crescent is highly suggestive of fungal infection but does not distinguish mucormycosis from aspergillosis. Nodular lesions and pleural effusions may be present. When pulmonary mucormycosis is recognized, it should not be presumed to be isolated to that location. It is especially important to perform a CT scan of the sinuses and brain in the setting of pulmonary disease because these will be the most common sites associated with disseminated disease.[43]

### MEDICAL TREATMENT

Early diagnosis and correction of the underlying abnormality such as control of diabetes and prompt institution of amphotericin B therapy is critical to survival. Neutropenia in association with hematologic malignancy and its treatment should be reversed, if possible, with the use of colony-stimulating factors and the withdrawal of cytotoxic chemotherapy. Attempts should be made to wean glucocorticosteroids and other immunosuppressive drugs. There is no role for flucytosine or the currently available azole antifungals in the therapy of this infection.

### SURGICAL TREATMENT

Most patients present with multilobar involvement, which may preclude surgical resection. When feasible, extensive surgical debridement of as much involved tissue as possible is necessary. Amphotericin B is used as adjunctive therapy after aggressive surgical debridement. There are reports of patients with early pulmonary infection who were cured with lobectomies.[44]

## Candidiasis (Moniliasis)

### ETIOLOGY AND PATHOLOGY

*Candida* species are ubiquitous fungi and are the most common fungal pathogens affecting humans. They are yeast-like fungi that can form true hyphae and pseudohyphae. The genus *Candida* encompasses more than 160 species. The most common of these are *Candida albicans, Candida krusei, Candida parapsilosis, Candida tropicalis,* and *Candida glabrata*. For the most part, *Candida* species are confined to human and animal reservoirs; however, they are frequently recovered from the hospital environment, including on foods, countertops, air-conditioning vents, floors, respirators, and medical personnel. Although *Candida* are considered normal flora in the gastrointestinal and genitourinary tracts of humans, they have the propensity to invade and cause disease when an imbalance is created in the ecologic niche in which these organisms usually exist. The growing problem of mucosal and systemic candidiasis reflects the enormous increase in the pool of patients at risk and the increased opportunity that exists for *Candida* species to invade tissues normally resistant to invasion. *Candida* species are true opportunistic pathogens that exploit recent technologic advances to gain access to the circulation and deep tissues. Thus, needles, IV cannulas, or urinary bladder catheters are examples of the portals of infection.

### CLINICAL PRESENTATION

The clinical manifestations of infection with *Candida* species range from local mucous membrane infections to widespread dissemination with multiorgan system failure. Pneumonia due to *Candida* is poorly defined as a clinical entity because positive cultures cannot distinguish between true infection and either colonization or contamination of samples with oropharyngeal contents.[45] In addition, the presence of clinical pneumonia may be due to coinfecting pathogens. Much more commonly, the lungs are one of many organs involved in the course of disseminated infection with *Candida* in immunosuppressed patients. The only criterion for the definitive diagnosis of candidal pneumonia was the histologic demonstration of fungus in lung tissue. In addition to the rare candidal pneumonia, other special clinical situations encountered by the thoracic surgeon in candidiasis include esophagitis and endocarditis.

### DIAGNOSIS

Species of *Candida* are present in 50 to 60 percent of respiratory secretions drawn from uninfected individuals. The presence of the fungi in bronchial or lung biopsies, in blood or deep tissue spaces is more likely due to invasive infection, especially in the immunocompromised host. This is particularly true for CSF culture, which is normally sterile. No reliable serologic test is available. Nonspecific patchy infiltrates may be noted on radiographic imaging.

### MEDICAL TREATMENT

If feasible, initial management should include removal of all existing portals such as central venous catheters. Management of serious and life-threatening invasive candidiasis remains severely hampered by delays in diagnosis and the lack of reliable diagnostic methods that allow for the detection of both fungemia and tissue invasion by *Candida* species.

Whenever possible, initiation of treatment for isolated candidal pneumonia should be based on histologic evidence in the nonneutropenic host. Most patients with isolated candidal pneumonia have been treated with conventional amphotericin B. In contrast, patients with hematogenously disseminated infection who develop secondary candidal pneumonia should be treated for disseminated disease rather than candidal pneumonia alone. In this case, initial medical therapy should involve caspofungin, fluconazole, an amphotericin B preparation, or combination therapy with fluconazole plus amphotericin B.

### SURGICAL TREATMENT

Surgical intervention is rarely indicated except for the occasional development of lung abscess and need for repair or replacement of valves due to candidal endocarditis.

## Sporotrichosis

### ETIOLOGY AND PATHOLOGY

Sporotrichosis is a subacute to chronic infection caused by the dimorphic fungus *Sporothrix schenckii,* which is found throughout the world in decaying vegetation, sphagnum moss, and soil. *S. schenckii* exhibits thermal dimorphism. It produces hyphae in the environment at temperatures that are lower than normal human body temperatures; in comparison, it exists as a yeast form when at 37°C in human tissues. The hyphae are rather thin and septate, showing branching and stranding. The characteristic infection involves suppurating subcutaneous granulomas that progress proximally along lymphatic channels (lymphocutaneous sporotrichosis). Other tissues are involved by direct extension and, less often, by hematogenous dissemination. The most common extracutaneous sites are in the bones, joints, tendon sheaths, and bursae.

Pulmonary sporotrichosis is a rare form that appears to result from inhalation of the organism from soil. Most patients have been involved in an occupation that exposes them to aerosols from soil, but discrete point sources have rarely been identified. A chronic cavitary pneumonia, which is clinically and radiographically indistinguishable from tuberculosis and histoplasmosis, occurs in patients who usually have severe underlying COPD. Rarely, a disseminated infection occurs with disseminated cutaneous lesions and involvement of multiple visceral organs, including meningitis; this occurs most commonly in patients with AIDS.

### CLINICAL PRESENTATION

Symptoms mimic those of tuberculosis, including constitutional complaints of fever, night sweats, weight loss, and fatigue as well as respiratory complaints including dyspnea, cough, purulent sputum, and hemoptysis. The typical patient is a Caucasian, middle-aged male who often smokes and abuses alcohol and may have underlying COPD. Physical examination of patients with pulmonary sporotrichosis is dominated by the findings of the underlying COPD.

The major differential diagnoses include tuberculosis; chronic fungal infections, especially histoplasmosis; and sarcoidosis. Some patients with pulmonary involvement have evidence of dissemination to skin, osteoarticular structures, or viscera. Almost without exception, untreated pulmonary sporotrichosis progresses to death.

### DIAGNOSIS

Culture is the "gold standard" for establishing a diagnosis of sporotrichosis and is also the most sensitive method. Aspirated material from a lesion, sample from a tissue biopsy, sputum, or body fluids should be inoculated onto Sabouraud medium or blood agar and incubated at room temperature. Incubation at this temperature facilitates growth of the mycelial phase of *S. schenckii,* with the characteristic arrangement of conidia on the hyphae. Occasionally, the organism (cigar-shaped yeast) can be visualized in biopsied tissue specimens that are stained with PAS, Gomori methenamine-silver, or immunohistochemical stains. Sporotrichosis is characterized histopathologically by a mixed granulomatous and pyogenic process with occasional asteroid bodies. Asteroid bodies consist of a central basophilic yeast surrounded by eosinophilic material radiating outward like spokes on a wheel, probably representing antigen–antibody complexes. Although previously thought to be specific for sporotrichosis, this tissue reaction can be seen in other fungal infections as well.

Serology is less useful in the diagnosis of sporotrichosis than in other endemic mycoses. The radiographic findings are also nonspecific and similar to those of tuberculosis.

### MEDICAL TREATMENT

Pulmonary sporotrichosis is difficult to treat, perhaps due to delayed diagnosis or the underlying illnesses in infected

patients. If the patient is seriously ill, amphotericin B should be used initially; if not, then itraconazole can be given. Another option is to begin therapy with amphotericin B and, when the patient is stable, switch to itraconazole. The duration of azole therapy should be at least 1 year, perhaps longer in some patient.[46]

### SURGICAL TREATMENT

The most effective therapy for pulmonary sporotrichosis appears to be a combination of amphotericin B and subsequent surgical resection. However, many patients are unable to tolerate such a procedure because of severe underlying pulmonary disease. Surgical resection is particularly useful for those patients who have focal lesions.

## TUBERCULOSIS AND ATYPICAL MYCOBACTERIAL DISEASES

### Tuberculosis

### ETIOLOGY AND PATHOLOGY

Tuberculosis (TB) is an infectious disease that has plagued humans since the neolithic era. After decades of declining incidence in the United States, an unprecedented resurgence in TB occurred in the late 1980s and early 1990s. Deterioration of the TB program infrastructure, the HIV/AIDS epidemic, drug-resistant TB, and, less so, TB among foreign-born persons contributed to the resurgence. Worldwide, TB continues to be a major health problem. There were an estimated 8.3 million new TB cases in 2000 and an estimated 1.8 million deaths from TB. TB is still on the top 10 list for all-cause, all-age worldwide mortality.[47]

Due to novel genetic markers, there are now five closely related mycobacteria grouped in the *M. tuberculosis* complex: *M. tuberculosis, Mycobacterium bovis, Mycobacterium africanum, Mycobacterium microti,* and *Mycobacterium canetti. M. tuberculosis* is transmitted through the airborne route and there are no known animal reservoirs. *M. bovis* may penetrate the gastrointestinal mucosa or invade the lymphatic tissue of the oropharynx when ingested in milk containing large numbers of organisms. Human infection with *M. bovis* has decreased significantly in developed countries as a result of the pasteurization of milk and effective TB control programs for cattle. Airborne transmission of both *M. bovis* and *M. africanum* can also occur.

*M. tuberculosis* is a rod-shaped, slow-growing bacterium. Its cell wall has high acid content, which makes it hydrophobic or resistant to oral fluids. The cell wall absorbs a certain dye and maintains a red color despite attempts at decolorization, hence the name acid-fast bacillus. TB is spread from person to person through the air by droplet nuclei, particles 1 to 5 μm in diameter that contain *M. tuberculosis* complex. A single cough can generate 3000 infective droplets. They may also be produced by aerosol treatments, sputum induction, aerosolization during bronchoscopy, and through manipulation of lesions or processing of tissue or secretions in the hospital or laboratory. Droplet nuclei, containing two to three *M. tuberculosis* organisms, are so small that air currents normally present in any indoor space can keep them airborne for long periods of time. Droplet nuclei are small enough to reach the alveoli within the lungs, where the organisms replicate. Four factors determine the likelihood of transmission of *M. tuberculosis*: (1) the number of organisms being expelled into the air, (2) the concentration of organisms in the air as determined by the volume of the space and its ventilation, (3) the length of time an exposed person breathes the contaminated air, and (4) presumably the immune status of the exposed individual.

After inhalation, the droplet nucleus is carried down the bronchial tree and implants in a respiratory bronchiole or alveolus. Whether or not an inhaled tubercle bacillus establishes an infection in the lung depends on both the bacterial virulence and the inherent microbicidal ability of the alveolar macrophage that ingests it. *M. tuberculosis* has no known endotoxins or exotoxins; therefore, there is no immediate host response to infection. The organisms grow for 2 to 12 weeks, until they reach $10^3$ to $10^4$ in number, which is sufficient to elicit a cellular immune response that can be detected by a reaction to the tuberculin skin test. Before the development of cellular immunity, tubercle bacilli spread via the lymphatics to the hilar lymph nodes and thence through the bloodstream to more distant sites.

In persons with intact cell-mediated immunity, collections of activated T cells and macrophages form granulomas that limit multiplication and spread of the organism. Antibodies against *M. tuberculosis* are formed but do not appear to be protective. The organisms tend to be localized in the center of the granuloma, which is often necrotic. For the majority of individuals with normal immune function, the proliferation of *M. tuberculosis* is arrested once cell-mediated immunity develops, even though small numbers of viable bacilli may remain within the granuloma. It is estimated that approximately 10 percent of individuals who acquire TB infection and are not given preventive therapy will develop active TB. The risk is highest in the first 2 years after infection, when half the cases will occur. The ability of the host to respond to the organism may be reduced by certain diseases such as silicosis, diabetes mellitus, and diseases associated with immunosuppression (e.g., HIV infection) as well as by corticosteroids and other immunosuppressive drugs.

### CLINICAL PRESENTATION

TB inoculation can result in latent infection or active disease. Depending on the population, 10 to 30 percent of inoculated individuals progress directly to active primary disease. More commonly, however, TB inoculation results in an asymptomatic latent infection. Purified protein derivative (PPD) skin test conversion and identification of a Ghon complex (characterized by a peripheral lesion with associated hilar

adenopathy) on chest radiography are the only means of identifying such cases. Patients often remain healthy for years; however, some experience reactivation of their disease due to subsequent immunologic stressors. Reactivated TB represents 90 percent of adult cases in the non-HIV-infected population and results from reactivation of a previously dormant focus seeded at the time of the primary infection. The apical posterior segments of the lung are frequently involved. Such reactivation occurs at a rate of approximately 1 percent per year in immunocompetent hosts. In immunocompromised hosts, the conversion rate increases to 10 percent. Roughly 80 percent of TB cases involve pulmonary disease, although TB can involve any organ system. In patients who are severely immunocompromised, extrapulmonary disease and atypical presentations are common.

Cough is the most common symptom of pulmonary TB. Early in the course of the illness it may be nonproductive, but subsequently, as inflammation and tissue necrosis ensue, sputum is usually produced and is key to most diagnostic methods. Fever, night sweats, anorexia, and weight loss are other classic symptoms. Hemoptysis may rarely be a presenting symptom but is usually the result of previous disease and does not necessarily indicate active TB. Hemoptysis may result from residual tuberculous bronchiectasis, caseous sloughing or endobronchial erosion, rupture of a dilated vessel in the wall of a cavity (Rasmussen's aneurysm), bacterial or fungal infection (especially *Aspergillus* in the form of a mycetoma) in a residual cavity, or erosion of calcified lesions into the lumen of an airway (broncholithiasis). Inflammation of the lung parenchyma adjacent to a pleural surface may cause pleuritic pain. Dyspnea can occur when patients have extensive parenchymal involvement, pleural effusions, or a pneumothorax. Overall, the symptoms in reactivated TB typically begin insidiously and are present for weeks or months before the diagnosis is made. It is noteworthy that classic symptoms are usually absent, especially in the elderly and immunocompromised patients. Rales may be heard in the area of involvement, as well as bronchial breath sounds if there is lung consolidation. Other nonspecific findings include cachexia, hypoxia, tachycardia, and lymphadenopathy.

## DIAGNOSIS

Early identification and diagnosis of cases of active TB is key to the effectiveness of control programs. However, maintaining a high index of suspicion for TB is crucial, and diagnostic testing remains problematic. Culture of appropriate specimens for isolation of *M. tuberculosis* and susceptibility testing is the cornerstone for a diagnosis of TB, but the organism still requires weeks to grow in culture.

Pulmonary TB is diagnosed by visualization of acid-fast bacilli on a sputum smear and isolation of the organism from a culture of this sputum. Most laboratories use auramine–rhodamine or auramine O to stain the sputum, allowing scanning for fluorescence as opposed to Ziehl–Neelsen stain, which requires more time and labor to identify organisms.[48] Both concentrating sputum specimens and obtaining a larger quantity of sputum (5 mL) have been shown to increase the probability of visualizing organisms by smear. The conventional teaching is that sputum specimens should be obtained on 3 consecutive days and that first morning specimens have the highest yield. If the patient has difficulty producing sputum, inhalation of an aerosol of sterile hypertonic saline, usually produced by an ultrasonic nebulizer, can be used to stimulate the production of sputum. Multiple samples increase the diagnostic yield of the test. For patients in whom a diagnosis of TB has not been established from sputum, fiberoptic bronchoscopy performed with appropriate infection control precautions may be needed with BAL. Gastric aspirates obtained in the morning can also be cultured for *M. tuberculosis* and reflect sputum swallowed over the course of the night. It is helpful in patients who cannot produce enough sputum even with induction, especially children. The disadvantage is that AFB smears cannot be done on gastric aspirates. Urine, blood, CSF, and other body fluids can also be obtained for culture. Invasive procedures to obtain specimens from the lung, pericardium, lymph nodes, and so on should be considered when noninvasive techniques do not provide a diagnosis. Many of these areas are amenable to closed techniques such as percutaneous needle biopsy or aspiration, transbronchial biopsy, or brushing, precluding a need for formal surgical procedures. In patients with hematogenous or disseminated disease, bone marrow biopsy, lung biopsy, and liver biopsy for histologic examination and culture should be considered. Appropriate measures must be taken in collecting these specimens to minimize aerosolation of *M. tuberculosis* organisms and prevent transmission of infection to personnel. Maintenance of laboratory proficiency requires continuing and frequent performance of the required tests. Adequate training in proper techniques and the availability of special containment areas are required for the safe manipulation of clinical specimens.

The tuberculin test is based on the fact that infection with *M. tuberculosis* produces a delayed-type hypersensitivity reaction to certain antigenic components of the organism that are contained in extracts of culture filtrates or "tuberculins." Tuberculin skin testing using 5 units (0.1 mL) of PPD injected intradermally (Mantoux method), usually into the volar or dorsal surface of the forearm, may be used for screening or to supplement other diagnostic testing. Induration, not erythema, is measured 48 to 72 h after injection. Tests read after 72 h tend to underestimate the true size of induration. On the basis of the sensitivity, specificity, and the prevalence of TB in different groups, three cut points have been recommended for defining a positive tuberculin reaction (Table 6-1).[48] Overall, skin testing for TB serves mainly as an epidemiologic tool to assess exposures. Patients with positive reactions may not have active TB, and 20 to 30 percent of those with a new diagnosis of active TB have negative reactions, particularly those with advanced disease.[49] Testing is also unreliable in infants, patients with immunosuppressive conditions, and those with serious illnesses. There is no reliable method of distinguishing tuberculin reactions caused by vaccination with bacillus Calmette–Guérin (BCG) from

**TABLE 6-1: Guidelines for Determining a Positive Tuberculin Skin Test Reaction[a]**

| Induration ≥5 mm | Induration ≥10 mm | Induration ≥15 mm |
|---|---|---|
| HIV-positive persons | Recent arrivals (<5 years) from high-prevalence countries | Persons with no risk factors for TB |
| Recent contacts of TB case | Injection drug users<br>Residents and employees[a] of high-risk congregate settings: prisons and jails, nursing homes and other health-care facilities, residential facilities for AIDS patients, and homeless shelters, mycobacteriology laboratory personnel | — |
| Fibrotic changes on chest radiograph consistent with old TB | Persons with clinical conditions that place them at high risk: silicosis diabetes mellitus, chronic renal failure, some hematologic disorders (e.g., leukemias and lymphomas), other specific malignancies (e.g., carcinoma of the head or neck and lung), weight loss of >10% of ideal body weight, gastrectomy, jejunoileal bypass | — |
| Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of >15 mg/day prednisone for >1 month) | Children <4 years of age or infants, children, and adolescents exposed to adults in high-risk categories | — |

[a]For persons who are otherwise at low risk and are tested at entry into employment, a reaction of >15 mm induration is considered positive.

those caused by natural mycobacterial infections. It is usually prudent to consider "positive" reactions to 5 tuberculin units of PPD in BCG-vaccinated persons as indicating infection with *M. tuberculosis*. Because most persons who have received BCG are from high-prevalence areas of the world, it is important that vaccinated persons who have a positive reaction to a tuberculin skin test be evaluated for TB and treated accordingly.

Nucleic acid amplification tests, such as the polymerase chain reaction (PCR) and other methods for amplifying DNA and RNA, may facilitate rapid detection of microorganisms. Both RNA and DNA amplification systems are commercially available. In clinical respiratory specimens that are AFB smear-positive, the sensitivity of the amplification methods is approximately 95 percent, with a specificity of 98 percent. In specimens that contain fewer organisms and are AFB smear-negative, the nucleic acid amplification test is positive in 48 to 53 percent of patients with culture-positive TB and the specificity remains approximately 95 percent. Thus, the CDC includes a positive nucleic acid amplification test in the setting of a positive smear as confirmation of the diagnosis of TB.[50]

Radiographic findings in TB depend on the stage of the infection. Primary pulmonary TB (primary exposure) is characterized by the Ghon complex and consists of (1) a subpleural (fissure) focus of inflammation and (2) infected (inflamed) lymph nodes draining the primary subpleural lesion, which manifests as ipsilateral hilar adenopathy (Fig. 6-7). Atelectasis may result from the compression of airways by enlarged lymph nodes. Overall, intrathoracic adenopathy is less common in immunocompetent adults than in children and immunosuppressed patients. Cavitation may occur in progressive primary TB if the process persists beyond the time when specific cell-mediated immunity develops and is more common in reactivation (secondary)

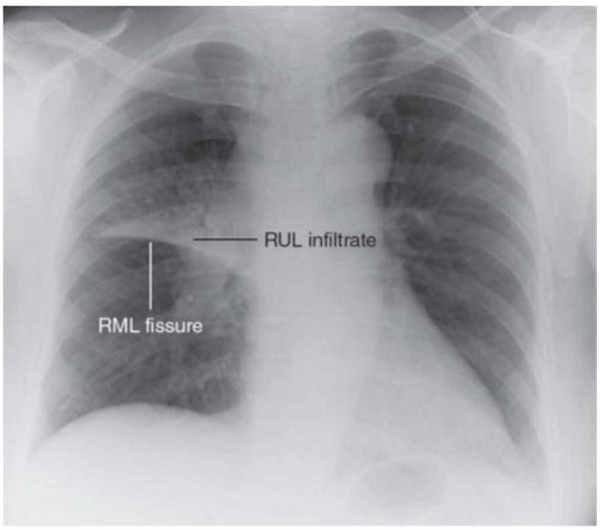

**FIGURE 6-7** Posteroanterior chest x-ray of a patient with tuberculosis. The combination of right-upper-lobe infiltrate and hilar adenopathy should raise suspicion of tuberculosis as the potential infectious agent. RML, right middle lobe; RUL, right upper lobe.

FIGURE 6-8 Chest x-ray of a patient with miliary tuberculosis.

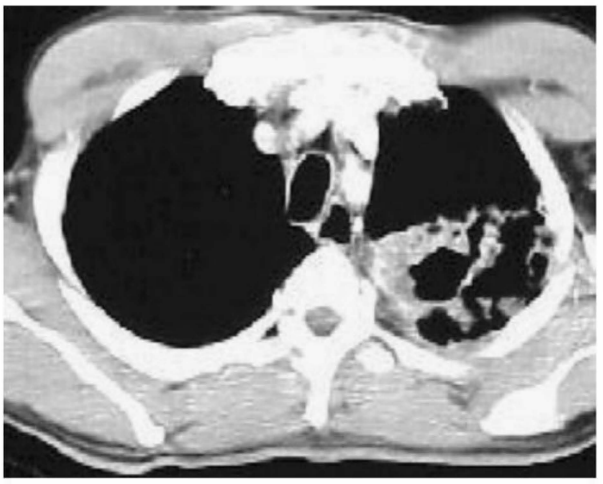

FIGURE 6-9 Chest CT of a patient with cavitary pulmonary tuberculosis involving the left upper lung.

TB. In this form, the most frequent sites of abnormalities are the apical and posterior segments of the right upper lobe and the apical-posterior segment of the left upper lobe. These lesions correspond pathologically with caseating granulomas. Miliary TB results from erosion of a parenchymal focus of TB into the blood or lymph vessel, leading to dissemination of the organism. This results in evenly distributed small nodules on chest film (Fig. 6-8). Healing of the tuberculous lesions usually results in the development of fibrosis with loss of lung parenchymal volume and, often, calcification. Nodules and fibrotic lesions of old healed TB have well-demarcated, sharp margins and are often described as "hard." Old TB can also cause pleural scarring. Bronchiectasis of the upper lobes is a nonspecific finding that sometimes occurs from previous pulmonary TB.

Notably, patients with endobronchial lesions and those who are immunosuppressed may have no associated abnormalities on chest x-ray. In patients with HIV infection, the nature of the radiographic findings depends to a certain extent on the degree of immunocompromise produced by the HIV infection. TB that occurs relatively early in the course of HIV infection tends to have the typical radiographic findings described above. With more advanced HIV disease, the radiographic findings become more "atypical": Cavitation is uncommon, and lower-lung-zone or diffuse infiltrates and intrathoracic adenopathy are frequent.[51]

CT scanning is more sensitive than plain chest radiography for diagnosis, particularly for smaller lesions located in the apex of the lung. CT scan may show a cavity (Fig. 6-9), centrilobular lesions, nodules, and branching linear densities sometimes called a "tree in bud" appearance.

## MEDICAL TREATMENT

The overall goals for treatment of TB are (1) to cure the individual patient and (2) to minimize the transmission of *M. tuberculosis* to other persons. It is necessary to isolate any patient with suspected TB infection in a private room with negative pressure. Anyone entering should wear high-efficiency disposable masks sufficient to filter the TB bacillus. Isolation should be continued until sputum smears return negative results three consecutive times. Such sterilization usually requires 2 to 4 weeks of treatment and must be accompanied by clinical improvement.

There are currently four broadly applicable recommended regimens for treating patients with TB caused by drug-susceptible organisms. Each regimen has an initial phase of 2 months followed by a choice of several options for the continuation phase of either 4 or 7 months. The initial phase is usually composed of different three- or four-drug combinations of isoniazid, rifampin, ethambutol, and pyrazinamide. The continuation phase is usually a combination of isoniazid and rifampin or rifapentin. Rifapentin is a rifampin with an increased half-life and enhanced activity against *M. tuberculosis*. Complete information can be found in the 2003 statement from the American Thoracic Society (ATS), the Centers for Disease Control and Prevention (CDC), and the Infectious Diseases Society of America (IDSA) on the treatment of TB.[52] This document contains details of specific drug therapy, including suggestions relating to monitoring for adequate response to therapy and details of monitoring for drug toxicity. Special treatment situations, including HIV infection, TB in children, extrapulmonary TB, culture-negative TB, pregnancy and breast-feeding, hepatic disease, and renal disease are discussed in detail. The use of less commonly employed antituberculous drugs for multidrug-resistant TB is also discussed.

## SURGICAL TREATMENT

Surgery has largely been supplanted by medical therapy for the treatment of pulmonary TB infection. This resulted

mainly from the introduction of effective antibiotics in the 1960s. With the emergence of multidrug-resistant TB (MDR-TB), surgery is again becoming a necessary treatment modality. In destroyed lungs, cavitary disease, and patients with advanced disease, medications are often unable to penetrate the lesions. In the setting of such permanent anatomic changes, medical therapy alone has a very high failure rate; the addition of surgery with removal of the nidus of infection improves the cure rate.[53]

Contemporary indications for surgery in patients infected with *M. tuberculosis* include:

- Surgery for diagnosis of pulmonary lesions or mediastinal adenopathy of unknown etiology
- Highly resistant *M. tuberculosis* with localized disease
- Persistent cavitary disease especially with Aspergillus colonization
- Continued sputum positivity especially in the setting of MDR-TB
- Destroyed lobe or lung (lung gangrene)
- Massive hemoptysis
- Bronchopleural fistula with failed tube thoracostomy
- Bronchial stenosis
- Complications resulting from previous or insufficient surgery (e.g., delayed complications of plombage)

Excisions (segmentectomies, lobectomies, and pneumonectomies) currently represent the majority of operations, followed by operations on the pleura (decortication) and rarely those on the thoracic wall (thoracoplasty). The basic principles remain unchanged: best available drug therapy, followed by complete resection of residual active foci of disease, accompanied by obliteration of abnormal pleural spaces using muscle/omental flaps, followed by best available drug therapy for 12 to 24 months.

Appropriate preoperative preparation of these patients is important. When feasible, attempts should be made to convert the patient's sputum to negative. Except in cases of emergency, such as massive hemoptysis, patients should receive at least 3 months of therapy prior to surgical consideration. Pulmonary function tests should be performed to assess the feasibility of resection, as well as CT scan of the chest to determine the extent of involvement of the lungs by the disease and to evaluate anatomic changes. Ventilation/perfusion scanning provides the important information about the amount of viable lung; if only 15 percent or less of lung tissue will remain after resection, then pneumonectomy of that lung is indicated. The nutritional status of the patient and pulmonary hygiene should also be improved prior to surgery. Bronchoscopy is essential to evaluate for tuberculous endobronchial disease and help avoid the serious postoperative complication of bronchopleural fistula. This is more likely to occur when bronchial closure encompasses an area involved by tuberculous bronchitis.

Pomerantz et al.[54] recently reported a large series of pulmonary resection for MDR-TB. During a 17-year period, 172 patients underwent 180 pulmonary resections, which included 98 lobectomies and 82 pneumonectomies, with an acceptable operative mortality of 3.3 percent; late mortality was 6.8 percent. Significant morbidity was 12 percent. Muscle flaps were frequently used to avoid residual space and bronchial stump problems. The authors concluded that surgery remains an important adjunct to medical therapy for the treatment of MDR-TB. In the setting of localized disease, persistent sputum positivity, or patient intolerance of medical therapy, pulmonary resection should be undertaken.

## Atypical Mycobacterial Infections

There is continued growth in the number and prevalence of mycobacteria species other than the *M. tuberculosis* complex and are collectively referred to as the nontuberculous mycobacteria (NTM).[55] The most common cause of NTM pulmonary disease is *Mycobacterium avium* complex (*M. avium* and *Mycobacterium intracellulare*), known as MAC complex, *Mycobacterium kansasii, Mycobacterium abscessus,* and *Mycobacterium fortuitum*. Other NTM (e.g., *Mycobacterium malmoence, Mycobacterium simiae, Mycobacterium szulgai,* and *Mycobacterium xenopi*) have been identified as causative agents of this disease with much lesser frequency. *M. kansasii* is the most common atypical mycobacterium in the Central United States, whereas MAC is the most common in the South and Southeast. NTM disease is not reportable in the United States; therefore, reliable estimates of its incidence or prevalence have been limited. A CDC study from 1991 to 1992, which included results from 33 state laboratories, demonstrated that there were more isolates of *M. avium* complex than *M. tuberculosis*, with the latter representing only 26 percent of the total mycobacterial isolates. The reasons for this dramatic increase in numbers for NTM is unknown, but better clinical recognition and more culturing for both pulmonary and disseminated disease are felt to play important roles. It is well documented that the reservoir for most of these infections is soil, natural waters, and aerosols created from these sources. Epidemiologic studies, skin test surveys, and, more recently, DNA fingerprinting studies suggest that person-to-person transmission of infection is rare. It is assumed that most persons are infected from environmental sources, by airborne mechanisms (especially in respiratory disease), and, for some situations, possibly via the gastrointestinal route.

Infections caused by NTM may take place without any obvious predisposing conditions. Coexisting medical conditions that increase the risk for developing an infection include HIV/AIDS, cystic fibrosis, diabetes mellitus, malignancy, dialysis, tissue/organ transplant, smoking, COPD, bronchiectasis, silicosis and other pneumoconiosis, and previous TB. There is higher prevalence of NTM infections in warm climate regions, with high rates among miners. Demographically, females in the sixth decade of life or later are considered the most vulnerable to NTM infections, especially pulmonary infection with *M. avium*.

## CLINICAL MANIFESTATIONS

The clinical manifestation of NTM, especially in HIV-negative patients, can be very similar to those of TB. They include chronic cough, sputum production, and fatigue. Less commonly, malaise, dyspnea, fever, hemoptysis, and weight loss can also occur, usually with advanced NTM disease. Pulmonary disease due to *M. avium* complex in HIV-negative patients may have two types of presentations, as clarified in the recent American Thoracic Society (ATS) statement.[55] One is an apical fibrocavitary disease that has a tendency to progress within 1 to 2 years if the patient does not receive antimicrobial therapy. The other type is a bilateral or isolated right middle lobe/lingular nodular and interstitial/nodular disease, with a much slower progression within a period of 5 to 10 years. In addition, some authors identify "atypical manifestations" of this disease; namely, the combination of bronchiectasis and small nodules (so-called Lady Windermere syndrome) and focal mass-like opacities. In immunocompromised patients, specifically AIDS patients, MAC is the most common bacterial complication. Disseminated disease is frequent, with manifestations such as hepatomegaly, diarrhea, splenomegaly, and abdominal pain.

*M. kansasii* causes lung disease that is clinically indistinguishable from TB. Symptoms may be less severe and more chronic compared to infection with *M. tuberculosis*. Asymptomatic infection may also occur. Rapidly growing mycobacteria include three clinically relevant species: *M. fortuitum, Mycobacterium chelonae,* and *M. abscessus*. Pulmonary disease due to rapidly growing mycobacteria is predominantly due to *M. abscessus*. It has a progressive and slow course that can cause death if left untreated.

## DIAGNOSIS

As recommended in the ATS statement, the diagnosis of pulmonary NTM disease should be based on an integrated assessment of clinical manifestations, radiographic findings, and laboratory data. These organisms are commonly found in nature, and contamination of culture material or transient infection does occur. Thus a single positive culture from sputum is insufficient for diagnosis but sufficient if the organism is isolated from a transbronchial or lung biopsy specimen as well as from a bronchial wash with high bacterial contents by either or both a smear and culture. To meet the current requirements for the diagnosis, examination of three separate sputum specimens should produce at least two positive cultures, with the third being at least smear-positive, or three positive cultures even from smear-negative specimens.[55]

Radiographically, NTM tend to cause thin-walled cavities with less surrounding parenchymal infiltrate; they are associated with less bronchogenic but more contiguous spread of disease; and they produce more marked involvement of pleura over the involved areas of the lungs. Occasionally, they may produce dense pneumonic disease or a solitary pulmonary nodule without cavitation. In the case of rapidly growing mycobacteria, radiology usually shows multilobar or predominantly upper-lobe infiltrates. They can be of patchy, reticulonodular, or mixed interstitial-alveolar type. Cavitation takes place in about 15 percent of patients.[56]

## MEDICAL TREATMENT

Most first-line anti-TB drugs have 10 to 100 times less *in vitro* activity against *M. avium* complex isolates than against *M. tuberculosis*. This diminished activity may be due to the lipophilic cell wall of *M. avium* complex, which prevents drug penetration. Clarithromycin and azithromycin have been found to be the most effective drugs in therapy of infections caused by *M. avium* complex and some other NTM, either pulmonary or disseminated (e.g., in patients with AIDS).[56] The three-drug regimen of clarithromycin, ethambutol, and rifabutin appears to be the most promising in the therapy of the disseminated *M. avium* infection in AIDS patients.

The current recommendation for the treatment of pulmonary disease caused by *M. kansasii* in adults is the regimen of isoniazid, rifampin, and ethambutol given daily for 18 months with at least 12 months of negative sputum cultures. In patients who are unable to tolerate one of these three drugs, clarithromycin would seem a reasonable alternative. Pyrazinamide is unacceptable as an alternate or third drug for *M. kansasii* because all isolates are resistant.[55] The treatment of lung disease due to the rapidly growing mycobacteria is generally difficult because of their resistance to virtually all antimycobacterial drugs.[56] *M. fortuitum* is usually susceptible to other oral antimicrobial agents including the newer macrolides (clarithromycin and azithromycin) and quinolones, doxycycline and minocycline, and sulfonamides. Combination therapy of low-dose amikacin plus high-dose cefoxitin for 2 to 4 weeks almost invariably produces clinical and microbiologic improvement in *M. abscessus* infection. Imipenem appears to be a reasonable alternative to cefoxitin.

## SURGICAL TREATMENT

For patients with MAC, if there has been poor response to drug therapy or if the patient's isolate has become macrolide-resistant, resectional surgery should be considered, especially if the disease is localized. Recent series even in the era of macrolide therapy have shown high sputum-negative conversion rates after surgery, although with relatively high morbidity.[57] There is a high incidence of bronchopleural fistula even with the use of a pedicle flap closure, especially after right pneumonectomy in patients with MAC. Whenever possible, this surgery should be performed at centers with thoracic surgeons who have considerable experience with this type of surgery. Overall, the bilateral nature of MAC lung disease, the advanced age of the patients, and the frequency of underlying chronic lung disease have limited the number of patients who are good candidates for surgery. With the advent of rifampin-containing regimens, surgery is now considered to have no role in managing routine cases of pulmonary disease due to *M. kansasii*.

For the rapidly growing mycobacteria, surgery is generally indicated with extensive disease, abscess formation, or in instances where drug therapy is difficult. Surgical resection for limited disease related to prior localized lung disease can also be curative especially in infections due to *M. abscessus.*

## THORACIC INFECTIONS BOARD REVIEW QUESTIONS (CHAPTER 6)

1. Which of the following is not an indication for surgical resection of lung abscess?
   A. Cavity size >4 cm
   B. Suspected cavitating neoplasm
   C. Infected pulmonary sequestration
   D. Bronchopleural fistula
   E. Recurrent hemoptysis

2. Which is the most common indication for surgical intervention in pulmonary actinomycosis?
   A. Abscess
   B. Bronchopleural fistula
   C. Empyema
   D. Suspected carcinoma
   E. Hemoptysis

3. Which is true regarding nocardiosis?
   A. It is not associated with immunosuppression
   B. Characterized by sulfur granules draining from a chest wall sinus
   C. Responds to high-dose penicillin
   D. Commonly requires lobectomy
   E. Typically forms a solitary encapsulated abscess

4. Which is not an indication for surgical intervention in tuberculosis?
   A. Diagnosis of mediastinal lymphadenopathy
   B. Persistent cavitary disease with subsequent aspergillus colonization
   C. Continued sputum positivity with DR-Tb
   D. Bronchial stenosis
   E. Miliary tuberculosis

5. Which is not an indication for surgery in histoplasmosis?
   A. Middle lobe syndrome
   B. Healed solitary pulmonary nodule after adequate medical therapy
   C. Symptomatic broncholithiasis
   D. Superior vena cava obstruction
   E. Esophageal obstruction

## ANSWERS

1. **Answer: A.** Cavity size should be larger than 6 cm in order to proceed with operation. Suspected cavitating neoplasm, infected pulmonary sequestration, bronchopleural fistula, and recurrent hemoptysis are all indications for surgical intervention.
2. **Answer: D.** Suspicion of underlying carcinoma is the most common indication for surgery in pulmonary actinomycosis.
3. **Answer: B.** Nocardiosis is characterized by sulfur granules on microscopy recovered from the draining chest wall sinus. It is often associated with immunosuppression and responds to the combination of trimethoprim and sulfdamethoxazole. Because it usually presents as widespread infection, pulmonary resection is rarely indicated.
4. **Answer: E.** Widespread disease is not amenable to surgical resection. Complications of tuberculosis infection, including persistent cavitation and bronchial stenosis, should undergo surgical repair after adequate antimicrobial therapy.
5. **Answer: B.** If adequate medical therapy is completed, there is no indication for resection of a solitary pulmonary nodule consistent with histoplasmosis. Complications of histoplasmosis include fibrosing mediastinitis, which can result in middle lobe syndrome, SVC obstruction, and esophageal obstruction. Surgical repair is indicated for these patients as well as those developing symptomatic broncholithiasis from calcified nodes.

7

# Surgical Management of Emphysema

*Alex G. Little*

**KEY CONCEPTS**

- Epidemiology
  - It is estimated that two to three million patients suffer from emphysema.
- Pathophysiology
  - Except for rare cases caused by enzyme deficiency, smoking is the cause of diffuse emphysema. The smoke destroys lung tissue in an irreversible fashion leading to bullous formation. The bullae may be relatively small or quite large.
- Clinical features
  - Patients are hypoxic and dyspneic. The dyspnea ranges from mild to the need for home oxygen supplementation with subsequent diminishment in the quality of life.
- Diagnostics
  - Clinically, emphysema is a subset of chronic obstructive pulmonary disease (COPD). The other causes of COPD including chronic bronchitis and hyperreactive airways can coexist. Emphysema is diagnosed by pulmonary function testing that shows a decrease in forced expiratory volume in 1 second ($FEV_1$) and increase in total lung capacity and residual volume.
- Treatment
  - Medical: Cessation of smoking eliminates progression of the disease but the tissue loss is irreversible.
  - Surgical: Appropriately selected patients benefit from lung volume reduction surgery and/or resection of giant bullae. Operative mortality is minimal. Operative morbidity is significant but most patients recover and benefit with an improved quality of life.

## INTRODUCTION

### Pathophysiology

Emphysema is a pulmonary disease that is one of the conditions that are together characterized as chronic obstructive pulmonary disease (COPD). The other diseases that are also constituents of the diagnosis of COPD are chronic bronchitis, formally defined as the presence of a productive cough for any three months of any two consecutive years, and hyperreactive airway conditions, particularly asthma. Any of these three disease processes can exist independently, but some overlap and coexistence is common. Figure 7-1 displays and discusses the interrelationships between these subsets of COPD which typically coexist.[1] "Asthma" in the figure should be understood as representing all hyperreactive airway conditions. The important understanding is that pure emphysema is uncommon.

Emphysema literally means to inflate. As illustrated in Fig. 7-2, emphysema is defined as enlargement of the airways distal to the terminal bronchiole in association with destruction of the normal architecture.[2] This is a result of a permanent and irreversible loss of alveolar septi as well as loss of the elastic tissues. This tissue loss is not recoverable and distinguishes emphysema from compensatory air space distention that, for example, is frequently seen in the remaining lung following pneumonectomy. Nearly all emphysema is secondary to the injury caused by cigarette smoke although there is a rare hereditary abnormality that is associated with $\alpha_1$-protease inhibitor deficiency.

After the cigarette smoke has damaged the airways and parenchyma causing loss of tissue and destruction of anatomic integrity, the natural tendency is for continued enlargement of the air spaces distal to the terminal bronchial. Although this disease progression is caused by multiple factors, the predominant factor is now thought to be continued

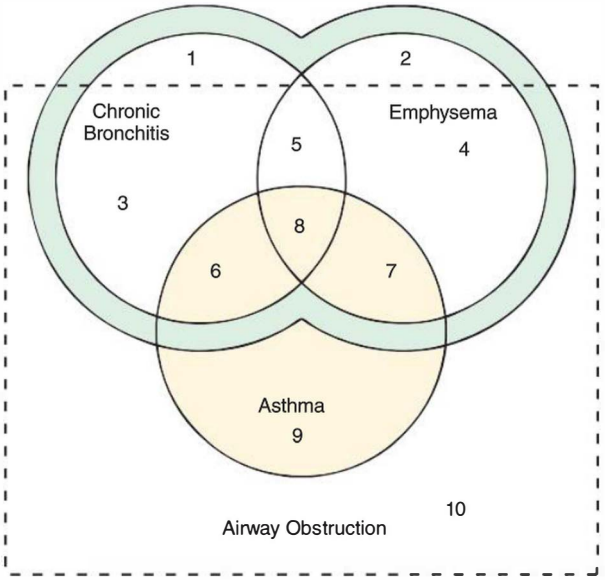

**FIGURE 7-1** Schema depicting chronic obstructive pulmonary disease (COPD). A nonproportional Venn diagram shows subsets of patients with chronic bronchitis, emphysema, and asthma in three overlapping circles. Subsets of patients lying within the rectangle have airway obstruction. Patients with asthma (subset 9) are defined as having completely reversible airway obstruction and lie entirely within the rectangle; their diagnosis is unequivocal. Patients in subsets 6 and 7 have partially reversible airway obstruction with chronic productive cough or emphysema, respectively. Patients in subset 8 have features of all three disorders. It may be difficult to ascertain whether patients in subsets 6 and 8 indeed have asthma or whether they have developed bronchial hyperreactivity as a complication of chronic bronchitis or emphysema; the history helps. Patients in subset 3 have chronic productive cough with airway obstruction but no emphysema; it is not known how large this subset is, because epidemiologic studies with the CT scan, the most sensitive in vivo imaging technique for the diagnosis or exclusion of emphysema, are not available. It is much easier to identify patients with emphysema determined by chest radiograph who do not have bronchitis (subset 4). Most patients who require medical care for their disease fall into subsets 5 and 8. Patients in subsets 1 and 2 do not have airway obstruction as determined by the $FEV_1$ but have clinical or radiographic features of chronic bronchitis or emphysema, respectively. Because COPD, when defined as a process, does not have airway obstruction as a defining characteristic, and because pure asthma is not included in the term COPD, patient subsets 1 to 8 are included within the areas outlined by the shaded band, which denotes COPD. (Reproduced with permission from Snider GL, Faling LJ, Rennard SI. Chronic bronchitis and emphysema. In: Murray JF (ed). *Respiratory Medicine*, 2nd ed. Philadelphia: WB Saunders, 1994:1334. Copyright Elsevier.)

traction on the damaged and weakened areas by the unopposed traction by the elastic tissue of the surrounding and less-damaged lung. These air spaces enlarge and eventually coalesce and are defined as bullae when their diameter is 2 cm or more. The expression "bullous" does not identify any particular size and the actual size may be as small as 2 cm or considerably larger, constituting the so-called giant bullae. All emphysema is bullous but the sizes of the bullae

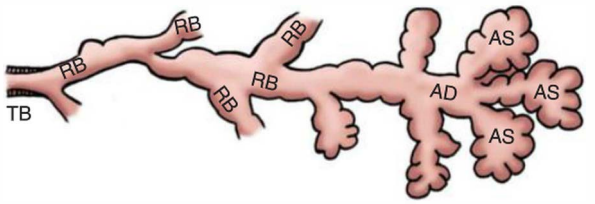

**FIGURE 7-2** This drawing shows normal respiratory airway anatomy. Emphysema affects the functional units, which are those distal to the terminal bronchiole (TB), the last airway to have cartilage in its wall. RB, respiratory bronchiole; AD, alveolar duct; AS, alveolar sac. (Reproduced with permission from Little AG. Surgical treatment of emphysema. In: Cameron JL, Balch CM, Langer B, et al. (eds). *Advances in Surgery*, Mosby, 1997:191. Copyright Elsevier.)

vary considerably. In most patients, the disease and the bullae are diffuse throughout the lung, although upper-lobe disease is more common than the lower-lobe disease. As the disease progresses and the bullae distend further, the actual lung size as well as total and residual lung volumes increase. Ultimately, the increase in lung volume and size causes an anatomic change in the chest with an increase in chest size including the anteroposterior dimensions of the rib cage with downward flattening of the diaphragm.

The most important physiologic alteration with diffuse emphysema is an increased tendency to premature collapse of smaller airways during expiration. The primary factor for this is the loss of normal elastic tissue with the recoil properties that hold the bronchioles open, although there is some compression of functional tissue by the bullae or air spaces. As pleural pressure increases during expiration, the relatively unsupported airways close, trapping air that is measured as residual volume.

Large or so-called giant bullae are relatively uncommon. They are usually multiple and nearly always associated with true, diffuse emphysema in the rest of the lung. The pathophysiology of these giant bullae is a variation on the previously described theme of diffuse, bullous emphysema. Once an area of parenchymal weakness is of sufficient size, it continues to fill with air preferentially. The force of elastic recoil in the better lung then retracts away from the bulla. The surrounding lung is not, as previously thought, compressed by high pressure within the bulla. Rather, the relatively more normal lung retracts away from the bulla and the lack of elastic recoil in adjoining airways leads to occlusion and atelectasis.

## Clinical Features

Although many patients with emphysema will also have bronchitis and/or hyperreactive airways, the following symptoms are typical. Dyspnea or difficulty breathing is the most frequently encountered symptom and generally present in all patients. Depending on the severity of the disease, this may occur at rest, even requiring oxygen supplementation, or may be more subtle and manifested by a decrease in exercise

tolerance. Many patients also have a cough that may or may not be productive of sputum. Wheezing is another very common symptom as well as excess mucous production. Some patients may exhibit cyanosis. In all circumstances, emphysema results in a diminished ability to deliver oxygen to the tissues. For example, if the brain is not receiving enough oxygen, the patient may demonstrate irritability, confusion, and/or mental instability.

# DIFFUSE EMPHYSEMA

## Diagnosis

The hallmark of emphysema is air-flow obstruction during expiration caused by the collapse of small airways that have lost the usual surrounding elastic tissue which promotes airway expansion. Pulmonary function testing (PFT) is essential to establish the diagnosis. Spirometry indicates expiratory air-flow obstruction with a reduction in the forced expiratory volume in 1 s ($FEV_1$) as well as a reduction in the ratio $FEV_1$/FVC (forced expiratory capacity). With worsening severity of the disease, lung volumes increase which leads to increases in total lung capacity, functional residual capacity, and residual volume. Further, eventually the diffusing capacity to carbon monoxide (DLCO) diminishes, which is a result and a measure of the severity of the parenchymal destruction and tissue loss characteristic of emphysema.

## Medical Therapy

Smoking cessation is essential and by far the most important therapeutic maneuver available to treat patients. Although not curative, middle-aged smokers who stop smoking experience a significant improvement in the rate of decline in pulmonary function and return to the annual changes seen in nonsmokers. To achieve this benefit, all possible aid to achieve this goal should be provided to these patients, including the use of pharmacologic agents and nicotine-replacement therapy.

Bronchodilator agents (both oral and inhalers) can also provide symptomatic benefit in patients with COPD and, in particular, those with emphysema. The inhaled route is preferable as side effects are less common with this route compared with parenterally delivered medications. β-Agonist drugs, such as albuterol, which are also bronchodilators, provide symptomatic benefit. Side effects including tremor and tachycardia are associated with these agonists.

The use of glucocorticoids is mildly controversial. Although inhaled glucocorticoids can reduce the frequency of disease exacerbations, their use has been associated with increased rates of oral pharyngeal candidiasis and bone density loss. In general, the chronic use of oral glucocorticoids is not recommended because of what is considered to be an unfavorable risk-to-benefit ratio.

## Surgical Therapy

### INDICATIONS

The history of surgery for emphysema is a fascinating one.[2,3] On the basis of flawed but well-intentioned logic, the early 20th century first saw interest in surgical enlargement of the chest cavity and therefore presumably lung capacity by operations such as transverse sternotomy with costochondrectomy. Initially employed in horses, this operation failed to improve pulmonary function. Subsequently, on the basis of the observation that the chest and lungs in emphysema patients were abnormally large, operations to reduce chest capacity became attractive. Accordingly, procedures such as reduction thoracoplasty and even phrenic nerve interruption to elevate the diaphragm were performed. Again, benefits did not result from these approaches.

Surgical efforts culminated in the 1950s and 1960s with a series of reports from Brantigan.[4–6] His prescient insight into the pathophysiology of emphysema led him to conclude that removal or exclusion of volume occupying, peripheral, and bullous regions of the lung would improve pulmonary function by restoring the chest wall to a more effective configuration. He also reasoned that, with resection of the diseased lung, the more normal remaining lung would be expanded by its preserved elastic recoil properties. Applying his theories to patients, the operations he performed were successful in improving pulmonary function in operative survivors, but the operations were associated with unacceptably high perioperative mortality rates and ultimately failed, in part because patients continued to smoke postoperatively. Consequently, this approach to emphysema patients was abandoned.

Brantigan's ideas and concepts were resuscitated in the 1990s. The first report by Wakabayashi and colleagues used a video-assisted thoracic surgical (VATS) approach and laser contraction/consolidation of the peripherally diseased areas.[7] Ultimately, this approach was shown to be less effective than operative resection of the more diseased areas when this concept was reintroduced by Cooper and his associates in 1994.[8]

The current operative procedure is termed lung volume reduction surgery (LVRS). Due to controversies and uncertainties surrounding patient selection for LVRS and, to a lesser extent, operative technique (i.e., sternotomy or VATS), a multi-institutional prospective, randomized investigation, identified as the National Emphysema Treatment Trial (NETT), was conducted. The impact of multiple clinical and laboratory variables on perioperative and long-term outcomes was assessed as LVRS was compared with "maximal" medical management in a prospective and randomized fashion. Tables 7-1 and 7-2 provide a detailed summary of the NETT conclusions regarding the indications and appropriate patient selection for LVRS.[9,10] In general, patients who benefit the most from LVRS are those with a low exercise capacity and upper-lobe predominant, heterogeneously distributed emphysema. Figure 7-3 is an illustrative chest CT scan. The upper lobes display severe emphysematous change,

**TABLE 7-1: Common Inclusion and Exclusion Criteria for Lung Volume Reduction Surgery**

| |
|---|
| **Inclusion criteria** |
| Radiographic evidence of emphysema, especially involving upper lobes |
| Hyperinflation |
| $FEV_1$ >20 and <45% predicted (postbronchodilator) |
| DLCO >20% predicted |
| Severe dyspnea |
| Restricted activities of daily living |
| Decreased quality of life |
| Abstinence from tobacco |
| **Exclusion criteria** |
| Active smoking |
| Bronchiectasis |
| Pulmonary nodule requiring evaluation |
| Excessive daily sputum production |
| Previous thoracotomy |
| Obvious pleural disease |
| Active or inducible coronary ischemia |
| Pulmonary hypertension |
| Depressed LVEF (<45%) |
| Obesity |
| Systemic steroids ≥20 mg prednisone/day |

DLCO, diffusion capacity for carbon monoxide; LVEF, left ventricular ejection fraction.

whereas the lower lobes are much less diseased. Appropriate candidates experience dyspnea that restricts their activities related to daily living and diminishes their quality of life. These characteristics must be present despite the patient's compliance with an appropriate medical regimen, including smoking cessation. On the other hand, the patient must have sufficiently diminished pulmonary function to require intervention but enough reserve to both tolerate the operation and possess the capacity for improvement. Appropriate LVRS candidates can, in part, be identified as having an $FEV_1$ greater than 20 percent of predicted but less than 45 percent. Tables 7-1 and 7-2 provide additional criteria used to identify appropriate and reasonable candidates for LVRS.

## LVRS Techniques

As for surgical technique, no difference in outcomes in terms of subjective or objective measures of pulmonary function between open and minimally invasive approaches was identified by NETT. However, the VATS approach resulted in earlier recovery at a lower cost compared with sternotomy.[11,12] Analogous to reports of patients undergoing VATS lung cancer resection documenting less pain, shorter hospital stays, and earlier chest tube removal compared with patients undergoing thoracotomy.[13] For these reasons, the VATS approach is most frequently employed for LVRS at present.

Independent of the approach, the operative goal for LVRS is to resect the most diseased lung parenchyma. These regions are, as mentioned, almost exclusively located in the upper lobes. The location of these regions is suggested by preoperative lung ventilation/perfusion and chest tomographic scans, and is definitively identified intraoperatively as the lung areas that are slowest to deflate when single-lung ventilation of the contralateral lung is instituted. Gentle handling of these fragile tissues and careful lysis of adhesions to the chest wall as the lung is mobilized are critically important to minimize lung trauma and the incidence and severity of postoperative air leaks. A linear stapler with buttressing material is used to resect the diseased areas. The buttressing adds integrity to the staple line, thereby minimizing postoperative air leaks. As the disease is diffuse, both lungs are involved. A sternotomy is therefore used for bilateral access when an open approach is used. The appropriate resection is performed on one lung during single-lung ventilation of the contralateral lung. This sequence is then reversed. For the VATS approval, the patient can be turned from one side to the other, allowing sequential left and right lung resections. Alternatively, the patient can be positioned so that both pleural spaces can be accessed without the need for repositioning.

## LVRS Outcomes

The postoperative management of patients after LVRS is frequently challenging. NETT identified that patients with an $FEV_1$ of 20 percent or less of predicted and either a DLCO of 20 percent or less of predicted or a homogeneous pattern of emphysema on chest CT was associated with a high perioperative risk of death and should not be considered appropriate candidates for LVRS.[14–16] Among patients without these high-risk factors, the 30-day mortality rate after LVRS was 2.2 percent compared with 0.2 percent in the medical therapy group. However, mortality rates among patients who are not at high risk were comparable. Mortality was 0.09 deaths per person-year in the surgery group compared with 0.10 deaths per person-year in the medical therapy group (risk ratio, 0.89; $p = 0.31$). When patients are appropriately selected, LVRS does not affect overall mortality. However, LVRS does expose patients to perioperative morbidity. Morbidity is minimized by selection of appropriate surgical candidates and having patients in maximal physiologic condition where pulmonary function has been optimized with a preoperative 6 to 10 weeks pulmonary rehabilitation program. Attention to nutritional needs, as approximately half of all emphysema patients are deficient nutritionally, is also helpful.[17] Despite these maneuvers, 58.7 percent of patients in the NETT trial experienced at least one complication.[18] Cardiac dysrhythmias, the most common complication,

**TABLE 7-2: Criteria for Determination of Candidacy for Lung Volume Reduction Surgery**

| Criteria | Good Candidates | Poor Candidates |
|---|---|---|
| History and physical examination | Age <75 years | Age ≥75 years |
| | Emphysema by clinical evaluation | History of recurrent bronchial infections with increased sputum production |
| | Ex-smoker >4 months | Cardiovascular comorbidities including significant coronary artery disease, recent MI, CHF, or uncontrolled hypertension or arrhythmias |
| | Clinically stable on no more than 20 mg prednisone daily | Pulmonary hypertension at rest |
| | Significant functional limitation after 6–12 weeks of pulmonary rehabilitation on optimal medical therapy | Nonpulmonary comorbidities causing significant functional limitation (morbid obesity) or that could limit survival (e.g., cancer) |
| | Demonstrated compliance with medical regimen | History of thoracic surgery or chest wall deformity that could interfere with pulmonary resection |
| Laboratory evaluation | Postbronchodilator $FEV_1$ ≤45% predicted for all ages and ≥15% if age ≥70 years | $FEV_1$ ≤20% predicted and either DLCO ≤20% predicted or homogeneous distribution of emphysema on HRCT scan |
| | Hyperinflation demonstrated by TLC ≥100% predicted and RV ≥150% predicted | Non-upper-lobe distribution of emphysema with high exercise capacity postrehabilitation (demonstrated by maximal achieved cycle ergometry watts) |
| | Postrehabilitation 6MWD >140 m | Significant pleural or interstitial changes on HRCT |
| | Low postrehabilitation exercise capacity (demonstrated by maximal achieved cycle ergometry watts) | |
| | HRCT demonstrating bilateral severe emphysema, ideally with upper lobe predominance | |

occurred in 23.5 percent of patients, with treatment required in 18.6 percent. Pneumonia was identified in 18.2 percent of patients. Predictably, pulmonary insufficiency was an issue and 21.8 percent of patients required at least one reintubation, tracheostomy was necessary in 8.2, and 5.1 percent could not be weaned from mechanical ventilation within 3 days of LVRS.

Prolonged air leaks following LVRS are a frustrating persistent issue contributing to postoperative morbidity.[10,19,20] In the NETT experience, 90 percent of patients experienced an air leak in the first 30 days after LVRS. Overall, the median duration of the air leak was 7 days and 66 of 496 (13.3%) patients suffered from air leaks that persisted 30 days or longer following their operation. Neither the surgical approach (i.e., open vs. VATS), choice of suture line buttressing material, performance of pleurodesis, nor construction of pleural tents was shown to affect either the incidence or the duration of the air leaks. Postoperative chest tube management with use of no or low (e.g., 10 mm Hg) negative pressure suction may be helpful by lessening the air flow through the visceral pleural defects.[19,20] Finally, patients with persistent air leak can be discharged from the hospital with a Heimlich valve placed on the chest tube to be removed when the air leak ceases.

Although LVRS does not provide a survival advantage, the benefit for LVRS patients is in their improved quality of life. The NETT study revealed that changes in exercise capacity, the 6-min-walk distance, percentage improvement in $FEV_1$, quality of life, and the degree of dyspnea at 6, 12, and 24 months favored patients undergoing LVRS[14,15] over those receiving maximal medical management. Although the number of patients who ultimately qualify for and undergo LVRS may not be large, the positive impact on appropriate patients is significant.

Another important benefit seen with LVRS is the reduction of health care costs.[12] In the first 12 months after randomization to treatment in the NETT trial, the total cost per patient was higher in the LVRS group than the medical group due to the cost of the operation and postoperative hospitalization. However, after 3 years, the cost-effectiveness ratio for LVRS compared with medical treatment was US$190,000 per quality-adjusted life-year gained per patient.

## Bronchoscopic Techniques

As LVRS is associated with significant mortality, morbidity, and costs, three bronchoscopic lung volume reduction (BLVR) approaches are currently being evaluated as potential alternatives to LVRS. The goal is to achieve a remodeling of the lung with exclusion and subsequent collapse of the same diseased lung areas resected during LVRS. The three

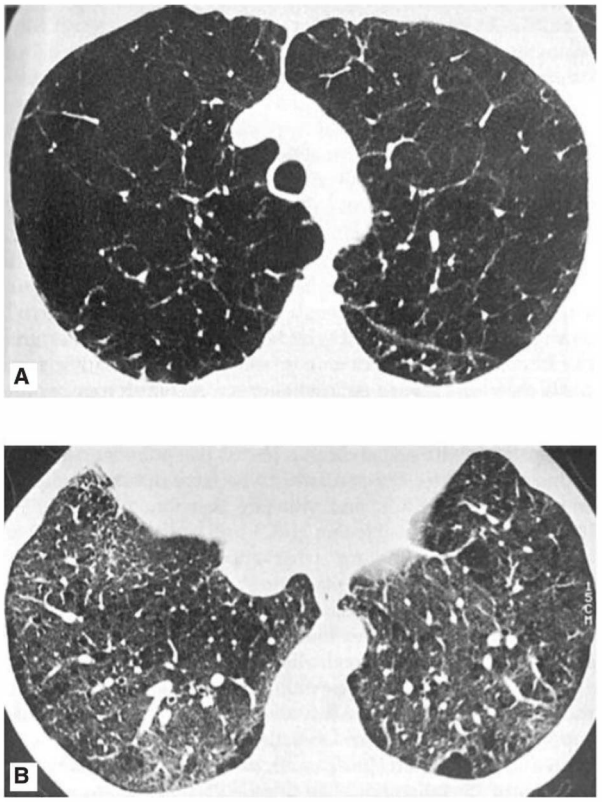

**FIGURE 7-3** Severe centrilobular emphysema in a patient being assessed for lung volume reduction surgery. The distribution of emphysema is markedly heterogeneous. **A.** Emphysema is concentrated mainly in the upper lobes. **B.** By comparison, the lower lobes are relatively spared. (Reproduced with permission from Hansell DM, Armstrong P, Lynch DA, McAdams HP. *Imaging of Diseases of the Chest*, 4th ed. Philadelphia: Elsevier Mosby, 2005:761. Copyright Elsevier.)

approaches currently being investigated include (1) placement of one-way valves in the appropriate bronchus to allow distal atelectasis and collapse of the targeted lung region by blocking inspiratory air flow, (2) use of a radiofrequency catheter to create a shunt pathway between a central airway and a region of hyperinflated lung to facilitate emptying of diseased lung regions that have delayed expiratory times, and (3) instillation of biological adhesives as separate liquid components that polymerize distally at the target sites, leading to alveolar collapse and ultimately remodeling of the hyperinflated areas.

## Bronchoscopic Outcomes

BLVR is performed to exclude the hyperinflated lung areas and achieve an anatomic and physiologic situation that resembles the outcomes of LVRS without the need for an operative procedure with its attendant morbidity and mortality. Up until now, results have been inconsistent and are not yet on a par with LVRS.[21,22] Consequently, BLVR is still considered to be an investigative procedure to be evaluated further. Most patients do not have the same objective improvements in exercise capacity and pulmonary function variables seen following LVRS, suggesting that much of the subjective improvement seen in BLVR patients may be related to a placebo effect.

## Lung Transplantation

Emphysema is currently the most common indication for lung transplantation, accounting for nearly half of all lung transplants.[23] The criteria for patient selection are essentially the same as those for LVRS. Although the original interest in lung transplantation was motivated by interest in prolonging life, a survival benefit has not been demonstrated. Actual benefits do occur but are related to documented improvements in quality of life through improvement in pulmonary function and exercise capacity. Ongoing uncertainties relate to the choice between LVRS and lung transplantation as the better alternative and whether single- or double-lung transplantation is the most appropriate procedure. The early hope that LVRS could serve as a bridge to transplantation has been diminished by the observation that prior LVRS increases the risk of bleeding during transplantation and is considered by some as a relative contraindication to transplantation for this reason.[23] Furthermore, the limited availability of donor lungs for transplantation limits its broad application to this patient population.

# GIANT BULLOUS EMPHYSEMA

## Diagnosis

Clinical and PFT characteristics of emphysema have been discussed and they all apply to patients with giant bullous disease. These patients cannot be differentiated from diffuse emphysema patients by their symptoms or other clinical criteria. The distinctive feature and distinguishing findings in these patients are large bullae as seen on either chest x-ray or chest CT scan. These bullae occupy a significant portion of the chest cavity and the remaining lung is significantly compressed. Figure 7-4 illustrates the typical chest CT scan appearance of bilateral large bullae with compression of the adjacent relatively normal lung.

## Medical Therapy

As these patients have diffuse emphysema along with large bullae, they can be helped through the medical interventions previously described, particularly through cessation of smoking. This initial approach may be sufficient to eliminate the need for surgical intervention. At present, however, there is no procedural modality that is specifically effective for giant bullous emphysema.

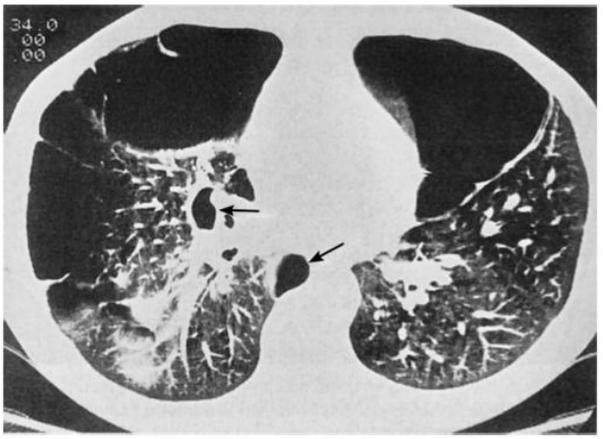

**FIGURE 7-4** Bullous disease on CT. Several large bullae are situated anterolaterally. Smaller bullae (arrows) are present in the azygoesophageal recess and against major vessels. Intervening lung, well seen paravertebrally, is reduced in volume but is otherwise normal and contains well-preserved vessels. (Reproduced with permission from Hansell DM, Armstrong P, Lynch DA, McAdams HP. *Imaging of Disease of the Chest*, 4th ed. Philadelphia: Elsevier Mosby, 2005:764. Copyright Elsevier.)

## Surgical Therapy

### INDICATIONS

Potential beneficiaries of surgical resection of giant bullous disease, namely bullectomy, are patients with both significant dyspnea that limits daily activities and nonfunctioning bullae that are large enough to compress the adjacent normal lung parenchyma. A chest CT scan with intravenous contrast helps identify those patients who will benefit from surgery. If a bulla or several bullae are shown to occupy a third or more of the hemithorax, bullectomy is likely to improve oxygenation translating into improved pulmonary function and an improved quality of life for the patient. Furthermore, reduced blood flow to the adjacent and compressed lung parenchyma, demonstrated on CT or pulmonary arteriogram, also suggests benefit from bullectomy.

### TECHNIQUES

Operations for diffuse emphysema include VATS or an open technique via thoracotomy for unilateral bullae or sternotomy for bilateral large bullae.[24–26] Regardless of the approach, the operation begins with single-lung ventilation of the contralateral lung. As the lung to be resected slowly deflates, the bullous extent is clearly identifiable. The roof of the bulla is incised, thus opening it and exposing its interior. Most of the bullous wall is excised, leaving a rim of 2 to 3 cm of residual wall. The base of the bullae is stapled by placing the stapler just on the adjacent true parenchyma, taking care not to remove potentially functional lung tissue. The remaining bullous wall is folded into the stapler where it serves as buttress material within the staple line, reducing the likelihood of severity and duration of postoperative air leaks.

### OUTCOMES

The reported perioperative mortality rate for bullectomy ranges from 2.3 percent to 10 percent, with most deaths related to pulmonary failure.[24–26] The perioperative course is similar to that of LVRS patients as postoperative complications occur in more than half of the patients. Cardiac dysrhythmias, pneumonia, and pulmonary insufficiency constitute the most common causes of morbidity, just as with LVRS. Preoperative optimization of the patient's pulmonary function with cessation of smoking, bronchodilator therapy, and participation in a rehabilitation program are again important and serve to reduce complications. The most common complication is a prolonged air leak defined as lasting more than 7 days. Drawing from the LVRS experience, applying minimal or no suction to the chest tube(s) may reduce the frequency with which this complication occurs.[19,20]

The long-term postbullectomy impact on quality of life and pulmonary function has not been as thoroughly assessed as in the NETT study. However, several reported experiences have identified both clinical and functional improvement for at least 5 years after bullectomy.[24–26] This improvement in quality of life correlates with improved $FEV_1$, decreased residual volumes, and improved vital capacity noted in appropriately selected patients.

## SURGICAL MANAGEMENT OF EMPHYSEMA BOARD REVIEW QUESTIONS (CHAPTER 7)

1. The pathogenesis of emphysema is related to:
   A. Smoking related increase in mucous production
   B. Smoking related tissue destruction
   C. Effects of aging
   D. Primary diaphragmatic dysfunction
   E. Radon exposure

2. Tissue destruction from emphysema is typically most severe in the:
   A. Upper lobes
   B. Lower lobes
   C. Perihilar areas
   D. Diffusely throughout
   E. Right lung

3. The most suitable candidate for lung volume reduction surgery would have which of the following findings on pulmonary function testing? (Percents are percent of the predicted value.)
   A. $FEV_1$ between 30 and 60 percent; increased TLC
   B. $FEV_1$ between 30 and 50 percent; decreased TLC
   C. $FEV_1$ between 20 and 40 percent; increased TLC
   D. $FEV_1$ between 20 and 40 percent; decreased TLC
   E. Normal RV and normal TLC

4. The following operative measure(s) have been shown to reduce the duration and severity of air leak after LVRS.
   A. Formation of a pleural tent
   B. Use of biological sealant spray
   C. Buttressing of the staple line
   D. All of the above
   E. None of the above

5. Giant bullae:
   A. Occur in normal as well as emphysematous lungs
   B. Are an indication for surgery
   C. Cannot be resected with VATS
   D. Regress if the patient stops smoking
   E. Compress adjacent lung parenchyma

## ANSWERS

1. **Answer: B.** Smoke and its constituents damage lung parenchyma in an irreversible fashion. When sufficient damage has occurred, air spaces called bullae are formed and the result is bullous emphysema.
2. **Answer: A.** While emphysema is generally diffuse and present in both lungs, the upper lobes typically manifest the most severe disease.
3. **Answer: C.** All patients have an increased RV and TLC because of air trapping during expiration. The NETT showed that the most suitable candidate for LVRS will have an $FEV_1$ between 20 and 40 percent.
4. **Answer: E.** None of the maneuvers listed has been shown to be efficacious in reducing the duration or the severity of air leak.
5. **Answer: E.** Giant bullae are a result of emphysema. They can be resected thoracoscopically but only when corrective measures fail. They do not regress. They do compress the remaining lung.

*Todd S. Weiser*
*Douglas J. Mathisen*

## KEY CONCEPTS

- Epidemiology
  - Primary tracheal tumors are rare, with an estimated 2.7 new cases diagnosed per million persons per year. The many remaining tracheal pathologies comprise heterogeneous epidemiologies.
- Pathophysiology
  - Congenital tracheal stenosis may present as a web-like diaphragm, most often at the subcricoid level. Primary tracheal tumors are largely (about two-thirds) made up of adenoid cystic and squamous cell carcinomas with roughly equal histologic frequency. Other tumors include pleomorphic adenomas, leiomyomas, chondromas, carcinoid tumors, mucoepidermoid tumors, and sarcomas. The laryngotracheal junction is the most frequent location of injury in airway trauma. Most tracheoesophageal fistulas are complications from mechanical ventilation.
- Clinical features
  - Patients with tracheal pathology usually present with signs and symptoms of upper airway obstruction: dyspnea on exertion, wheezing, stridor, and obstructive pneumonia. Tracheal tumors most commonly present with cough, hemoptysis, and signs of progressive airway obstruction, although signs and symptoms vary with tumor histology. Tracheoesophageal fistulas (TEFs) typically manifest as a sudden increase in tracheal secretions and ingested material in the trachea.
- Diagnostics
  - Anteroposterior and lateral tomography is useful to define upper tracheal pathology. Fluoroscopy demonstrates functional vocal cord asymmetry and other details (e.g., airway collapse with malacia). Computed tomography (CT) is helpful in malignant disease to assess extramural extent and lymphadenopathy. Inspiratory/expiratory CT is the easiest, most accurate noninvasive method to diagnose tracheomalacia. Flexible and rigid bronchoscopy is critical in the definitive assessment of the trachea.
- Treatment
  - Tracheal resection can be performed using a cervical or transthoracic approach, depending on the location and the extent of the lesion. Tracheal release maneuvers are primarily intended to prevent excessive tension on the anastomosis and avoid the need for excessive tracheal dissection.
  - Laryngotracheal injuries should be treated with airway establishment (e.g., tracheostomy). Traumatic lacerations of the lower trachea can be approached via partial or full sternotomy or right posterolateral thoracotomy.
  - Congenital tracheal stenoses may be treated with anterior tracheoplasty and patch repair or slide tracheoplasty.
  - Most TEFs require tracheal resection. Anastomotic complications are reduced if definitive single-stage correction of the fistula is delayed until after the patient has been successfully weaned from mechanical ventilation. Fistula control can be achieved by placing a tracheostomy with the balloon placed below the fistula, draining gastrostomy, and feeding jejunostomy.
  - Idiopathic laryngotracheal stenoses have been treated with complex, multistaged or single-stage procedures involving partial resection of the subglottic larynx and immediate plastic reconstruction.
- Outcomes/prognosis
  - At the Massachusetts General Hospital, operative mortality for primary tracheal tumor resection

has improved from 21 percent in the 1960s to 3 percent in the last decade. The overall 1-, 5-, and 10-year survival rates for primary tracheal carcinoma have been reported to be 84, 45, and 25 percent respectively. All tracheal surgery is subject to anastomotic complications, including suture line granulomas, stenosis, and tracheal separation. Predictors of anastomotic complications include reoperation, diabetes, lengthy resections, laryngotracheal resections, age 17 years or less, and preoperative tracheostomy. Anastomotic complications are associated with a 7.4-percent mortality, compared with 0.06 percent in patients who did not experience anastomotic complications.

# BACKGROUND

## Historical Perspective

Early in the evolution of tracheal surgery, it was believed that the amount of trachea that could be excised safely was four rings or approximately 2 cm. Because of this belief, much of the early work in this area focused on the use of prosthetics for tracheal replacement. Although early clinical reports of tracheal replacement with bioengineered materials have been reported,[1,2] consistent success is not yet attained for replacement of the airway.

In parallel with the efforts to find a suitable prosthetic device, efforts were underway to determine the possibilities of resection and primary reconstruction. Grillo and colleagues[3] systematically investigated the limits of resection of the trachea that might permit primary reconstruction without excessive tension and without destruction of its vital blood supply. Experiments in human cadavers demonstrated that the blood supply of the trachea entered in its lateral pedicles and that mobilization of the trachea is best accomplished only by anterior and posterior dissection. These studies concluded that a median length of 4.5 cm or approximately seven rings could be resected and primarily reconstructed with an acceptable amount of tension.

As the issues of extent of resection, methods of mobilization, limits of acceptable tension, and preservation of blood supply were established, primary resection and reconstruction became the accepted mode of managing most diseases that involved the trachea. Reports of resection and primary reconstruction of lengths of the trachea followed, which had been previously thought to be impossible.[4,5]

## Anatomy

The adult trachea measures 11 cm in average length from the anterior border of the cricoid cartilage to the carinal spur. There are 18 to 22 cartilaginous rings in the human trachea, with approximately two rings per centimeter. The only complete cartilaginous ring in the normal airway is the cricoid cartilage of the larynx. The remainder of the rings is C-shaped, connected posteriorly by the membranous portion of the trachea. The blood supply of the trachea is shared with the esophagus laterally and with the main bronchi below. Above, the blood supply originates from the inferior thyroid artery, and vessels to the lower trachea are derived from the bronchial vessels (Fig. 8-1). Importantly, branches of these vessels enter the trachea laterally.

# PATHOLOGY

## Congenital Lesions

Congenital tracheal stenosis may present as a web-like diaphragm, most often at subcricoid level. More lengthy stenoses may involve the entire trachea, sometimes with a

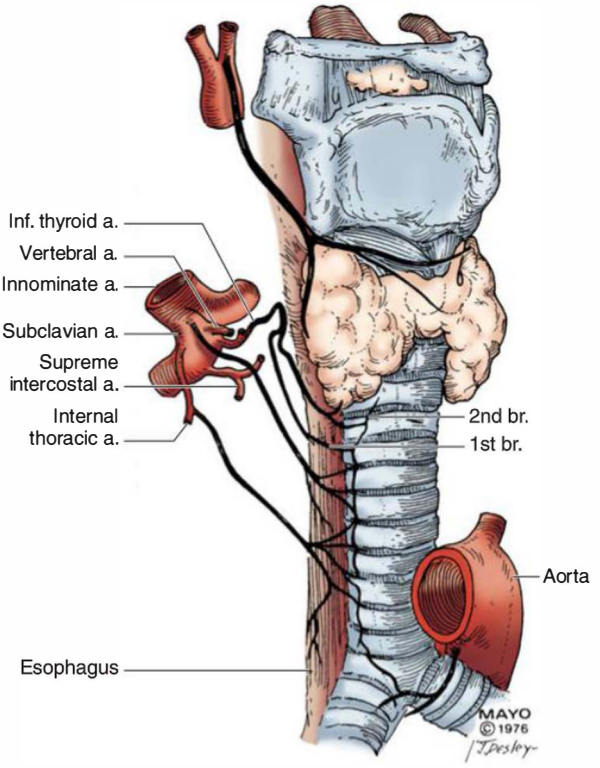

**FIGURE 8-1** Arterial supply to the thoracic trachea. Inf, inferior; a, artery; br, branch. [From Salassa JR, Pearson BW, Payne WS. Gross and microscopical blood supply to the trachea. Reprinted with permission from the Society of Thoracic Surgeons (*Ann Thorac Surg* 1977;24:100–107). By permission of Mayo Clinic.]

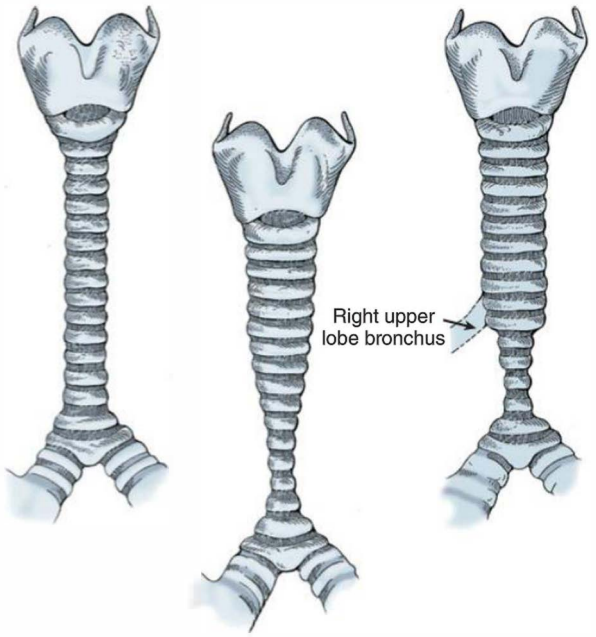

**FIGURE 8-2** Congenital tracheal stenosis. Type I (left): Generalized hypoplasia of the trachea. The airway has a normal caliber at the level of the cricoid cartilage and also in the main bronchi. Type II (center): Funnel-like narrowing. The trachea has a normal caliber immediately below the cricoid cartilage but funnels to its narrowest point, most frequently above the carina. Type III (right): Segmental stenosis may be accompanied by bronchial anomalies. The segmental stenosis may vary in length and may be at various levels. (From Cantrell JR, Guild HC. Congenital stenosis of the trachea. *Am J Surg* 1964;108:297. With permission. Copyright Elsevier.)

normal larynx and main bronchi, or they may involve variable lengths of the trachea (Fig. 8-2). Funnel-like narrowing is sometimes seen, with gradual narrowing to the stenotic segment. Segmental stenosis of the lower trachea may be accompanied by bronchial anomalies such as origin of all or part of the right upper-lobe bronchus from the trachea just above the stenotic segment. Most often the cartilaginous rings are circular in the area of stenosis. Other developmental anomalies may occur in a patient with congenital tracheal stenosis.

## Trauma

### EXTERNAL TRAUMA

The trachea, carina, and main bronchi may be damaged by either blunt or penetrating trauma. Blunt cervical injury may result in injury to the airway at any level from the hyoid bone to the carina.[6] Subcutaneous emphysema may be detected in the neck or, if the injury involves the more distal trachea, pneumomediastinum may be seen. Pneumothorax may result from tracheal injury within the chest cavity. Patients may present with varying severities of dyspnea from airway obstruction caused by these injuries or from tracheal transection. A patient with an initially satisfactory airway may rapidly decompensate while under observation or as intubation or examination of the airway is attempted.

If the airway is partially separated, a flexible bronchoscope with an endotracheal tube threaded over it is the best way to assess it. If difficulty is encountered, emergency tracheostomy should be quickly performed before the airway is lost. A completely transected trachea may retract into the mediastinum but is easily located by finger palpation and grasped by clamps and delivered into the field.

Blunt intrathoracic tracheal injury is a result of high-impact trauma, and as a result, it is usually associated with concomitant chest wall, pulmonary, and great vessel injury. Injuries to the carina and the main and lobar bronchi may occur from crush injuries to the chest. These tend to occur more frequently than tracheal injuries.

### INHALATIONAL INJURIES

Tracheal injury may also occur in the form of thermal or chemical damage by inhalation. Inhalation burns of the larynx, trachea, and bronchi may be particularly difficult injuries. The degree of inflammatory change, granulation tissue response, and scarring will depend on the depth of mucosal injury. In most cases, the tracheal rings are not destroyed. Resection is generally precluded, as lengthy injuries often occur. A number of cases of airway obstruction caused by burns have been managed initially by a tracheostomy placed at the second or third ring, typically within the area of burn injury, followed later by placement of a silicone T tube to span the injured area.

## Iatrogenic Injuries

### ACUTE INTUBATION INJURIES

Lacerations of the trachea during intubation occur most often in the membranous wall. These may be long and may also damage the esophagus, resulting in a tracheoesophageal fistula (TEF). Respiratory symptoms and concomitant esophageal injuries are indications for immediate repair.

### POSTINTUBATION INJURIES

Postintubation injuries to the trachea include granulomas, strictures, malacia, and tracheoesophageal and tracheoinnominate artery fistulas (Fig. 8-3).

Tracheal strictures represent the most common postintubation injuries. These occur principally at either the level of the tracheal stoma or that of the tracheal cuff. Both result from proliferative and cicatricial responses to tracheal injury. Granulomas result from erosion by the tip of a tracheostomy or endotracheal tube and can also occur at the site of a healed tracheostomy. Stomal stenosis results from

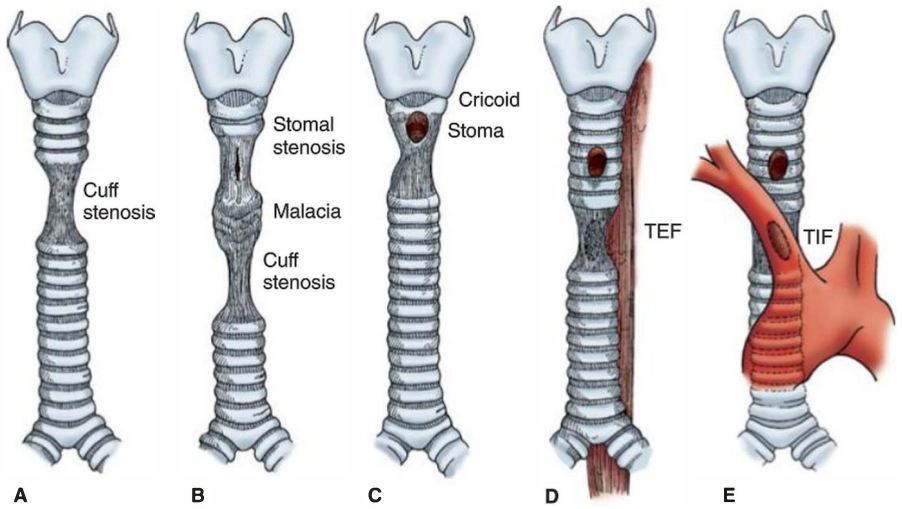

**FIGURE 8-3** Diagrams of principal postintubation tracheal lesions. **A.** Cuff stenosis from the cuff of an endotracheal tube. **B.** Cuff stenosis from the cuff of a tracheostomy tube, usually lower in the trachea than that from an endotracheal tube. Stomal stenosis also occurs at the site of the tracheostomy itself. Malacia may occur either at the level of the cuff or in the segment between the stoma and the cuff stenosis. **C.** Cuff stenosis at the site of a high tracheostomy stoma, which has eroded into the lower margin of the cricoid cartilage. In older patients, this may erode back further into the subglottic larynx, producing a laryngotracheal stenosis. **D.** Tracheoesophageal fistula (TEF) produced by pressure of the cuff against the membranous wall, often abetted by an indwelling firm nasogastric tube. **E.** One type of tracheoinnominate fistula (TIF), the result of a high-pressure cuff erosion. The more common type, but also rare, is that seen with a low-placed tracheostomy stoma, which rests against the innominate artery itself. Not shown here are the lesions that occur in the larynx as a result of endotracheal tubes. (From Grillo HC. Surgical management of postintubation tracheal injuries. *J Thorac Cardiovasc Surg* 1979;78:860. With permission. Copyright Elsevier.)

the gradual enlargement of a tracheal stoma and its eventual healing by contraction. This pulls the sides of the defect together, distorting the tracheal lumen to a triangular configuration with the base of the triangle located posteriorly, consisting of the uninjured membranous wall. The instigating large stoma may result from overzealous excision of tracheal wall at the time of the initial tracheostomy, from erosive infection around the margins of the stoma, or most commonly from erosion secondary to leverage by equipment attached to the tracheostomy tube during ventilation. The stenotic process may extend into the subglottic larynx if the previous tracheostomy was placed inappropriately high in the trachea.

Cuff stenosis, on the other hand, is caused by circumferential erosion of the trachea by excessive pressure exerted by the sealing cuff. In the healing process, cicatricial connective tissue is formed, which contracts in a circumferential fashion. The route of entry of the ventilatory tube does not affect the occurrence of cuff injury, only its level. These lesions are seen in patients who have had only endotracheal intubation as well as those with previous tracheostomy. Cuff injuries have been observed in patients with only 48 h of exposure to a high-pressure cuff.[7] However, since the length of exposure increases the risk of injury, these lesions are seen more frequently in patients after prolonged ventilation.

The development of the large-volume, low-pressure cuff for tracheostomy and endotracheal tubes for ventilation has greatly lowered the incidence of cuff stenoses. However, since the compliance curve of the plastic from which these cuffs are made is unsatisfactory when the cuff is inflated beyond its normal filled volume, pressure rises rapidly with additional filling. Therefore, overinflation of these cuffs converts them to high-pressure cuffs. This fact leads to a continued incidence of cuff stenosis.

Malacia of the trachea rather than stenosis may also occur at the level of cuff injury. The mucosa generally reveals squamous metaplasia in contrast to the scar tissue seen in the stenotic lesion. It is not clear why some patients develop malacic lesions rather than stenosis. Areas of malacia can also be seen between the level of a tracheal stoma and a cuff stenosis.

TEFs occur most often in patients who have an infected cuffed tube in the trachea for a long period of time concomitant with a nasogastric tube in the esophagus. These may represent large fistulas that can extend from one cartilaginous margin to the other. In most cuff fistulas, there is a circumferential injury to the trachea at the level of the fistula. Smaller fistulas are occasionally seen, which may be related to the tip of the tube pointing against the membranous wall. These variations must be considered in surgical repair.

Anterior injuries of the trachea may lead to the development of tracheoinnominate artery fistulas. These are most often due to direct erosion of the inner elbow of the tracheostomy tube in an inferiorly placed stoma. Placement of the tracheal stoma at the conventional level of the second or third tracheal ring prevents these fistulas.

Radiation therapy can produce late stenosis of the larynx and trachea. Because of the intrinsic damage to these tissues, surgical repair is hazardous. Tracheal stenosis due to irradiation may be treated with T-tube placement or carefully considered reconstruction with omental transfer to augment healing in select patients.[8]

## Idiopathic Laryngotracheal Stenosis

A minority of patients present with stenosis of the airway at various levels without history of trauma, infection, inhalation injury, or airway intubation. This diagnosis is one of exclusion and is characterized by an inflammatory cicatricial stenosis at the level of the subglottic larynx, cricoid, and upper trachea. An overwhelming majority of these patients are female and typically present with signs and symptoms of upper airway obstruction.[9] This process is confined intrinsically to the wall of the airway and the immediately surrounding connective tissue. Histology shows extensive fibrosis, acute and chronic inflammation, and dilation of mucus glands with relatively normal cartilage.[10] All patients should be screened for connective tissue disorders and Wegener's granulomatosis by serum ANA and ANCA.

It is impossible to predict the future course of the disease. The presence of active inflammation is best treated by serial dilation until the inflammatory process subsides. When airway obstruction becomes severe and does not respond for sufficiently long intervals to dilatation, surgery is indicated. Patients are best treated with definitive single-stage laryngotracheal resection and primary reconstruction.[9] The goal of reconstruction is removal of all of the scarred tissue and reconstruct with healthy tissue.

## Tracheobronchomalacia

Acquired tracheomalacia may result from postintubation injury. However, in patients with chronic obstructive pulmonary disease, malacia may develop in the lower trachea, main bronchi, and sometimes the more distal bronchi in the absence of prior intubation. When the patient attempts to expire or to cough, the membranous wall approximates to the anterior, softened cartilaginous wall, causing nearly total obstruction. Consequently, the posterior membranous wall elongates and becomes redundant. It is possible to ameliorate the deformity by pulling the ends of the cartilages toward one another posteriorly, restoring a more circular shape to the airway. The redundant membranous wall must be tacked to the posterior splinting material to prevent it from falling forward into the lumen. Various materials have been used for splinting, none with complete success. These have included fascia lata, pericardium, lyophilized bone, polytetrafluoroethylene, and rigid plastic splints. We currently use sheets of polypropylene mesh to plicate the membranous wall as described by Rainer.[11]

## Tracheal Tumors

Primary tracheal tumors are rare. It is estimated that tracheal tumors occur in about 2.7 new cases per million per year.[12] The rarity of these tumors and their often insidious presentation frequently lead to a delay in diagnosis and inappropriate treatment until the definitive diagnosis is made.

### TUMOR CLASSIFICATION

About two-thirds of primary tracheal tumors are of two histologic types: squamous cell carcinoma (SCC) and adenoid cystic carcinoma (ACC), formally known as "cylindroma." These two types occur with equal frequency. The remaining third of the tumors are widely distributed in a heterogeneous group, both malignant and benign. A variety of secondary tumors involve the trachea. These include carcinomas of the larynx, thyroid, lung, and esophagus. Rarely, tumors may metastasize to the submucosa of the trachea or to the mediastinum, with secondary invasion of the trachea. Thus, carcinoma of the breast and mediastinal lymphoma may invade the trachea.

SCC may be either exophytic or ulcerative. It may also be multiple and extend over a considerable length of trachea. The tumor metastasizes to the regional lymph nodes and, in its more aggressive and late forms, invades mediastinal structures. In general, its progress appears to be relatively rapid in comparison with that of ACC. A number of these patients have returned with a second SCC of the lung or oropharynx. SCC occurs predominantly in men, usually cigarette smokers.[13]

ACC often has an indolent course, frequently eluding diagnosis for years. Tumor recurrence may occur years after surgical resection. ACC may extend over long distances submucosally in the airways and also perineurally. It spreads to regional lymph nodes, although less frequently than SSC. Although it may invade the thyroid or muscular coats of the esophagus by contiguity, ACC frequently displaces mediastinal structures before actually invading them. Metastases to the lungs are not uncommon. These may grow very slowly over a period of years and remain asymptomatic until they become quite large. Metastases to bone and other organs can also occur. In contrast to tracheal SSC, men and women are equally affected and there is no clear association with tobacco smoke exposure.[12]

The group of tumors other than SCC and ACC, although representing only about one-quarter of the population, is composed of a multitude of tumor types and varying degrees of malignancy, including both epithelial and mesenchymal neoplasms. This list includes pleomorphic adenomas, leiomyomas, chondromas, carcinoid tumors, mucoepidermoid tumors, and sarcomas.

Secondary tumors involving the trachea should be briefly noted. Both papillary and follicular carcinoma of the thyroid and mixed varieties of the two may invade the trachea primarily, usually at the level of the isthmus.[14] Invasion of the trachea by thyroid carcinoma is best managed by resection

with airway reconstruction. Localized extension of tumor may also require partial esophageal resection or radical resection, including laryngectomy with mediastinal tracheostomy. More commonly, invasion is seen after thyroidectomy for carcinoma, in cases where surgeons were aware that they were "shaving off" the tumor from the trachea. In such cases, concurrent or early resection of the involved trachea should be considered.

## CLINICAL FEATURES

Patients with pathologic lesions of the trachea usually present with signs and symptoms of upper airway obstruction: dyspnea on exertion, wheezing, stridor, and obstructive pneumonia. The most common presentation, wheezing and dyspnea on exertion, is frequently misinterpreted as adult-onset asthma. It is not uncommon for the symptoms in these patients to become progressively worse and correspondingly be treated with corticosteroids before the correct diagnosis is finally made. It should be a diagnostic rule that any patient who presents with such symptoms and has been intubated and ventilated must be considered to have organic stenosis unless proven otherwise.

Tumors of the trachea may also present insidiously. Their most common signs and symptoms are cough (37 percent), hemoptysis (41 percent), and the signs of progressive airway obstruction, including shortness of breath on exertion (54 percent), wheezing and stridor (35 percent), and, less commonly, dysphagia or hoarseness (7 percent).[12] Signs and symptoms may vary with the histology of the tumor. Hemoptysis is prominent in patients with SSC and usually leads to earlier diagnosis. ACC more commonly presents with wheezing or stridor as a predominant symptom, often leading to delay in diagnosis. In one study, the mean duration of symptoms prior to diagnosis in patients with SCC of the trachea was only 4 months, whereas in those with ACC, it was 18 months.[15]

Among nonintubated patients, TEF is manifest by episodes of choking while swallowing, suctioning of food or beverage from trachea, or an increase in tracheal secretions. Among intubated patients, there may be gastric distention or loss of delivered tidal volume. Tracheoinnominate arterial fistulas are rare but may be announced by a premonitory hemorrhage. In treating bleeding from a tracheostomy, it is important to differentiate between erosion of tracheal granulations or mucosa and arterial fistula. Any suspicious hemorrhage from a tracheal stoma should be immediately investigated.

## DIAGNOSTIC MODALITIES

### Radiographic Assessment

Definitive diagnosis of airway problems is often delayed because of an apparently normal chest radiograph. Closer inspection will often reveal abnormality of the tracheal air column. Lesions can frequently be seen on overpenetrated views or tomograms of the larynx and trachea. The location of the lesion, its linear extent, extratracheal involvement, and the amount of airway uninvolved can be determined. Lateral neck views, using soft tissue technique with the patient swallowing and the neck hyperextended to bring the trachea up above the clavicles, are useful to define pathology in the upper trachea. Fluoroscopy not only demonstrates functional asymmetry of the vocal cords if present but may also give additional information about the extent of the lesion and collapse of the airway if malacia is present. In some cases, polytomography (AP and lateral views) gives additional detail, particularly of mediastinal involvement. Computed tomography (CT) offers little overstandard radiologic techniques for benign disease but is especially helpful in malignant disease to assess extramural extent and enlarged lymph nodes. A combination of inspiratory and expiratory images from a CT is currently the easiest and most accurate noninvasive method of diagnosing tracheomalacia.[16] The exact role of magnetic resonance imaging (MRI) is yet to be defined. Sagittal and coronal views, however, have been helpful in certain cases and may provide more accurate detail than standard radiographic techniques.

### Bronchoscopy

Certainly the role of both flexible and rigid bronchoscopy in the diagnosis of tracheal pathology cannot be overstated. Biopsy specimens of both benign and malignant lesions of the trachea are made with these techniques. In planning surgical resections, bronchoscopy is invaluable. Definitive assessment of the airway is performed by meticulous endoscopic measurements with a rigid bronchoscope. Measurement of the carina, bottom of the lesion, top of the lesion, and level of the vocal cords will determine the extent of the disease process and likelihood of reconstruction. At the time of bronchoscopy, it is important to assess the adequacy of the larynx and degree of inflammation of the mucosa.

#### AIRWAY MANAGEMENT AND ENDOSCOPY

Crucial to the management of all problems of the trachea is the ability to control the airway. Tracheal trauma, tumors, and postintubation stenosis may present with acute airway obstruction. Endotracheal intubation may be impossible and even dangerous, especially in patients with high tracheal lesions. Simple maneuvers to elevate the head of the patient, administration of cool mist, oxygen, and careful sedation may allow control of the airway to be accomplished in a semielective manner. Control is best accomplished in the operating room, where an assortment of rigid bronchoscopes, dilators, biopsy forceps, and instruments to perform emergency tracheostomy are available. Anesthesia, as in elective tracheal operations, is best accomplished by inhalation technique

to allow spontaneous ventilation.[17] Muscle-relaxing agents should not be used to avoid the lethal combination of airway obstruction and an apneic patient.

Initial evaluation should be performed with a rigid bronchoscope carefully inserted through the vocal cords, stopping just proximal to the level of obstruction. This can be passed beyond most tumors, even those causing nearly total obstruction. Once the status of the distal airway has been assessed, the tumor can be partially removed with biopsy forceps to determine its consistency and vascularity. For most tumors, the tip of the rigid bronchoscope can be used to core out most of the tumor.[17] The tumor can then be grasped with biopsy forceps and removed. If bleeding ensues, the bronchoscope may be passed into the distal airway for ventilation, and this will also serve to tamponade bleeding.

Postintubation stenoses pose a slightly different problem in airway control. Bronchoscopy is invaluable in determining the extent of airway involvement and, just as importantly, the amount of uninvolved airway. Measurements as accurate as possible should be recorded. The quality of the mucosa should be carefully assessed. Marked inflammation and erythema may dictate delay of definitive surgical correction to a time when this has subsided. Both flexible and rigid bronchoscopes are used in these situations.

Caution must be taken with flexible bronchoscopy in the assessment of critical airway stenosis. The flexible bronchoscope may precipitate airway obstruction in patients with critical stenoses by increasing secretions or causing bleeding or edema. If the physician performing the endoscopy is unprepared to dilate the patient emergently, lethal airway obstruction may occur. Whenever severe airway stenosis is encountered, it is best not to manipulate the stenosis with the flexible bronchoscope. Proper evaluation should be performed in the operating room with facilities available to dilate the stenosis if necessary. In nonemergent cases, endoscopy is best performed as part of the planned surgical procedure.

As a general rule, the rigid bronchoscope is much more valuable in assessing airway pathology. Attempting to pass a large rigid bronchoscope beyond a tough, inflammatory stricture may be impossible, may result in tracheal rupture, or may cause total airway obstruction secondary to bleeding or edema. Jackson dilators passed through the rigid bronchoscope under direct vision and an assortment of graduated rigid bronchoscopes can be used to serially dilate postintubation and idiopathic strictures. By gradually dilating these tight, rigid strictures, the risk of perforation and bleeding is minimized. Racemic epinephrine and steroids are often used for 24 to 48 h to minimize subsequent reactive edema.

It is important to understand that dilation or endoscopic removal of malignant or inflammatory strictures is often only a temporizing measure. In the case of inflammatory stricture, restenosis usually develops within days to weeks. The use of these techniques in emergent situations allows more thorough evaluation of the patient and enables surgery to be performed electively. Many patients are on corticosteroids at the time of presentation and, by improving the airway, these may be tapered and discontinued. This will enable the operation to be performed at a later time without the threat of impaired healing.

The above maneuvers are also used in an elective operation when the patient has presented with a narrowed but not critical airway. Dilation with rigid bronchoscopy permits assessment of the distal airway, placement of an endotracheal tube, and provision of an adequate lumen to prevent carbon dioxide accumulation early in the procedure.

Tracheostomy may be necessary in some patients as the only method to secure an airway. If feasible, this should be placed through the most damaged portion of the trachea to preserve the maximal amount of normal trachea for subsequent reconstruction. If tracheostomy is contemplated at the completion of tracheal resection, which is rarely necessary, it should be placed at least two rings away from the anastomosis. The anastomosis should then be protected with the thyroid gland or strap muscles to avoid contamination of the suture line. This will lessen the likelihood of subsequent dehiscence or stenosis. A tracheostomy tube should never be placed through an anastomosis.

## Surgical Therapy

### ANESTHESIA

Anesthesia for tracheal reconstruction, especially where there is a high degree of airway obstruction distally, is best administered by inhalational agents.[17] A slow, patient induction may be necessary if there is a high degree of airway obstruction. This is preferable and safer than paralysis of respiration with a consequent urgent need to establish an airway.

The surgeon should be available with an array of rigid bronchoscopes from pediatric to adult sizes as the induction commences. The residual airway through which the patient is breathing may measure as little as 2 or 3 mm in diameter. In most cases, tumors are not circumferential. After bronchoscopy, a small endotracheal tube can often be insinuated past a highly obstructive tumor. In other cases, the tube is left above the tumor. This contrasts with the circumferential stenoses seen in some inflammatory lesions. In rare cases, it may be necessary to resect portions of tumor with biopsy forceps to enlarge the channel for passage of a tube.

At the time of tracheal division, this tube is pulled back or removed and a sterile cuffed, flexible, and armored endotracheal tube is inserted into the distal airway across the operative field. Sterile connecting tubing is passed to the anesthesiologist to allow ventilation of the patient. This armored tube is removed whenever necessary for suctioning or placement of sutures. Toward the completion of the operation, the original endotracheal tube is advanced into the distal airway and the anastomotic sutures are tied. The patient should be breathing spontaneously at the end of the procedure so that extubation can be performed in the operating room. High-frequency ventilation has been used

with equal success intraoperatively, but we have been quite satisfied with the technique described. High-frequency ventilation is especially useful in certain complex carinal reconstructions.

Ideally, the patient should be extubated and breathe spontaneously at the conclusion of the procedure. Particularly where the trachea has been greatly shortened, it is desirable not to have even a low-pressure cuff lying in contact with the anastomosis for any period of time. The use of cardiopulmonary bypass is not usually necessary in adult tracheal surgery, even in complex carinal reconstructions. However, it may be requisite in repairing congenital airway lesions in the pediatric population, especially in the presence and correction of cardiac anomalies.[18]

## Maneuvers to Minimize Tension

Most tracheal operations can be performed without complex tracheal release maneuvers. The location of the lesion is an important factor in determining which procedures will be of benefit. Certain maneuvers are more effective for achieving additional length in performing surgery for disease in the cervical trachea, whereas others are more effective for the intrathoracic trachea. A release maneuver is primarily performed to prevent unnecessary tension on the anastomosis and avoid the need for excessive dissection of the trachea, which might jeopardize the lateral blood supply.

The simplest maneuver to minimize tension after tracheal resection for cervical pathology is flexion of the neck and mobilization of the pretracheal plane, avoiding the lateral blood supply to the trachea. Flexion of the neck between 15 and 35 degrees may result in downward movement of the trachea by as much as 4.5 cm, or the equivalent of seven tracheal rings. Flexion beyond this may achieve up to 1.5 cm of added length. The amount of trachea that may be removed with simple flexion varies greatly with the patient's age and physical habitus as well as other conditions. When these simple maneuvers fail to provide sufficient length, a Montgomery suprahyoid laryngeal release can be performed, generally before the anastomosis is completed.[19] This is accomplished by dividing the muscles that insert on the superior aspect of the hyoid bone. The hyoid bone is then divided just medial to the lesser cornua. When this maneuver is performed, an additional 1.5 cm of length can be obtained.

Flexion of the head and mobilization of the anterior surface of the trachea is also important for lower tracheal lesions. Laryngeal release has not been helpful in gaining additional length for intrathoracic tracheal lesions. Mobilization of the right hilum and inferior pulmonary ligament should be completed first. A U-shaped incision in the pericardium below the inferior pulmonary vein will allow the hilar structures and bronchus to advance in a cephalad fashion.[20] Additional length may be obtained by completely incising the pericardium around the hilar vessels.

## Tracheal Resection

### CERVICAL APPROACH

The cervical or upper cervicomediastinal approach is used for limited tumors of the upper trachea and for almost all benign strictures of the trachea at any level. The patient is usually anesthetized by inhalation and a rigid bronchoscope is passed. A stricture less than 6 mm in diameter is dilated under direct vision with rigid pediatric bronchoscopes. If the stricture is greater than 6 mm in diameter, an endotracheal tube may be placed just above the lesion. If the lesion is subglottic, the stricture must be dilated and a small endotracheal tube passed through it. An endotracheal tube may be slipped past most tumors or through the cored center of the rare circumferential tumor. If jet ventilation is employed, a tube as small as 14F suffices.

The trachea is explored through a collar incision, which may circumcise an existing tracheal stoma (Fig. 8-4A). The anterior surface of the trachea is exposed from the cricoid cartilage to the carina. The thyroid isthmus is then divided, dissected from the trachea, and retracted laterally with sutures. In inflammatory lesions, it is essential to keep the dissection close against the trachea to avoid the risk of injury to the back wall of the innominate artery. If the lesion extends below the sternal notch, making it easily accessible through the collar incision, the exposure is increased by making a "T" incision with the vertical arm extending downward to a point 1 cm below the sternal angle (Fig. 8-4B). The sternum is divided to that point only and is separated with a small chest spreader. Exposure is not improved with a full median sternotomy, since the carina lies at the level of the angle of Louis, and the great vessels, lying anteriorly, inhibit better visualization.

In cases of inflammatory stenosis, meticulous dissection is performed along the lateral aspects of only the involved trachea. If there is difficulty in identifying the level of the lesion, intraoperative bronchoscopy will facilitate its recognition. The position of the bronchoscope light is identified at the upper and then the lower extent of the lesion while an assistant pushes a #25 needle through the tracheal wall for precise localization. Dissection close to the tracheal wall or the scar replacing it avoids injury to the recurrent laryngeal nerves, which lie in the tracheoesophageal groove on either side. The nerves are intentionally not exposed. This is a particularly important point if the stenosis is located just below the cricoid cartilage, since the recurrent nerves enter the larynx just medial to the inferior cornua of the thyroid cartilages.

The trachea is then circumferentially dissected at the level immediately below the distal margin of the lesion (Fig. 8-4C). Sterile anesthesia equipment is assembled on the field prior to division of the trachea. Lateral traction sutures of 2-0 Vicryl are placed on either side of the trachea in the midlateral portion approximately 1 cm below the anticipated level of transection. These pass vertically through the full thickness of the tracheal wall and around one or more rings (Fig. 8-5A). The trachea is opened anteriorly just distal to the lesion, staying close to the lesion if it is benign. If the

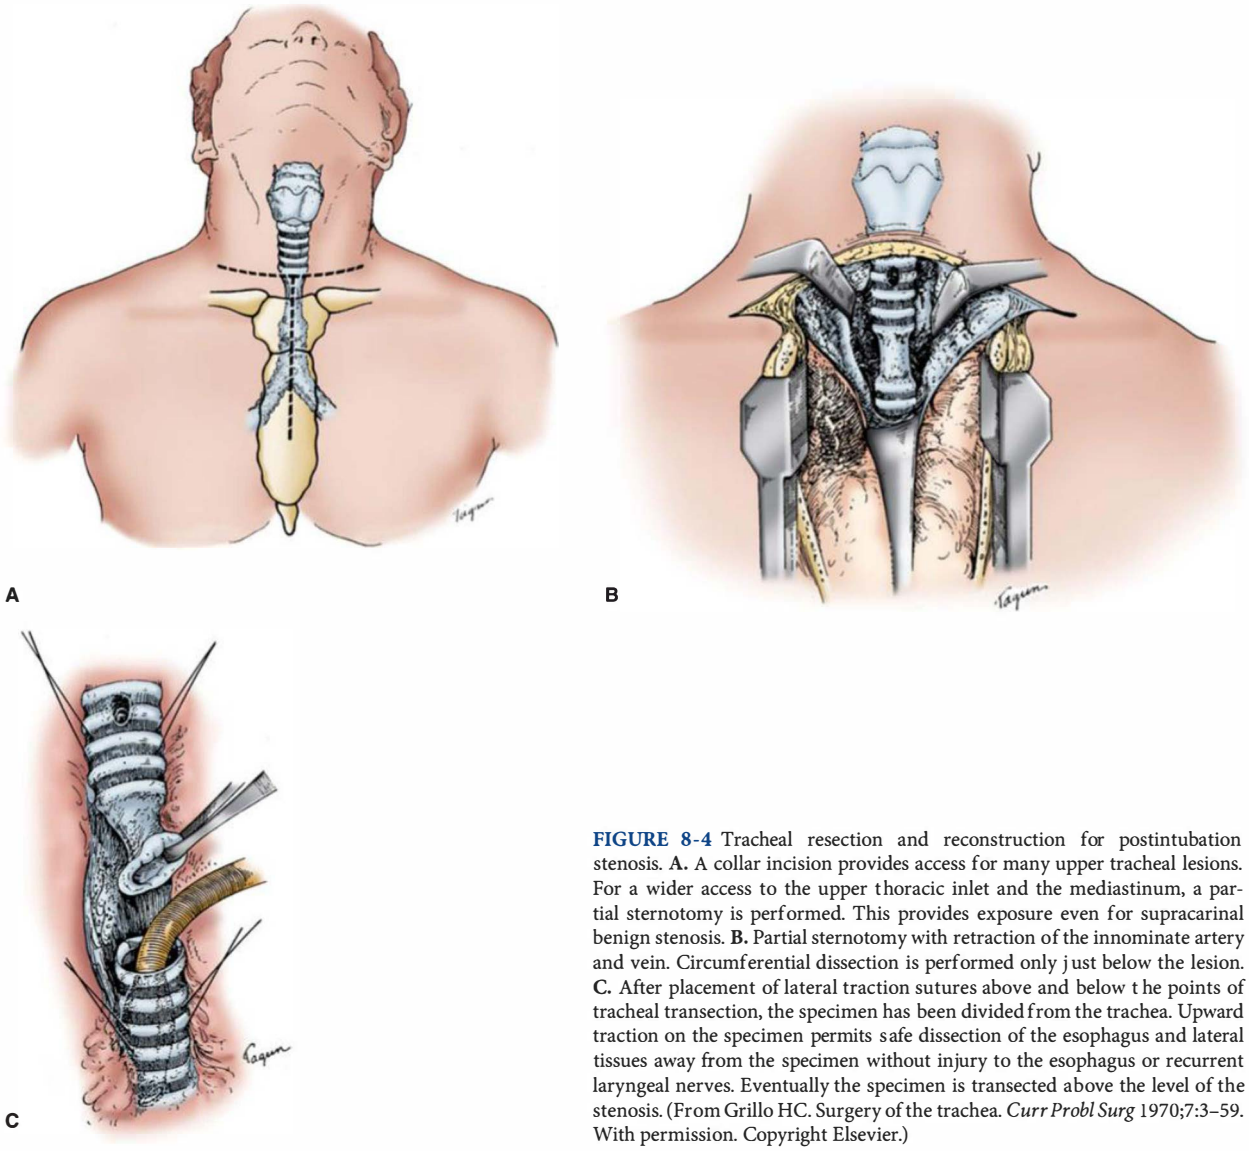

**FIGURE 8-4** Tracheal resection and reconstruction for postintubation stenosis. **A.** A collar incision provides access for many upper tracheal lesions. For a wider access to the upper thoracic inlet and the mediastinum, a partial sternotomy is performed. This provides exposure even for supracarinal benign stenosis. **B.** Partial sternotomy with retraction of the innominate artery and vein. Circumferential dissection is performed only just below the lesion. **C.** After placement of lateral traction sutures above and below the points of tracheal transection, the specimen has been divided from the trachea. Upward traction on the specimen permits safe dissection of the esophagus and lateral tissues away from the specimen without injury to the esophagus or recurrent laryngeal nerves. Eventually the specimen is transected above the level of the stenosis. (From Grillo HC. Surgery of the trachea. *Curr Probl Surg* 1970;7:3–59. With permission. Copyright Elsevier.)

wall is still diseased at this point, a second incision is made one ring lower until good tissue is identified; then the trachea is transected. After the transection, an assistant maintains tension on the two lateral traction sutures and holds the flexible armored ventilating tube in the distal trachea. Circumferential dissection of the residual distal trachea is limited to its first 1 to 2 cm to protect the segmental blood supply. Devascularization invites necrosis and a possibly irreparable restenosis.

In the case of tumors of the upper trachea, since there is no peritracheal inflammation, the recurrent laryngeal nerves are usually identified and followed to above the level chosen for tracheal transection. This permits excision of paratracheal lymph nodes immediately adjacent to the tumor-bearing segment. To determine the appropriate level of tracheal transection, the trachea is initially opened through a tumor-free area at the level of the tumor.

Lateral traction sutures are placed proximally 1 cm above the proposed proximal level of transection. Again, no more than 1 cm of trachea is freed circumferentially. If the upper level of transection is at the inferior border of the cricoid cartilage, no attempt is made to dissect more cephalad posteriorly, since this would involve the zone of fusion between the upper esophagus and the cricoid, risking esophageal injury. To test the ease with which the tracheal ends can be brought together, the anesthetist flexes the patient's neck and

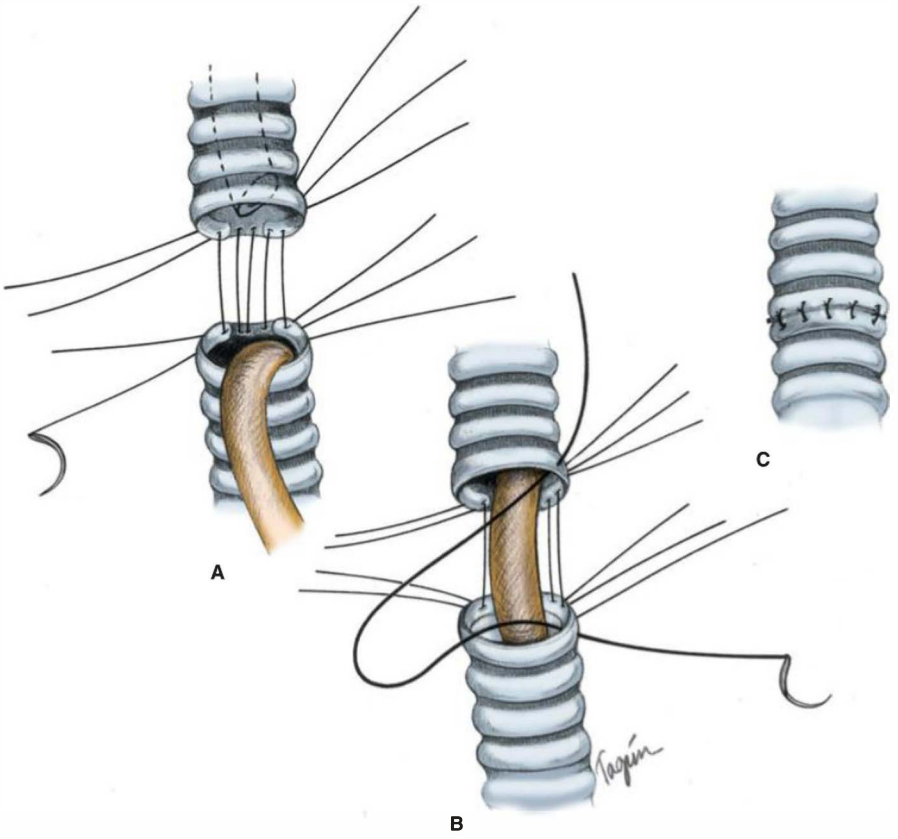

**FIGURE 8-5** **A.** Tracheal anastomosis. Sutures are placed individually, beginning in the midline posteriorly and ranging anteriorly on either side. **B.** After the sutures have been placed on either side up to the level of the midlateral traction sutures, the anterior sutures are placed. Frequently, the endotracheal tube is not advanced from above until after all sutures have been placed. **C.** The neck is placed in the flexed position and the lateral traction sutures are tied on either side (not shown) to remove tension from the anastomotic sutures. After this, anastomotic sutures are tied from anterior to posterior on either side. The completed anastomosis is airtight. (From Grillo HC. Surgery of the trachea. *Curr Probl Surg* 1970;7:3–59. With permission. Copyright Elsevier.)

the proximal and distal traction sutures are crossed, bringing the tracheal ends together. Importantly, the length of trachea that may be safely removed must be determined prior to division. Whether resection is feasible is usually based on radiologic and bronchoscopic measurements made prior to skin incision and rarely on surgical exploration.

Once it has been demonstrated that the anastomosis can be performed without excessive tension, the neck is again hyperextended. The first anastomotic suture—we prefer 4-0 coated Vicryl—is placed in the posterior midline with the knots outside, and the suture is clipped to the drapes above. The next suture is placed lateral to this and clipped to the drapes just caudad to the previous one. The sutures are thus serially inserted until a point is reached just posterior to the midlateral tracheal traction suture (Fig. 8-5A). The same placement of sutures is now carried out on the opposite side, from the posterior midline to the midlateral suture. Serial sutures are placed anteriorly, proceeding from the lateral traction sutures to the midline (Fig. 8-5B). The cross-field ventilatory tube may have to be removed intermittently for the placement of difficult sutures or drawn to one side as the sutures are inserted.

When all sutures have been placed, the oral endotracheal tube is advanced from above until the end is visible in the wound. The distal trachea is suctioned, the tube in it is withdrawn, and anesthesia is now resumed via the original endotracheal tube, which is advanced into the distal trachea beyond the anastomosis. The patient's head is firmly supported on blankets in full flexion and then the lateral traction sutures are crossed, pulled together on either side, and tied. The tracheal ends are apposed end-to-end, not deliberately intussuscepted.

The anterior anastomotic sutures are tied first, without tension, and the ends are cut after tying each. The assistant now rotates the trachea by gently drawing medially on the traction sutures on the surgeon's side of the table. The suture just posterior to the lateral traction suture is tied, as then are the rest of the posterior sutures. This is then repeated on the opposite side (Fig. 8-5C). The ends of

traction sutures are removed, leaving their knotted loops in place to guard against tension on the anastomotic sutures. The integrity of the anastomosis is checked under saline. Flat, closed suction drains are placed in the pretracheal and substernal spaces, and the strap muscles are approximated in the midline.

After the incision has been closed, a heavy suture is placed through the skin crease beneath the chin and through the presternal skin. Two sutures, one on each side, may be used if a midline incision was necessary. These sutures are tied with the patient's neck in flexion to guard against sudden hyperextension of the neck in the first week following operation.

The patient is usually extubated in the operating room. An unsatisfactory airway at this point is not likely to improve unless the problem is secondary to laryngeal edema. If this is the case, a small endotracheal tube can be left in position until the problem subsides. It is preferable to leave the cuff deflated if possible.

### TRANSTHORACIC APPROACH

The transthoracic approach using a posterolateral thoracotomy through the fourth intercostal space is used for tumors of the lower trachea and carina and for a few inflammatory lesions. The right arm is draped free, and the neck and anterior chest are included in the field. This allows for alteration of the incision or the addition of a cervical component should laryngeal release or other maneuvers may be necessary. An extra long, single-lumen endotracheal tube with sufficient diameter is used to intubate a main bronchus.

Dissection of the thoracic trachea is carried out in a similar fashion to that for more proximal pathology. In cases of malignancy, an effort is made to resect surrounding tissues with the tumor. Eventually, the trachea is dissected circumferentially below the tumor and sometimes above it, although the upper portion of the dissection can be completed after division of the trachea below. Traction sutures are placed in the midlateral tracheal wall distal to the tumor. If the transection is close to the carina, the sutures are placed in the lateral walls of the right and left main bronchi. Again, anesthesia tubing brought across the field is joined to a flexible armored tube placed in the distal trachea or, preferably, the left main bronchus to allow collapse of the right lung for better exposure during the anastomosis. If this results in significant intrapulmonary shunting, the right pulmonary artery may be gently clamped.

Flexion of the neck, even with the patient in the lateral thoracotomy position, delivers the proximal trachea into the thorax. Dissection anterior to the trachea and both main bronchi will provide additional mobility. These are important maneuvers in obtaining a tension-free anastomosis. In the resection of a malignant tumor, paratracheal and subcarinal lymph nodes that are not in proximity to the mass should not be radically resected for fear of devascularizing the airway. The technique of anastomosis is similar to that used in the upper trachea.

## Laryngotracheal Trauma

The laryngotracheal junction is the most frequent location of injury in airway trauma. The most important initial aspect of treating a laryngotracheal injury is the establishment and maintenance of an airway. The wound is debrided and those familiar with the techniques of tracheal repair may directly anastomose the trachea. If the surgeon lacks experience or if other life-threatening injuries demand, it is preferable to anchor the distal trachea to the base of the neck and place a tracheostomy tube in the distal separated end. In this case, distal tracheostomy should not be done, as it will only further injure tracheal tissue and provide no advantage over a tube placed in the already divided end. Secondary repair can be performed at a later date. If tracheal repair is performed, it will be necessary in most cases to place a small protective tracheostomy approximately 2 cm below the anastomosis. This serves to compensate for severely impaired glottic function due to concurrent injuries to the recurrent laryngeal nerve.

Traumatic lacerations of the lower trachea can often be repaired through an anterior approach. This can be achieved either through a partial sternotomy or, if addressing cardiac injuries, through a full sternotomy with additional exposure obtained using anterior and posterior pericardiotomies between the superior vena cava and aorta. For those less familiar with this approach, the lowermost trachea as well as carinal and bronchial ruptures are best approached through a right posterolateral thoracotomy.

## Slide Tracheoplasty

Three surgical techniques have been described for correction of congenital tracheal stenoses. First, tracheal resection and reconstruction in children has been described.[21] This has limited utility in the pediatric population, as only a finite length of trachea, approximately 25 to 30 percent, can be resected and followed by end-to-end suture before excessive anastomotic tension may result in separation.[22] To address this issue, patients with long congenital stenoses have been treated with an anterior tracheoplasty and patch repair with costal cartilage or pericardium.[23] The latter must be suspended to the mediastinum, and all patch techniques require prolonged stenting with intubation during early healing. This approach has also been complicated by the formation of excessive granulation tissue arising from the mesenchymal surface of the patches, often requiring multiple bronchoscopic debridements. These patches can also suffer from necrosis and/or collapse, necessitating reoperation. Goldstraw introduced slide tracheoplasty as an alternative to the management of patients with long-segment congenital tracheal stenosis.[24]

The surgical approach for these lesions is similar to that used for tracheal pathology in adults. The upper and lower ends of the stenotic segment are precisely identified, so that the lesion might be divided horizontally at its midpoint (Fig. 8-6A). Dissection is carried circumferentially around

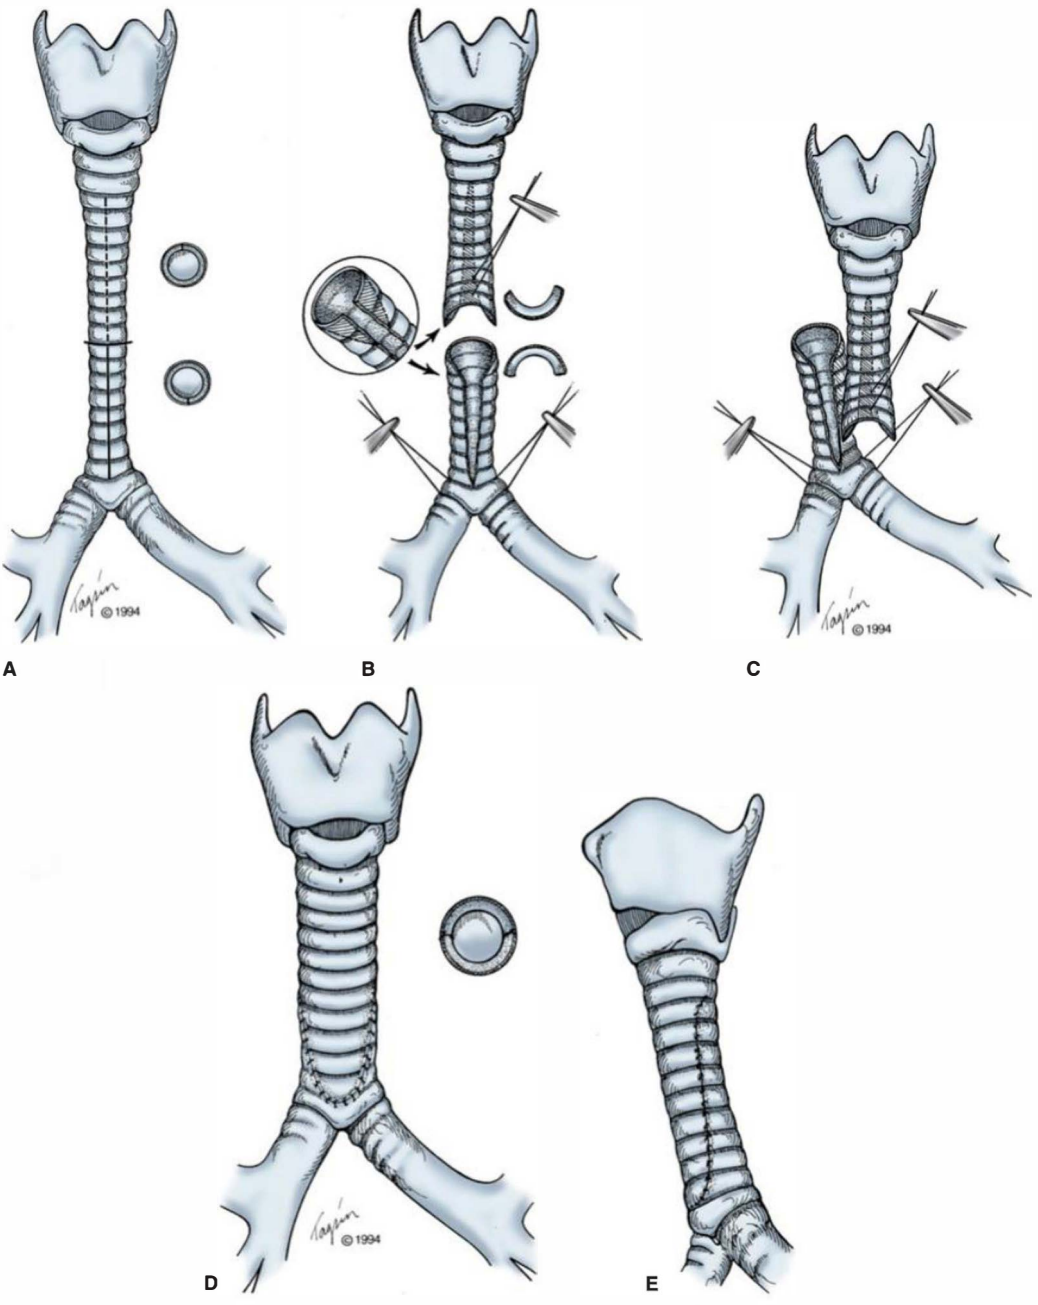

**FIGURE 8-6** Technique of slide tracheoplasty. **A.** The extent of stenosis is precisely identified. The stenotic segment is divided transversely in its midpoint after circumferential dissection at that locus only. The upper stenotic segment is incised vertically posteriorly, and the lower segment is incised anteriorly for the full length of stenosis. **B.** The right-angled corners produced by these divisions are trimmed above and below. A stay suture near the tip of the superior flap and traction sutures at the tracheobronchial angles or main bronchi are both helpful. Minimal dissection of lateral blood supply is performed. **C.** The two ends are pulled together after placement of individual anastomotic sutures around the entire oblique circumference of the tracheoplasty. **D** and **E.** The circumference is doubled, resulting in a fourfold increase in cross-sectional area. (From Grillo HC. Slide tracheoplasty for long segment tracheal congenital stenosis. *Ann Thorac Surg* 1994;59:613–621. Reprinted by permission from the Society of Thoracic Surgeons.)

the midpoint of the stenotic segment only. It is helpful to place traction sutures of 3-0 Vicryl in the midlateral point of the tracheobronchial junction on either side or in the proximal right and left main bronchi (Fig. 8-6B). Following transection of the trachea, intubation and ventilation are carried out across the operative field.

Vertical divisions of the proximal and distal segments are next carried out (Fig. 8-6B and C). It is essential that the full length of stenosis be incised. The right-angled corners of tracheal wall represented by the meeting points of the vertical and horizontal incisions are trimmed to make a gently sloping corner (Fig. 8-6D). The lateral blood supply is hardly disturbed for the lower segment, as the vertical incision is based anteriorly. For the upper segment, however, somewhat more circumferential dissection is necessary. A single 3-0 Vicryl suture is placed through and through the tracheal wall close to the distal tip of the upper flap for traction (Fig. 8-6C). The anastomosis is created using techniques similar to those described earlier (Fig. 8-6D and E).

## Tracheoesophageal Fistulas

We have proposed a conservative approach to the management of acquired, nonmalignant TEFs.[25] As stated previously, the majority of these result from complications of mechanical ventilation and most are actually diagnosed while patients are being mechanically ventilated. This important fact dictates our approach to this problem.

It is known from our experience with tracheal reconstruction for postintubation tracheal stenosis that postoperative mechanical ventilation is associated with a higher incidence of anastomotic complications.[26] Most TEFs require tracheal resection because of circumferential injury to the trachea or size of the fistula. We have therefore adopted an approach that delays definitive correction of the fistula until patients have been successfully weaned from mechanical ventilation.

The devastating pulmonary complications from TEFs can be minimized by a few simple maneuvers. A new tracheostomy tube should be placed so that the balloon is below the fistula, so as to minimize soiling of the tracheobronchial tree. A draining gastrostomy tube should be placed to minimize gastroesophageal reflux, and a feeding jejunostomy tube should be placed for nutritional supplementation. These measures should obviate the need for esophageal diversion and ligation of the gastroesophageal junction. Esophageal diversion should be reserved for continued soilage of the tracheobronchial tree despite the previously mentioned measures or for supracarinal fistulas that cannot be controlled otherwise. Once the patient is weaned from mechanical ventilation, single-stage repair can be undertaken without the risks of postoperative ventilation.

The principles of tracheal surgery must be closely followed, since many of these cases are reoperations or associated with more than the usual amount of inflammation. The most important initial decision is to determine whether the fistula can be simply resected and closed or whether tracheal resection and reconstruction will be required.

Most TEFs are approached through a low collar incision often including the tracheostomy stoma, if present. A right lateral thoracotomy through the fourth interspace is preferable for fistulas at or just above the carina or in the case of a reoperation if the previous procedure was performed through the chest.

The small TEF that does not require tracheal resection poses unique technical problems (Fig. 8-7A). Care must be taken to avoid injury to the recurrent laryngeal nerves, as local inflammation may make their identification difficult. In these circumstances, it is best to identify the nerves at a location remote from the fistula. The nerves should be elevated with the trachea during exposure of the fistula.

Once the fistula is identified, it should be divided. We prefer to close the tracheal defect with absorbable suture material (4-0 Vicryl). The esophageal defect is then closed in two layers (Fig. 8-7B). A local strap muscle is mobilized to buttress and separate the tracheal and esophageal suture lines (Fig. 8-7C). This should minimize the risk of recurrent fistula.

The fistula that requires tracheal resection, although technically more complicated, provides significantly improved exposure. Circumferential dissection above and below the fistula should be very close to the trachea to avoid injury to the recurrent nerves. Resection of the damaged portion of the trachea gives excellent exposure of the esophageal defect (Fig. 8-8A). The esophageal defect is closed longitudinally in two layers (Fig. 8-8B). It is essential to separate the esophageal suture line with a local strap muscle to help prevent recurrent TEF (Fig. 8-8C). Tracheal reconstruction is performed as detailed earlier (Fig. 8-8D).

## Idiopathic Laryngotracheal Stenosis

Inflammatory stenosis of the upper trachea, which also involves the subglottic larynx, cannot be treated by simple circumferential resection, since this would destroy the function of the recurrent laryngeal nerves. Many complex and multistaged procedures have been devised to solve this problem. In an effort to improve the results obtained by such operations, single-stage procedures involving partial resection of the subglottic larynx and immediate plastic reconstruction by varying techniques have evolved yielding good results. In those patients in whom the stenotic process involves only the anterior portion of the subglottic larynx, resection of this portion of the cricoid arch is sufficient (Fig. 8-9). The posterior margin of resection is along the lower border of the cricoid cartilage.

In patients with circumferential subglottic lesions extending in front of the posterior plate of the cricoid,

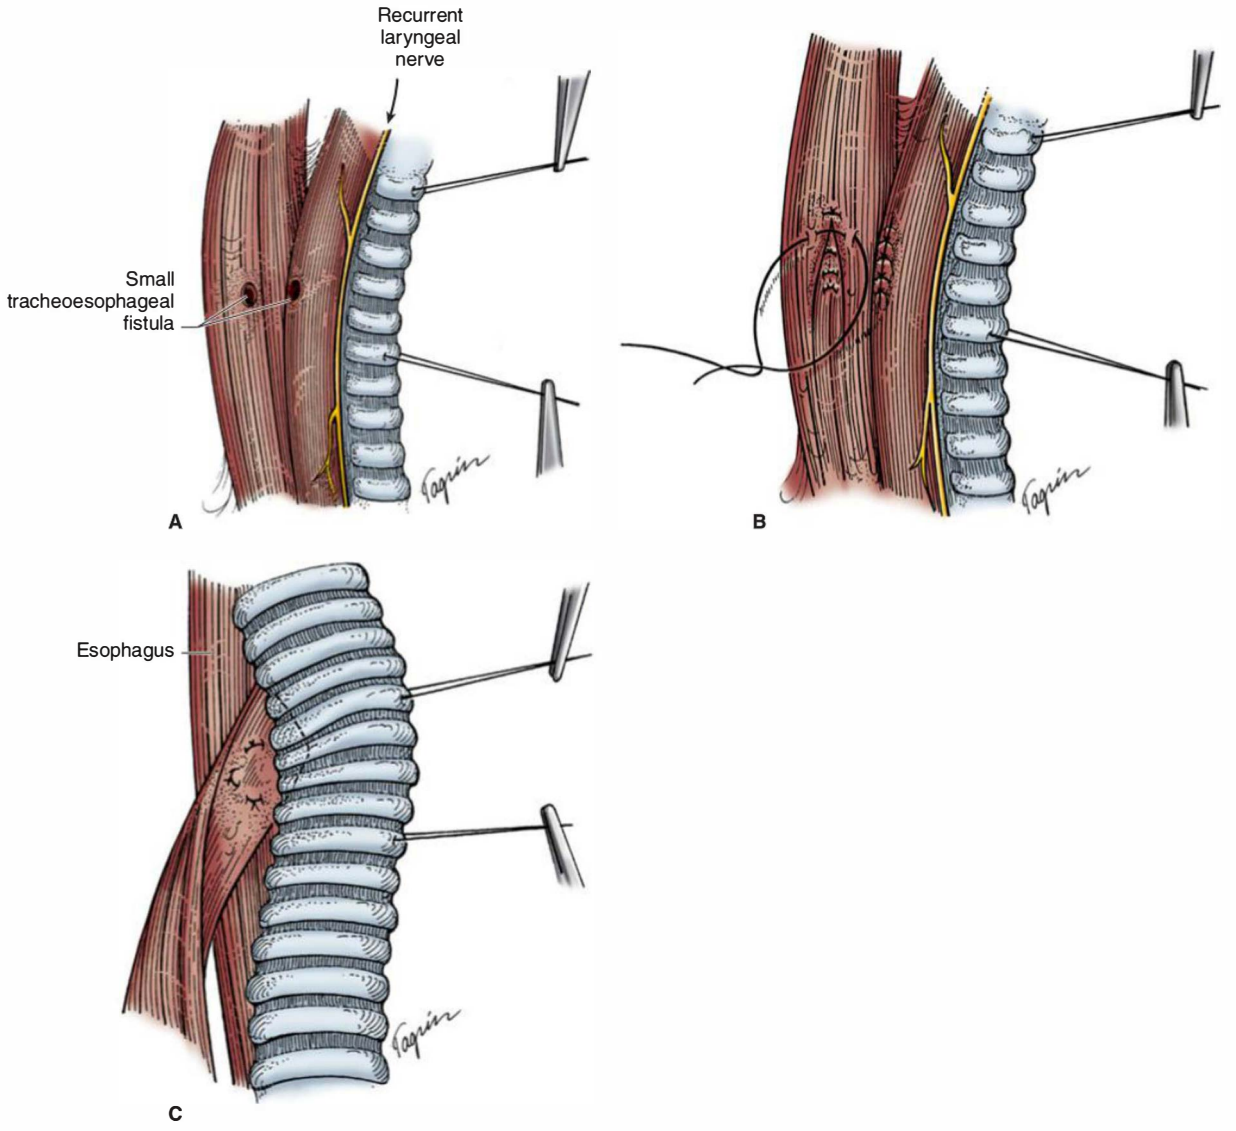

**FIGURE 8-7** **A** and **B.** Small tracheoesophageal fistula treated by division and local repair. The recurrent laryngeal nerve is elevated with the trachea. The esophagus is closed in two layers. **C.** A strap muscle is used to cover the esophageal suture line and separate it from the tracheal suture line. (From Mathisen DJ, Grillo HC, Wain JC, Hilgenberg AD. Management of acquired nonmalignant tracheoesophageal fistula. *Ann Thorac Surg* 1991;52:759–765. Reprinted with permission from the Society of Thoracic Surgeons.)

the line of posterior mucosal resection is incised above the level of stenosis, approaching the arytenoid cartilages (Fig. 8-10A). All involved mucosa and scar tissue is excised from the front of the posterior cricoid plate, leaving the cartilage intact posteriorly to be surfaced by a broad-based flap of membranous trachea advanced from below (Fig. 8-10B). The posterior cricoid plate itself is usually not significantly involved. The plane between mucosa and cartilage can be dissected with a scalpel or bluntly with a fine dental spatula. One must stop short of the superior border of the cricoid plate, which lies immediately below the arytenoid cartilages. No attempt is made to groove or otherwise alter the posterior cricoid cartilage itself. Division of the trachea is also carried out differently. Posteriorly, a flap of membranous wall is fashioned (Fig. 8-10C). When the anastomosis is made, the posterior mucosal sutures pass only through the full thickness of mucosa and submucosa of the posterior wall of the larynx and then through the full thickness of the membranous wall of the trachea (Fig. 8-10D).

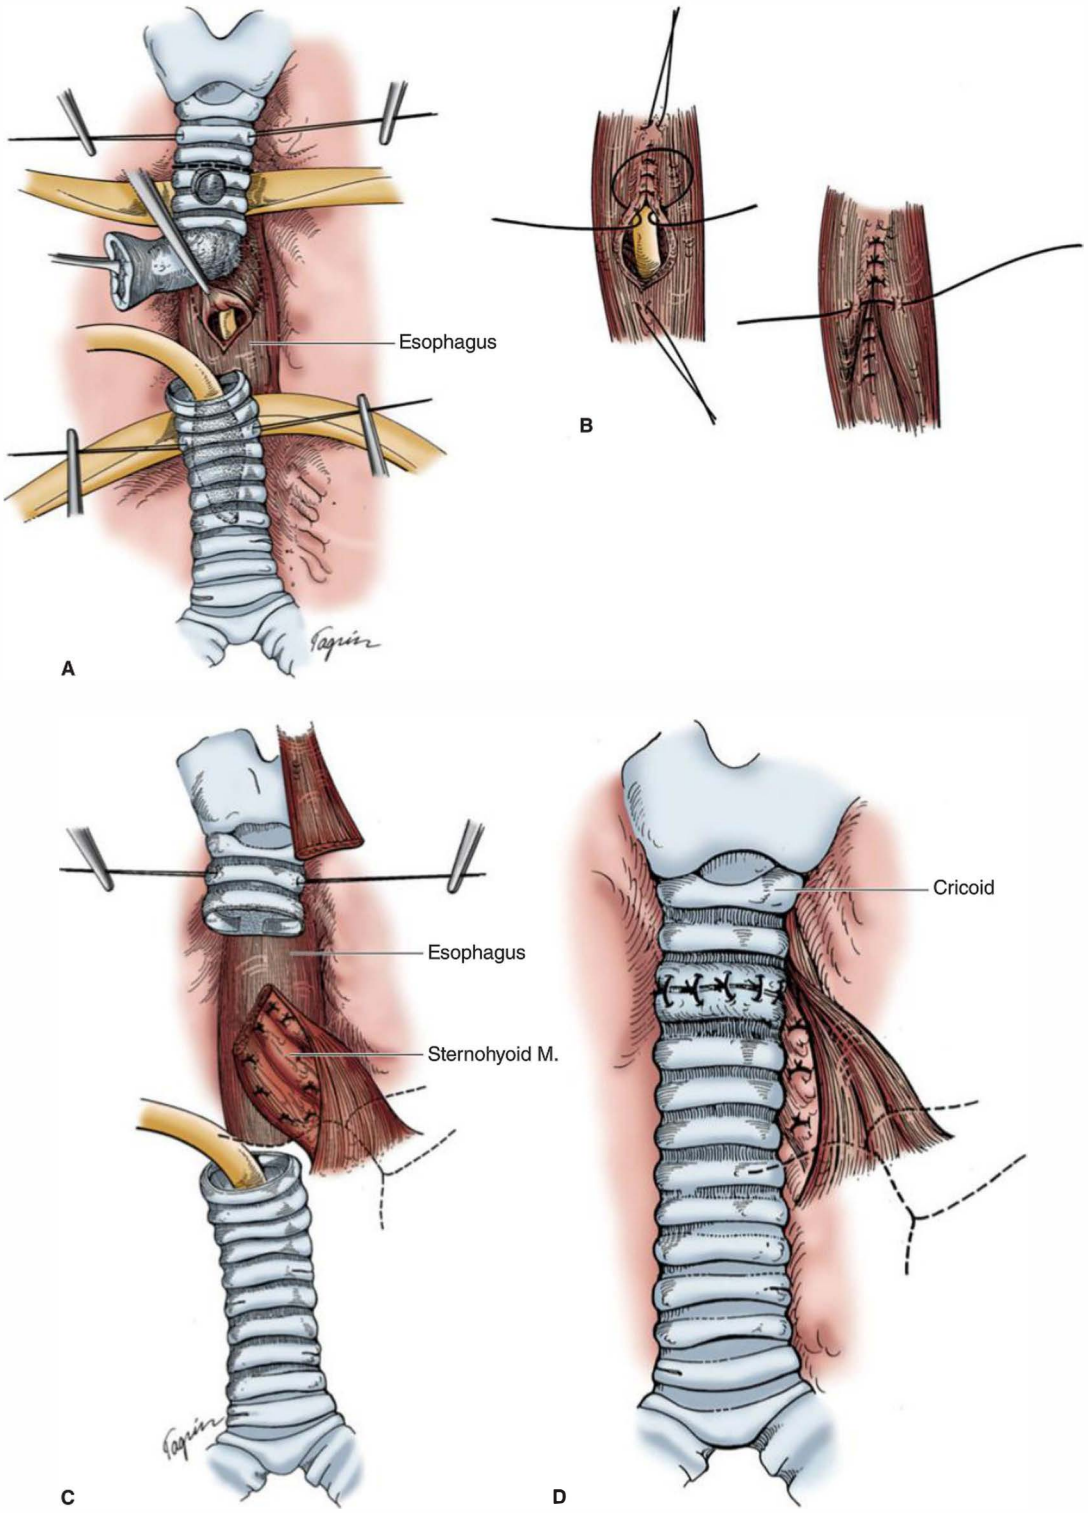

**FIGURE 8-8** **A.** Circumferential dissection above and below the fistula is near the trachea to avoid injury to the recurrent nerves. Division of damaged trachea gives excellent exposure to the esophageal defect. **B.** The esophageal defect is closed in two layers. **C.** A local strap muscle is used to buttress the esophageal closure and separate it from the tracheal suture line. M, muscle. **D.** Completed tracheal anastomosis, with strap muscle posterior to it separating it from the esophageal suture line. (From Mathisen DJ, Grillo HC, Wain JC, Hilgenberg AD. Management of acquired nonmalignant tracheoesophageal fistula. *Ann Thorac Surg* 1991;52:759–765. Reprinted with permission from the Society of Thoracic Surgeons.)

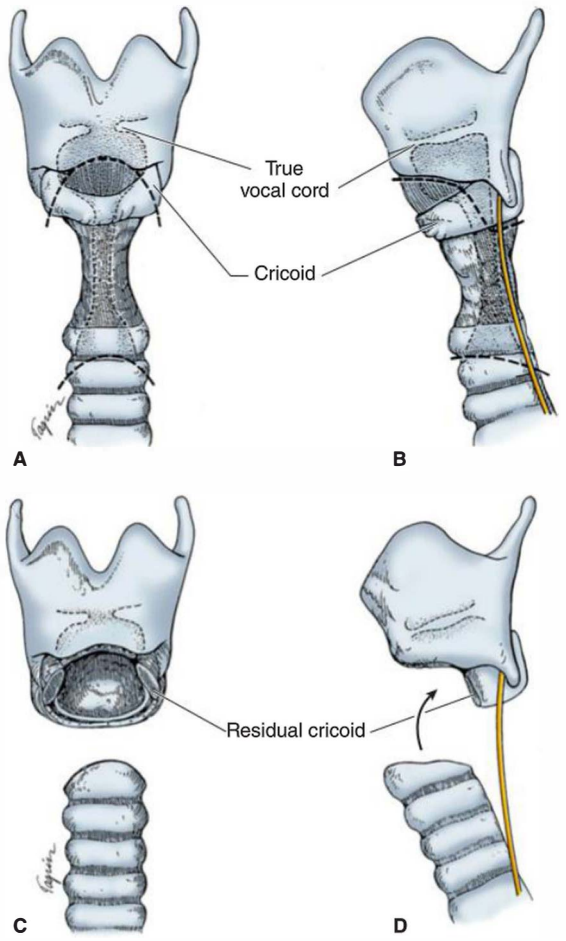

**FIGURE 8-9** Operative repair of anterolateral stenosis of the subglottic larynx and upper trachea. **A.** Anteroposterior view. **B.** Lateral view. The figures demonstrate the extent of stenosis and ultimate lines of transection. The stenosis extends into the subglottic larynx well above the border of the cricoid anteriorly. There is, however, no involvement of the posterior mucosal wall of the subglottic larynx or of the upper trachea. The proximal line of transection is centered in the midline to divide the larynx from the trachea posteriorly at the lower border of the posterior cricoid lamina or cricoid plate. Inferiorly, the most proximal tracheal ring of residual trachea is cut backward to posterior ends. **C** and **D.** Larynx and trachea after removal of the specimen. The recurrent laryngeal nerves have been left intact but are not dissected out, as might be suggested by the diagrammatic representation. The mucous membrane of the larynx has been transected sharply at the same level of division as the cartilage.

The margin of the anterior defect in the subglottic larynx is sutured in both types of resection to a prow-shaped segment of one distal tracheal ring (Fig. 8-9D). The midline of the thyroid cartilage is approximated to the midline of the peak of the most proximal cartilage of the trachea. The traction sutures are tied and followed by the individual anastomotic sutures.

# RESULTS

## Congenital Stenosis

We have generally followed a conservative therapeutic approach to airway lesions in infants and small children. As indicated earlier, the juvenile trachea tolerates anastomotic tension less well than the adult. Furthermore, following anastomosis, a small amount of edema in a small airway may cause more significant obstruction than a similar thickness of edema in the adult. While growth of a stenosis is in general proportional to that of the normal tissues and does not actually correct congenital stenosis, sufficient improvement may obviate the need for correction or permit the patient to grow, so that surgical reconstruction can be performed with less risk. As described earlier, most cases of congenital tracheal stenosis are best addressed with slide tracheoplasty.

On completion of this procedure, the circumference of the trachea is doubled, the cross-sectional area is quadrupled, and the stenotic segment is shortened by half. It is clearly advantageous to have the trachea repaired with the tracheal wall containing native cartilages and normal tracheal epithelium. It has been demonstrated that this repair provides a permanent enlargement of the airway diameter and does not inhibit subsequent tracheal growth.

Since the introduction of slide tracheoplasty at the Massachusetts General Hospital in 1991, we have treated eight patients ranging in age from 10 days to 19 years with stenoses varying in length and location as well as other associated congenital lesions.[27] All patients survived and obtained a widely patent and stable airway. In all juvenile patients, the repaired tracheal segment continued to grow. Given the intolerance of tension in juvenile tracheal anastomosis, slide tracheoplasty should, in our opinion, be considered for all but the shortest stenotic segments.

## Posttraumatic Stenosis

Earlier we published our experience in treating traumatic injuries to the airway.[6] In this series, 10 patients with acute injuries and 17 with delayed traumatic laryngotracheal stenosis were evaluated and treated. All 10 of the acute injuries had excellent airway preservation; voice was preserved and successful repair of the esophagus made in one. Repair of delayed stenosis was successful in 16 of 17 patients. All but one patient had preservation of voice, despite the presence of vocal cord paralysis in 14 patients preoperatively. The cases of concomitant esophageal injury, present in four patients, were successfully repaired without development of TEF.

## Postintubation Stenosis

Postintubation tracheal injuries remain the most common indication for tracheal resection and reconstruction, despite definition of the etiology of these lesions and development

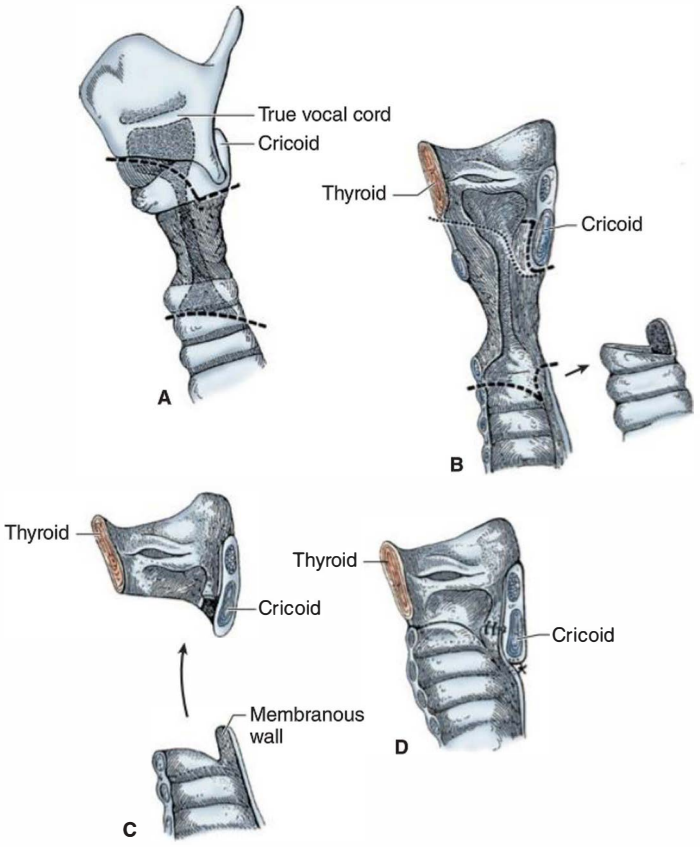

**FIGURE 8-10** Resection and reconstruction of circumferential stenosis of the subglottic larynx and upper trachea. **A.** External line of cartilaginous division of both larynx and trachea is the same as for anterolateral stenosis. **B.** Interior views of the larynx and trachea demonstrate modifications necessary when the stenosis involves the mucosa and submucosa just in front of the posterior cricoid plate. The superior dotted line indicates that the mucosa with its scarring will be cut back to within a short distance, if necessary, of the arytenoid cartilages. Inferiorly, the posterior membranous wall has been retained as a broad-based flap. **C.** Resected specimen, leaving a bare area of the intraluminal portion of the lower part of the cricoid posterior lamina. The flap of membranous wall of the trachea will be fitted into this defect to provide prompt and complete mucosal coverage. **D.** The mucosa of the larynx has been anastomosed to the mucosa of the membranous wall of the trachea. External to the lumen, connective tissue of the membranous wall has been fixed with four sutures to the inferior margin of the cricoid cartilage, ensuring that the flap will stay firmly applied to the surface. (From Grillo HC. Reconstruction after subglottic laryngeal and upper tracheal stenosis resection. *Ann Thorac Surg* 1982;33:3–18. Reprinted with permission from the Society of Thoracic Surgeons.)

of techniques for their avoidance. We reported 503 patients who underwent tracheal resection and reconstruction for postintubation lesions.[26] The balloon cuff of an endotracheal or tracheostomy tube accounted for 251 lesions; 178 lesions were at the site of a tracheostomy, and 38 patients had evidence of both lesions. In 36 patients, the exact site was uncertain, often due to prior attempts at treatment including multiple tracheostomies. Of the 503 patients, 441 had lesions that were isolated to the trachea, while 62 had concomitant involvement of the subglottic larynx.

Many patients had undergone prior attempts at surgical treatment before referral. These included resection ($n = 53$); tracheal operations such as wedge resection, splinting, or fissure ($n = 31$); and laryngeal procedures such as stenting, grafting, or fissure ($n = 20$). Sixty patients had had T tubes placed and at least 45 had had laser treatment. Eight patients had prior repairs of TEF, three of which had failed.

The initial procedure was carried out through a cervical incision in 350 patients. In 145 patients a partial upper sternal division through the sternal angle was used, with two more patients requiring the addition of right anterior thoracotomy to this approach. Six patients underwent repair via a high posterolateral thoracotomy. The amount of trachea resected ranged from 1.0 to 7.5 cm and was most commonly between 2 and 4 cm.

Of the 503 initial operations, 324 involved a trachea-to-trachea anastomosis and 117 patients had reconstructions involving partial resection of the cricoid cartilage with laryngotracheal anastomosis. In the total series of 503 patients 9.7 percent underwent laryngeal releases. However, only 8 percent of the 450 patients who had not undergone tracheal resection and reconstruction previously were deemed to need laryngeal release to reduce anastomotic tension, in comparison with 24.5 percent of the 53 who had prior resection and reconstruction. Many in the former group represent our earlier experience in tracheal surgery. Only one patient required intrapericardial hilar release.

The results have been classified as good, satisfactory, failure, and death. The result is described as good if the patient is functionally able to perform usual activities and postoperative roentgenograms or bronchoscopic examinations show an anatomically good airway. Patients are placed in the satisfactory category if they can perform normal activities but are stressed on exercise. In the absence of symptoms, this is also applied to those with abnormalities involving the vocal cords or those with significant airway narrowing evident on either endoscopic or roentgenologic examination. Failure indicates the need for a permanent tracheostomy or T tube.

The average length of follow-up was 3 years. The results were categorized as good in 440 patients and satisfactory in

31 patients; there were 20 failures and 12 deaths. Failure was treated with tracheostomy ($n = 11$), T tube ($n = 7$), or dilations ($n = 2$).

## Idiopathic Laryngotracheal Stenosis

In experienced hands, laryngotracheal resection and reconstruction is associated with excellent results and minor complications. In our experience treating this rare entity, all but 2 of 73 patients were female.[10] The duration of symptoms before evaluation varied between 4 months and 32 years, with the greatest number reporting 1 to 3 years of symptoms. At the time of referral, a total of at least 75 procedures had been performed on 28 of the 73 patients. The extent of surgical resection ranged from 1 to 5 cm with an average of 2.6 cm. Resection of the entire anterior cricoid was performed in 59 patients, while only partial or no cricoid resection was necessary in 10 and 4 patients, respectively. Thirty-six patients required mucosal resection from the posterior cricoid plate, with tracheal membranous wall advancement flap reconstruction.

Extubation in the operating room was possible in 67 of the 73 patients. These patients did not require further airway intervention during their initial hospital stay. Immediate protective tracheostomies were placed in five patients; however, only one was used in the last 30 patients of this series. One patient had a negative reexploration for postoperative cervical subcutaneous emphysema. Six patients underwent early dilation for obstructing granulation tissue.

In long-term follow-up, 66 (92 percent) patients had either excellent ($n = 19$) or good ($n = 47$) results. Of the remainder, five required only occasional dilations. A poor result was seen in one patient in whom at least yearly dilations became necessary. No patients in this series have required permanent tracheostomies or T tubes. In addition, there was no perioperative mortality.

## Tracheoesophageal Fistula

We have reported our results on the treatment of benign acquired TEFs in 38 patients.[25] The vast majority resulted from the combined effects of a nasogastric tube and either an endotracheal tube or a tracheostomy tube. The remainder were secondary to laryngotracheal trauma ($n = 5$) and complications of radiation therapy ($n = 2$) and anterior spinal fusion ($n = 2$).

Eight patients had undergone attempted repair at other institutions. Many had more than one attempted repair. The reasons for failure included the need for postoperative mechanical ventilation and failure to interpose tissue between tracheal and esophageal suture lines. Seven patients from other institutions underwent esophageal diversion with cervical esophagostomy or pharyngostomy and three had ligation or interruption of the gastroesophageal junction.

Tracheal resection and reconstruction was performed in 31 patients. This was done to address the presence of full-thickness circumferential damage at the level of the tracheal pathology or when the defect in the membranous tracheal wall was too large for direct closure. Six of these patients additionally had longitudinal closure of the membranous wall of the trachea where the fistula had been located. The amount of injured trachea would have been too excessive to allow reconstruction otherwise. Five patients had laryngotracheal resection because of pathology involving the subglottic larynx. Tracheal damage was too extensive in one patient to allow tracheal resection; therefore a T tube was placed following repair of the fistula. There has been no recurrence of the fistula in this patient and a good airway is maintained in this fashion.

Thirty-three patients had direct closure of the esophageal fistula by using a two-layer closure as described. Some narrowing of the esophageal lumen is inevitable in this situation but is well tolerated by most patients. Because of prior cervical esophagostomy, five patients underwent end-to-end esophageal anastomosis. Thirty-four patients had interposition of a local strap muscle between the esophageal and tracheal suture lines. Cervicomediastinal exenteration with creation of a mediastinal tracheostomy and a substernal colon bypass was required for a TEF following laryngectomy and irradiation.

Four patients died following the repair of TEFs (10.5 percent). Three of these died following attempted transthoracic repair of very distal TEF. All had extensive mediastinal sepsis at the time of repair and required mechanical ventilation after surgery. The fourth death occurred in a young man who underwent extensive tracheal resection with laryngeal release. Tracheal separation occurred on the sixth postoperative day and the patient could not be resuscitated.

Two patients developed small recurrent TEFs requiring reoperation. Both had previous cervical esophagostomies and required end-to-end anastomoses. Theses recurrent fistulas were small and were successfully managed by short tracheal resection and closure of the esophageal defect. Tracheal stenosis developed at the level of the retained stoma in one patient and was corrected by a second tracheal resection.

Of the 34 surviving patients, 33 were able to take aliment orally. Five patients required esophageal dilatation for narrowing at the level of the repair of the esophageal fistula. None still require dilation. The one patient who does not take aliment orally is also one of two patients requiring a tracheal appliance to provide an airway. Another patient requires a T tube because of the extent of injury to her airway.

Single-stage repair of a TEF gives excellent results, with a low incidence of recurrent fistulas. These results continue to support the approach outlined for management of acquired nonmalignant TEFs.

## Primary Tracheal Tumors

Gaissert summarized the 40-year cumulative experience at Massachusetts General Hospital of treating primary ACCs and SCCs of the trachea.[13] During this time, 270 patients

**TABLE 8-1: Experience with Primary Tracheal Carcinoma Over Four Decades a t Massachusetts General Hospital[a]**

| Decade | Total Patients (*N*) | ACC Patients (*N*) | SCC Patients (*N*) | Resections Performed (*N*) | Resection Rate (%) | Hospital Mortality (%) |
|---|---|---|---|---|---|---|
| 1962–1971 | 19 | 7 | 12 | 13 | 68 | 21 |
| 1972–1981 | 54 | 29 | 25 | 33 | 61 | 11 |
| 1982–1991 | 107 | 54 | 53 | 71 | 66 | 5 |
| 1992–2001 | 88 | 43 | 45 | 72 | 82 | 3 |
| Total | 268 | 133 | 135 | 189 | 71 | 7 |

ACC, adenoid cystic carcinoma; SCC, squamous cystic carcinoma.

[a]Two patients operated on in 2002 were excluded from the table.

were evaluated, with histologic distribution equally distributed between ACC and SCC. Resection was performed in 191 (71 percent) patients, with an operative mortality of 7.3 percent (14 of 191). Importantly, both rates of resection and hospital mortality have improved with e ach decade (Table 8-1). As our experience has grown, operative mortality has decreased from 21 percent in the 1960s to 3 percent in this last decade.

Resection was not performed in 79 patients, 34 in those with ACC (25 percent) and 45 patients with SCC (33 percent). Contraindications to resection have included tumor length (67 percent) and locoregional extent (24 percent) in the vast majority of cases, with distant metastases only rarely present (7 percent). The determination of unresectability was made during operative exploration in 17 of 208 patients (8 percent). ACCs tended to be longer lesions and were also associated with more significant locoregional extension. This explains the more frequent observation of ACC resection with positive microscopic tracheal and radial margins (59 percent) as compared with SCCs (18 percent).

The overall survival for all patients with primary tracheal carcinoma was 84 percent at 1 year, 45 percent at 5 years, and 25 percent at 10 years. Mean survival was 38 months in resected SCCs, 8.8 months in resectable SCCs, 69 months in resected ACCs, and 41 months in unresectable ACCs. Notably, survival after incomplete resection of ACCs was still 14.5 percent at 15 years.[16] Multivariate analysis identified ACCs and complete resection to be associated with 5-year survival and ACCs, complete resection, and age to be associated with 10-year survival. Tumor length, lymph node status, or type of resection did not influence long-term survival.[28]

The presence of tumor at the resection margins of ACCs, even by frozen section during operation, has particular importance in airway reconstruction. The surgeon must often compromise complete resection for the sake of safety, and the above data indicate that a small though not statistically significant survival benefit exists in these patients. All these patients now receive postoperative irradiation. Suture line recurrence thus far has been rare, and late recurrence has been that of distant disease. In contrast, irradiation of unresected tumor is all but uniformly characterized by local recurrence in 3 to 5 years despite a good response early.

We separately analyzed clinical and pathologic characteristics of resected squamous cell tumors to determine prognostic factors. All five patients with tumor extension into the thyroid gland died of disease within 3 years. Lymphatic invasion and poorly differentiated tumors were associated with worse prognosis, while keratinization, necrosis, and tumor thickness were not.[29]

The analysis of this 40-year experience with surgical management of primary tumors of the trachea appears to confirm and extend conclusions based on previously reported experiences.[30] Primary ACCs and SCCs of the trachea are best treated by resection when primary reconstruction may be safely accomplished. Resection should be followed by full-dose mediastinal irradiation in most cases.

## COMPLICATIONS

Complications following tracheal surgery are similar regardless of the problem for which resection and reconstruction is performed. Wright and colleagues[31] recently presented the most complete analysis of anastomotic complications after tracheal resection. This review of 901 patients identifies relevant risk factors for the development of these problems and further describes their management. Anastomotic complications include granulations at the suture line, stenosis, and tracheal separation.

A significant reduction in suture granuloma formation has been seen since the conversion to absorbable suture material used for the anastomosis. In fact, the use of absorbable Vicryl sutures since 1978 has all but eliminated suture-related granulations. These can be successfully managed with bronchoscopic suture removal and local steroid injection. More extensive processes may require reoperation for resection, T-tube placement, or tracheostomy.

Stenosis and separation of a tracheal, carinal, or bronchial anastomosis are feared complications of airway reconstructive surgery. Excessive tension on an anastomosis is probably the most frequent cause of technical failures.

Dangerous tensions may appear after resection of more than 50 percent of the trachea in the adult and of more than 30 to 40 percent in the child. These are very general percentages and do not apply to specific individuals, who may vary widely with respect to age, body habitus, pathology, prior surgery, and other comorbidities. Carinal resections are particularly at risk because of the complex nature of the reconstructions required and the fact that primary tumors may involve a considerable length of trachea as well as of main bronchi.

Several predictors of anastomotic complications were demonstrated: reoperation, diabetes, lengthy (≥4 cm) resections, laryngotracheal resections, age ≤17 years, and need for a tracheostomy before operation. The frequency of anastomotic complications was higher in patients undergoing operations for TEF than in those being treated for tracheal tumors, postintubation stenoses, and idiopathic laryngotracheal stenoses. Of note, corticosteroid use was not associated with an increase in complication rate. This is most likely secondary to the management strategy of our group, which is to defer tracheal operations in the presence of high-dose steroids until such drugs can be effectively tapered.

Overall, 81 patients experienced anastomotic complications in this series. Thirty-seven patients had separation of the suture line, another 37 patients developed anastomotic stenosis, and 7 had airway obstruction from granulation tissue formation.

Complications were treated with multiple dilations ($n = 2$), temporary tracheostomy ($n = 7$) or T-tube ($n = 16$) placement, permanent tracheostomy ($n = 14$) or T-tube ($n = 20$) placement, and reoperation ($n = 16$). The mortality of patients who had anastomotic complications was 7.4 percent (6 of 81), compared with 0.06 percent (5 of 820) in those without anastomotic complications. In this series, no patient has died due to their anastomotic complications since 1988. This success is attributed to the routine use of postoperative bronchoscopy and the early recognition and subsequent definitive management of anastomotic complications.

With attention to detail, even complications can be successfully managed. Successful management not only saves a life but also preserves the airway and voice.

## TRACHEAL DISEASES BOARD REVIEW QUESTIONS (CHAPTER 8)

1. Predictors of anastomotic complications after tracheal resection include all of the following except?
   A. Diabetes
   B. Reoperative tracheal surgery
   C. Female gender
   D. Length of resection
   E. Age less than 18 years

2. A 45-year old woman is undergoing tracheal resection for adenoid cystic carcinoma. A 4-cm tracheal resection is performed through a cervical incision, with the distal extent of resection located 4 cm from the carina. The tumor has been grossly resected, but there are malignant cells at the distal margin. Which of the following is the correct next course of action?
   A. Partial sternotomy, laryngeal release, and resection of additional trachea with primary reconstruction, postoperative radiotherapy.
   B. Right thoracotomy, pericardial release, and resection of additional trachea with primary reconstruction.
   C. Right thoracotomy, resection of additional trachea with mediastinal tracheotomy.
   D. Tracheal reconstruction, postoperative chemotherapy.
   E. Tracheal reconstruction only.

3. A 74-year-old man develops a tracheoesophageal fistula due to prolonged ventilator support and tracheostomy. Which of the following is the most appropriate treatment?
   A. Tracheal and esophageal covered stent deployment.
   B. Immediate repair of fistula with muscle interposition.
   C. Replacement of tracheostomy appliance with balloon below fistula and decompressive gastrotomy and jejunostomy until no longer requiring mechanical ventilation.
   D. Treatment with antibiotics and tube feeding until no longer requiring mechanical ventilation.
   E. Esophageal exclusion.

4. A patient with known postintubation stenosis presents to the ER with progressive dyspnea after an upper respiratory infection. Although well saturated with face mask oxygen, she cannot speak in full sentences and is anxious. Which of the following is the most appropriate initial treatment?
   A. Rigid bronchoscopy with tracheal dilation in the operating room.
   B. Flexible bronchoscopy in the emergency department.
   C. Immediate fiberoptic intubation.
   D. Tracheostomy in the operating room.
   E. Intravenous steroids and nebulized epinephrine.

5. Which of the following does not decrease tension during tracheal resection?
   A. Neck flexion
   B. Mobilization of the pretracheal plane
   C. Circumferential tracheal dissection
   D. Suprahyoid laryngeal release
   E. Pericardial hilar release

## ANSWERS

1. **Answer: C.** Female gender is not a predictor of anastomotic complication after tracheal resection.
2. **Answer: A.** Partial upper sternotomy, with or without laryngeal release, will allow for additional tracheal resection from a cervical approach.
3. **Answer: B.** Single-stage repair provides a definitive treatment with excellent results. Muscle or omental interposition is the key to reducing the incidence of fistula recurrence in patients on mechanical ventilation.
4. **Answer: A.** Patients with airway strictures are best managed in the controlled setting of the operating room with rigid bronchoscopy and dilation. Tracheostomy should be avoided, as this can result in more extensive stricture formation of a longer segment of trachea.
5. **Answer: C.** Circumferential tracheal dissection has little effect on mobilization and can result in devascularization of the trachea with associated suture line breakdown.

# 9 Primary Lung Cancer

*Min P. Kim*
*Ara A. Vaporciyan*

**KEY CONCEPTS**

- Epidemiology
  - Lung cancer is a leading cause of preventable death attributed to smoking and environmental exposure. Its highest incidence is in men but recent trends have shown a significant increase in women paralleling the trend of smoking prevalence in different genders.
- Pathophysiology
  - Most of lung cancer is the result of a series of genetic changes caused by environmental factors that allow cells to grow, proliferate, and metastasize.
- Clinical features
  - Most lung cancer patients present with late-stage disease. Patients' clinical symptoms depend on the location and size of the tumor and the presence of metastasis.
- Diagnostics
  - Lung cancer diagnosis is accomplished through the pathologic examination of a biopsied specimen of the mass. Clinical staging is based on a combination of patient history, physical exam, and radiographic information along with pathologic examination of the primary tumor, mediastinal lymph nodes, and any suspected sites of metastasis.
- Treatment
  - Lung cancer patients are treated with surgery, radiotherapy, and/or chemotherapy. Surgery and radiotherapy are used for local and regional lung cancer; surgery is the primary therapy, and radiotherapy is used in patients who cannot tolerate surgery. Chemotherapy is used to treat patients with regional or metastatic lung cancer.
- Prognosis
  - Overall, the prognosis for lung cancer is poor. The estimated overall 5-year survival rate for all of the patients with lung cancer is about 16 percent; however, patients with resected pathologic early-stage lung cancer can achieve a 5-year survival rate of 70 to 80 percent. The type and pathologic stage of lung cancer is the best predictor for prognosis.

## INTRODUCTION

### Historical Highlights

Lung cancer, once considered rare at the beginning of the 20th century, became a frequently diagnosed disease by the mid-1930s. Oschner and Debakey attributed the increased incidence to the rise in smoking, a link that was later supported by the findings of a case-control study in 1939.[1] The surgical treatment of lung cancer has evolved over time. The first successful single-stage pneumonectomy was performed by Graham and Singer in 1933,[2] and the modern technique of ligating individual pulmonary vessels and suturing the bronchus was first described by Reinhoff in 1947.[3]

## PATHOLOGY

Lung cancer originates from epithelial cells. The two broad categories of lung cancer are nonsmall cell lung cancer (NSCLC), which constitutes about 80 percent of lung cancers, and small cell lung cancer (SCLC).

### Nonsmall Cell Lung Cancer

#### ADENOCARCINOMA

Adenocarcinoma, the most common type of NSCLC, is a malignant epithelial tumor with glandular differentiation or mucin production. Adenocarcinomas are white, fleshy

solid tumors that are usually located in the periphery of the lung and involve the pleura and chest wall in 15 percent of patients. There are five macroscopic growth patterns of adenocarcinoma; the most common pattern is peripheral tumor with desmoplastic fibrosis retracting the overlying pleura. Other patterns include central or endobronchial adenocarcinoma, diffuse pneumonia-like consolidation or papillary growth, diffuse pleural thickening or pseudomesotheliomatous carcinoma, and adenocarcinoma arising in the background of underlying fibrosis. There are four distinct histologic patterns or subtypes of adenocarcinoma. They are acinar, papillary, bronchioloalveolar, and solid adenocarcinoma with mucin production. It is uncommon to have an adenocarcinoma consisting entirely of one histologic pattern. Most tumors have mixed histology although one subtype is frequently dominant. Immunohistochemistry of adenocarcinoma reveals the expression of the epithelial markers cytokeratin 7 (CK7) and thyroid transcription factor-1 (TTF-1).[4] As the name implies, TTF-1 is a protein that not only regulates transcription of genes specific for thyroid, but is also specific for lung. Patients with lung tumor that is positive for TTF-1 but negative for thyroglobulin, a protein produced exclusively by thyroid, confirm that the tumor arises from the lung.

#### SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma, which constitutes approximately 40 percent of NSCLC, is a malignant, typically cavitary tumor that arises centrally from bronchial epithelium. Squamous cell carcinomas are usually white or gray and grow laterally along the bronchial mucosa ("creeping type") or downward ("penetrating type"). Squamous cell carcinomas tumors show keratinization, pearl formation, and/or intercellular bridges on histopathologic examination, and immunohistochemistry reveals keratin, carcinoembryonic antigen, and cytokeratin 5 and 6 expression.[4]

#### LARGE CELL CARCINOMA

Large cell carcinoma, which constitutes about 9 percent of NSCLC, is a poorly differentiated epithelial tumor consisting of sheets or nests of large polygonal cells with vesicular nuclei and prominent nucleoli. Large cell carcinoma is usually diagnosed by excluding other tumor types during histopathologic examination. Most large cell carcinomas are located in the peripheral lung and invade the visceral pleura, chest wall, or adjacent structures.

#### NEUROENDOCRINE TUMORS

Neuroendocrine tumors range from indolent to aggressive. The four types of neuroendocrine tumors—typical carcinoid, atypical carcinoid, small cell lung cancer, and large cell neuroendocrine carcinoma—all exhibit organoid nesting, palisading, a trabecular pattern, and a rosette-like structure. The main criterion used to distinguish the different types of neuroendocrine tumor is the number of mitoses per 10 high-power fields of magnification. Typical carcinoid tumors have two mitoses or less and do not have necrosis, atypical carcinoid tumors have between 2 and 10 mitoses or evidence of necrosis, and small cell lung cancers and large cell neuroendocrine carcinomas have 11 or more. A constellation of features distinguishes small cell lung cancer and large cell neuroendocrine carcinoma. Large cell neuroendocrine carcinoma has cytologic features of NSCLC with large cell size, low nuclear-to-cytoplasmic ratio, vesicular chromatin, and frequent nucleoli. On the other hand, small cell carcinoma has scant cytoplasm and absent or faint nucleoli. Immunohistochemistry of neuroendocrine tumors reveals cytokeratin, chromogranin, synaptophysin, CD57, and CD56 expression.[4]

#### OTHER TUMORS

Adenosquamous carcinoma, mucoepidermoid carcinoma, adenoid cystic carcinoma, epithelial–myoepithelial carcinoma, and sarcomatoid carcinoma compose about 2 percent of NSCLC.[5]

### Small Cell Lung Cancer

Small cell lung cancer is an epithelial tumor that consists of small cells with scant cytoplasm, ill-defined borders, finely granular nuclear chromatin, and absent nucleoli. Small cell lung cancer is usually a hilar or perihilar mass with mediastinal lymphadenopathy. The tumors are typically white-tan, soft, friable masses with extensive necrosis. Immunohistochemistry of small cell lung cancer reveals TTF-1, CD56, chromogranin, and synaptophysin expression.

## PATHOPHYSIOLOGY

Development of lung cancer is considered as a series of genetic changes induced by environmental factors, which leads a normal cell to develop into a cancer. These genetic changes are mutations of the tumor oncogenes and tumor suppressors as well as the change in the tumor microenvironment that allows the tumor to grow and metastasize into other organs.

### Oncogenes and Tumor Suppressors

The two most common types of NSCLC are adenocarcinoma and squamous cell carcinoma, both of which develop from normal epithelium into invasive cancer through a series of genetic mutations of tumor oncogenes and tumor suppressors. In adenocarcinoma, the first histologically noticeable change is the development of atypical adenomatous alveolar hyperplasia, which then develops into bronchoalveolar carcinoma and ultimately invasive adenocarcinoma. The genetic changes that have been associated

with this progression include mutations of the Kirsten rat sarcoma (K-RAS) viral oncogene homolog and epithelial growth factor receptor (EGFR) oncogenes as well as the p53 and p16 tumor suppressor genes. K-RAS encodes a membrane-associated G protein that serves as a link between tyrosine kinase receptors at the membrane and cytoplasmic second messenger molecules. Mutated K-RAS, which is found in 10 to 30 percent of lung adenocarcinomas, constitutively activates guanosine triphosphatase, which causes tumor cells to proliferate.[6] About 10 to 40 percent of adenocarcinomas with wild-type K-RAS have an EGFR mutation, which has been associated with women, nonsmokers, and patients with bronchoalveolar adenocarcinomas.[6] Mutated EGFR binds such ligands as EGF or transforming growth factor alpha and activates tyrosine kinase-containing signaling pathways, leading to tumor cell proliferation.[7,8]

The p53 and p16 tumor suppressor genes are also involved in adenocarcinoma development. The p53 encodes a transcription factor that mediates cell cycle arrest and cell death after DNA damage.[9] When p53 is mutated, cell division is uninhibited, and cell death is not induced, thus allowing tumor cells to proliferate. In contrast to p53's mechanism of action, the p16 tumor suppressor gene activates the retinoblastoma (Rb) gene to cause cell cycle arrest at the $G_1$/S boundary. The most common p16 mutation is a loss of heterozygosity that is found in about 50 percent of lung adenocarcinomas and allows tumor cells to proliferate without inhibition.

Similar multistage changes lead to invasive squamous cell carcinoma of the lung. The transition from normal epithelium to squamous hyperplasia is the first detectable histologic change of the squamous cell epithelium. The cells then develop into squamous metaplasia, dysplasia, carcinoma in situ, and ultimately invasive carcinoma. Oncogene and tumor suppressor mutations occur at each stage of development. As in adenocarcinoma, p53 mutations are common in squamous cell carcinoma with a mutation rate of 60 to 70 percent[6]; however, very few K-RAS mutations (<1%) and EGFR mutations (<1%) occur in squamous cell carcinoma.[6]

About 90 percent of small cell lung carcinomas have p53 and/or Rb mutations. The Rb gene, which is downstream of the p16 pathway, impacts cell cycle regulation, and mutation of Rb leads to tumor cell proliferation. The Myc oncogene, a nuclear phosphoprotein that regulates cell growth and tumorigenesis, is amplified in 30 percent of small cell lung carcinomas.[4]

### Tumor Microenvironment

Invasive carcinomas alter their environment to enable their growth, survival, and metastasis by releasing certain factors such as vascular endothelial growth factor (VEGF), which signals for angiogenesis.[10] Invasive carcinomas also recruit leukocytes such as T cells and macrophages to enable metastasis. It is a complex interplay between the tumor and the environment, which allows the cancer to grow and escape its primary site of origin.

## CLINICAL FEATURES

### Epidemiology

In 2009, nearly 220,000 people were diagnosed with lung cancer in the United States and over 159,000 people died of the disease.[11] The overall 5-year survival for all lung cancer patients is 16 percent. Survival depends heavily on the stage of the disease at diagnosis. The lifetime risk for developing lung cancer in the United States is 1 in 14.[11] In the United States, the population-attributable risk of developing lung cancer is 90 percent from smoking, 10 percent from radon, 9 to 15 percent from other occupational exposures, 1 to 2 percent from outdoor pollutants, and <1 percent from dietary factors.

Lung cancer is one of the leading causes of preventable death. Smoking has long been known to cause lung cancer. The number of years and the volume of cigarettes (packs per day) that a person smokes are directly related to the risk of that person developing lung cancer. Active cigarette smokers are 20 times as likely as nonsmokers to develop lung cancer. Quitting smoking reduces a smoker's risk of developing lung cancer; however, this reduced risk never equalizes to that of a never-smoker. In never-smoker, 25 percent of lung cancers are due to secondhand smoke. Studies have shown that people regularly exposed to secondhand smoke have a 30 percent higher risk of developing lung cancer than people who have never been or are rarely exposed to secondhand smoke.[12]

The second leading cause of lung cancer is radon, the first occupational carcinogen associated with lung cancer. Other occupational hazards include arsenic, chromates, chloromethyl ethers, nickel, polycyclic aromatic hydrocarbons, and asbestos. Both smoking and asbestos exposure are independent risk factors for lung cancer; combined, they act synergistically to further increase the risk of developing lung cancer.[12]

The pattern of lung cancer incidence in the United States over the years reflects cigarette use among men and women. The rapid rise in smoking prevalence first occurred in men and then a parallel rise was seen in women 30 years later. This same pattern has also been seen in lung cancer prevalence. The lung cancer incidence among men, although still much higher than that among women, has peaked and begun to decline; however, lung cancer incidences in women continue to rise.

Racial differences have also been identified. Currently, African American men are at the highest risk for lung cancer. Although African American women and white women have the same risk for developing lung cancer, African American men have a significantly higher risk than white men for unknown reasons. Latinos, Native Americans, and Asians/Pacific Islanders have a significantly lower risk of lung cancer than whites and African Americans. A family history of lung cancer also increases one's risk of developing the disease. Some researchers have postulated that consuming fruits and vegetables has a protective effect against lung cancer.[12]

## Screening

A randomized control trial performed by The National Lung Screening Trial Research Team showed that patients who had low-dose CT performed yearly for 3 years showed a 20% relative reduction in mortality from lung cancer compared with patients who underwent three annual screenings of chest radiography. The group enrolled 53,454 patients who were at high risk for developing lung cancer and followed them for 5 years. The study showed that patients who were between 55 and 74 years of age with at least 30 pack-years history of smoking, or if former smoker, quit within the previous 15 years, had benefits from CT screening.[13] This study provides definitive data on the role of CT screening for lung cancer and it should be recommended for patients who are at high risk for developing lung cancer.

## Clinical Presentation

Lung cancer patients are typically in the fifth to seventh decades of life. Patients with early-stage lung cancer have clinically silent tumors and they are a minority. Most patients present with symptoms due to advanced disease.

### PULMONARY SYMPTOMS

Cough is the most common presenting pulmonary symptom in lung cancer patients. Other pulmonary symptoms include dyspnea, hemoptysis, and sputum production. Tumors obstructing the airway may cause atelectasis, obstructive pneumonitis, and/or pneumonia. Tumor invasion into the bronchial artery or other major blood vessels can cause hemoptysis. Pleural effusion caused by the tumor may result in dyspnea.[14]

### NONPULMONARY SYMPTOMS

Like many other cancer patients, lung cancer patients sometimes present with weight loss, fatigue, malaise, and anorexia. Patients can also present with symptoms caused by the tumor invading adjacent structures. Focal chest pain suggests chest wall or spinal involvement from local invasion or bone pain stemming from metastatic disease. Direct invasion or nodal involvement may lead to superior vena cava syndrome or invasion of the recurrent laryngeal nerve resulting in hoarseness. Involvement of the superior cervical ganglion can cause Horner syndrome, which is characterized by unilateral facial anhidrosis, ptosis, and miosis. Shoulder and arm pain may occur if an apical tumor invades the brachial plexus.

Although lung cancers can metastasize to every part of the body, they most commonly metastasize to the brain and bones, causing a number of distinct symptoms. Lung cancer metastasis in the bone can cause bone pain and/or pathologic fractures. Metastatic lesion in the brain is seen in about 10 percent of patients with lung cancer and it can cause neurologic changes. Additional common sites of metastasis include residual lung, the liver, and the adrenal glands.

About 10 percent of NSCLC patients present with paraneoplastic syndrome. The most common sign associated with the paraneoplastic syndrome is clubbing. In addition, patients may manifest endocrine symptoms such as hypercalcemia, Cushing syndrome, syndrome of inappropriate antidiuretic hormone hypersecretion, carcinoid syndrome, hypercalcitoninemia, hyperglycemia, and hyperthyroidism.

# DIAGNOSIS AND STAGING (SEE ALSO CHAPTER 3)

## Diagnostic Studies

Chest radiographs showing lung nodules should be compared with previous imaging studies to determine whether the nodule is new or has grown. Patients with new or growing nodules and patients for whom previous imaging studies are unavailable should undergo chest CT to determine whether the nodule has features indicative of malignancy. Features such as a noncalcified spiculated lesion are very concerning for malignancy. There are predictive scoring systems based on both radiologic and clinical features.[15] If malignancy is suspected, diagnostic CT-guided fine-needle aspiration biopsy of the nodule should be performed. Endobronchial ultrasonography or magnetic navigation system can be used to guide fine-needle aspiration biopsy if CT guidance is not possible. If image-guided fine-needle aspiration biopsy is not possible or if the risk of malignancy, based on clinical and radiographic features, is very high then video-assisted thoracoscopic surgery (VATS) or open thoracotomy and biopsy can be done to obtain a definitive diagnosis.

## Staging

The clinical staging is performed using different tests to obtain the most accurate tumor–node–metastasis (TNM) staging of the patient. The T or tumor size and extent can be determined best by the CT scan of the chest. Next, the M and N stages are determined using a positron emission tomography (PET)/CT to identify metastatic disease and determine mediastinal lymph node involvement. If patient has a high-stage tumor based on PET/CT or if the patient has any neurologic symptoms, magnetic resonance imaging of the brain is performed to evaluate the brain for evidence of metastatic disease. A PET/CT used for lung cancer staging is not ideally suited to detect metastatic lesions to the brain. If there are positive lymph nodes in the mediastinum based on the PET/CT or the patient has a very large or central primary tumor then endobronchial ultrasonography with transbronchial biopsy or mediastinoscopy is used to evaluate the mediastinum for metastatic disease.

### SMALL CELL LUNG CANCER

Small cell lung cancer has classically been staged as either limited or extensive disease. The limited disease is restricted to one hemithorax and may be accompanied by ipsilateral pleural effusion and/or regional metastases in the ipsilateral and contralateral hilar, mediastinal, or supraclavicular lymph nodes. All other small cell lung cancers are defined as extensive disease. The recent edition of the staging system does advocate that TNM staging should also be used in staging small cell lung cancer.

### NONSMALL CELL LUNG CANCER

The guidelines for the 7th edition of the NSCLC staging system were set forth by the International Association for the Study of Lung Cancer (IASLC).[16] This TNM system (Table 9-1) provides information about the extent of the primary tumor, extent of metastatic disease in regional lymph nodes (Fig. 9-1), and absence or presence of distant metastasis. The system can be applied to both clinical (cTNM) and postresection histopathologic (pTNM) assessments of NSCLC.[16]

Stages IA and IB describe small tumors that have not metastasized to the lymph nodes or other organs. Stage IA disease includes T1a tumors <2 cm and T1b tumors 2 to 3 cm (Fig. 9-2). Stage IB disease includes T2a tumors 3 to 5 cm (Fig. 9-3). Stages IIA and IIB describe larger tumors without lymph node involvement and small tumors with ipsilateral hilar lymph node involvement. Stage IIA disease includes T1a, T1b, and T2a tumors with N1, ipsilateral hilar lymph node involvement (Fig. 9-4) as well as T2b tumors 5 to 7 cm. Stage IIB disease includes T2b tumors with N1 involvement and T3 tumors. T3 is defined by size (>7 cm) but also includes tumors that invade resectable structures (the chest wall, diaphragm, phrenic nerve, mediastinal pleura, and parietal pericardium) endobronchial tumors that are <2 cm from carina (but not involving the carina), obstructing tumors that cause atelectasis or pneumonitis of an entire lung, and satellite tumors in the same lobe (Fig. 9-5).

Stage IIIA describes a set of tumors that involve the ipsilateral mediastinal lymph nodes (N2 disease; Fig. 9-6), advanced tumors with hilar lymph node involvement, or T4 tumors. They are T1, T2, or T3 tumors with N2, ipsilateral mediastinal lymph node involvement, T3 or T4 tumors with N1 involvement. T4 describes very advanced tumors that invade structures that are difficult to resect (heart, great vessels, recurrent laryngeal nerve, esophagus, vertebral body, and carina) or that possess a satellite tumor in a different lobe but within the ipsilateral lung (Fig. 9-7).

Stage IIIB describes T4 tumors with N2 disease or any tumor with N3, contralateral mediastinal lymph node disease (Fig. 9-8). Finally, stage IV describes any tumor with metastatic disease to other organs including the contralateral lung or malignant effusions (pleural or pericardial) (Figs. 9-9 and 9-10).

**TABLE 9-1: Summary of TNM Characteristics**

| | |
|---|---|
| TX | Positive Cytology Only |
| T1 | ≤3 cm |
| T1a | ≤2 cm |
| T1b | >2–3 cm |
| T2 | Main bronchus ≥2 cm from carina, invades visceral pleura, partial atelectasis |
| T2a | >3–5 cm |
| T2b | >5 cm–7 cm |
| T3 | >7 cm; chest wall, diaphragm, pericardium, mediastinal pleura, main bronchus <2 cm from carina, total atelectasis, separate nodule(s) in same lobe |
| T4 | Mediastinum, heart, great vessels, carina, trachea, oesophagus, vertebra, separate tumor nodule(s) in a different ipsilateral lobe |
| N1 | Ipsilateral peribronchial, ipsilateral hilar |
| N2 | Subcardial, ipsilateral mediastinal |
| N3 | Contralateral mediastinal or hilar, scalene or supraclavicular |
| M1 | Distant metastasis |
| M1a | Separate tumor nodule(s) in a contra-lateral lobe; pleural nodules or malignant pleural or pericardial effusion |
| M1b | Distant metastasis |

## Future of Staging

Despite the improvements in prognostication with the revised staging system, patients in each stage remain heterogeneous with respect to their individual outcome. For example, 20 to 30 percent of T1aN0M0 tumor still recurs despite their early stage. Clearly this is due to the inherent biology of the tumor, which is not reflected in an anatomical staging system. Kratz et al. have shown that the 14 gene signature can be used to determine prognosis in patients with small node-negative lung tumors.[17] The study shows that the 14 gene signatures can show which subgroup of patients may have worse prognosis. This may eventually lead to the addition of "biologic" or B category to our TNM classification system in the future.

## MULTIMODALITY THERAPY

There are three modalities to treat lung cancer: surgery, radiotherapy, and chemotherapy. Conceptually radiotherapy and surgery are therapies directed at local and regional disease whereas chemotherapy can address regional and metastatic disease. For curative intent, surgery does provide better overall survival compared with radiation for local disease. Radiotherapy is still a curative option especially for patients who cannot tolerate lung resection secondary to reduced lung function or significant comorbidities. Radiotherapy can also be used for palliation of

symptomatic metastatic disease especially the brain and the bone. Below are some general guidelines for specific clinical stages.

## Stage I and II Nonsmall Cell Lung Cancer

Surgery is the recommended initial treatment for patients with stage I or II lung cancer (Table 9-2). If pathology reveals positive margins following lung cancer resection, and the patient cannot tolerate additional pulmonary resection, radiotherapy can be offered to reduce the rate of local recurrence. Radiotherapy is also advocated in patients with early-stage disease who cannot tolerate lung resection because of poor medical condition or poor pulmonary function. Adjuvant chemotherapy should be considered for patients with pathologic stage II lung cancer as it has been shown to improve disease-free survival.

### SURGERY

The main goals of lung cancer surgery in patients with stage I or II disease are to completely remove the tumor, all associated hilar and intrapulmonary lymph nodes, and at least sample the ipsilateral mediastinal lymph nodes. If the tumor is locally invasive to nearby structures, en bloc resection should be performed and the margins sampled using frozen section biopsy to ensure that all of the tumor is resected. Similarly, frozen section evaluation of the bronchial margin should be performed. If either margin is positive, then the appropriate resection should be performed until a negative margin is obtained. If a positive margin remains and the patient cannot tolerate a further resection, postoperative radiotherapy to the involved margin is warranted.

Two surgical issues must be addressed when treating patients with stage I or II lung cancer. The first issue concerns the volume of lung that should be removed with the tumor (lobectomy or sublobar resection). The Lung Cancer Study Group randomized stage I tumors to lobectomy versus a sublobar resection. Lobectomy provided significantly longer disease-free survival and a lower recurrence rate than sublobar resection. However, the survival advantage was unable to achieve a statistically significant difference. On the basis of these findings, lobectomy remains the standard surgical treatment for NSCLC.[18] Improvements in imaging have allowed tumors to be identified at an

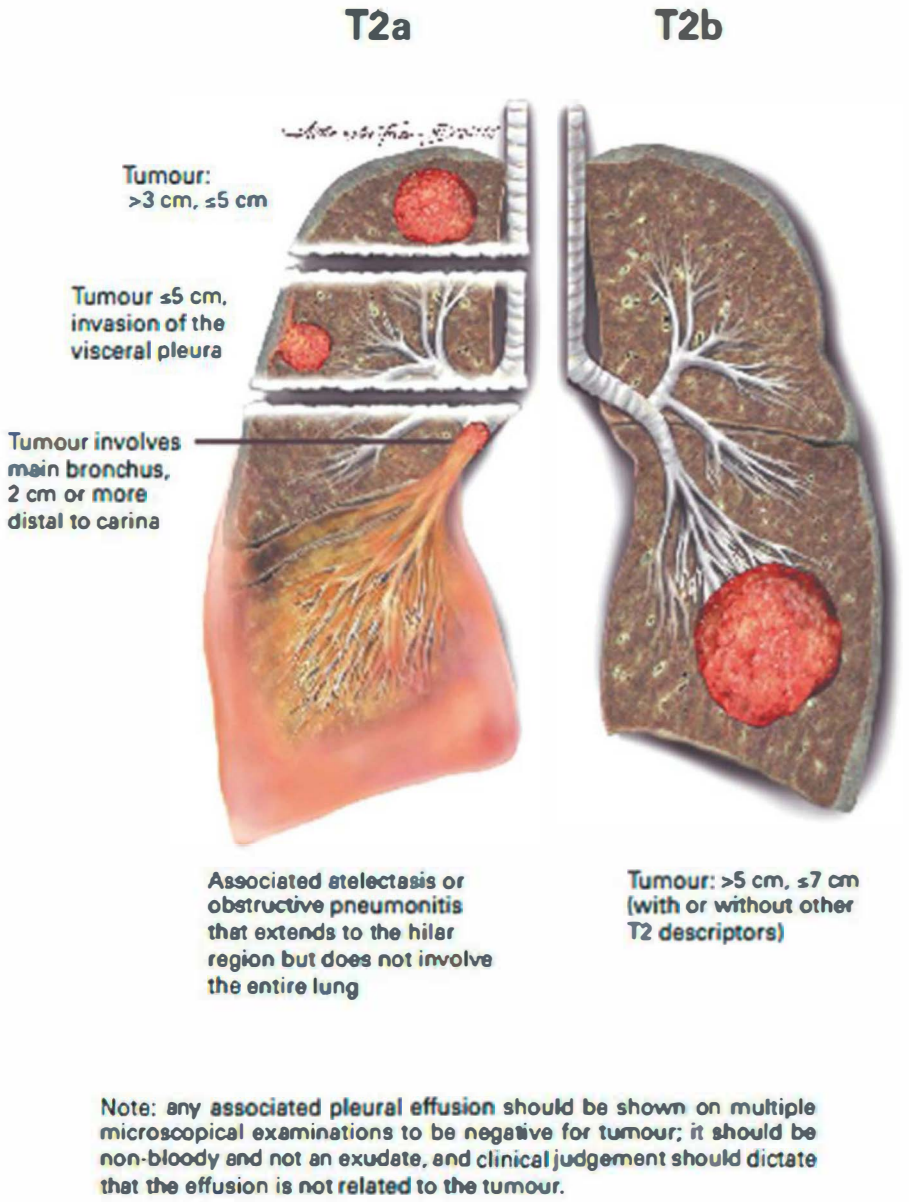

**FIGURE 9-3** Representation of T2a and T2b lung cancer. (Reprinted with permission courtesy of the International Association for the Study of Lung Cancer. Copyright 2008 Aletta Ann Frazier, MD.)

even smaller size prompting many investigators to reexamine this question. Retrospective studies have shown that sublobar resection offers good overall survival for the very small (T1a) tumors. This has prompted a new randomized multi-institutional trial initiated by the Cancer and Leukemia Group B (CALGB 140503) to investigate the disease-free survival in patients with NSCLC less than or equal to 2 cm who undergo sublobar resection versus lobectomy.

The second issue concerns the value of extended mediastinal nodal dissections. Specifically, does the addition of a complete nodal dissection in a patient with no evidence of mediastinal nodal involvement confer any survival benefit? The American College of Surgeons Oncology Group (ACOSOG Z0030) trial investigated whether mediastinal lymph node dissection provided any benefit in lung cancer patients with T1 or T2 tumors, N0 or N1 disease, and no evidence of N2 disease based on intraoperative nodal sampling (1 to 2 nodes removed from each accessible nodal station) at the time of thoracotomy. Their initial findings revealed no increased risk associated with the addition of a complete nodal resection.[19] However, subsequent findings

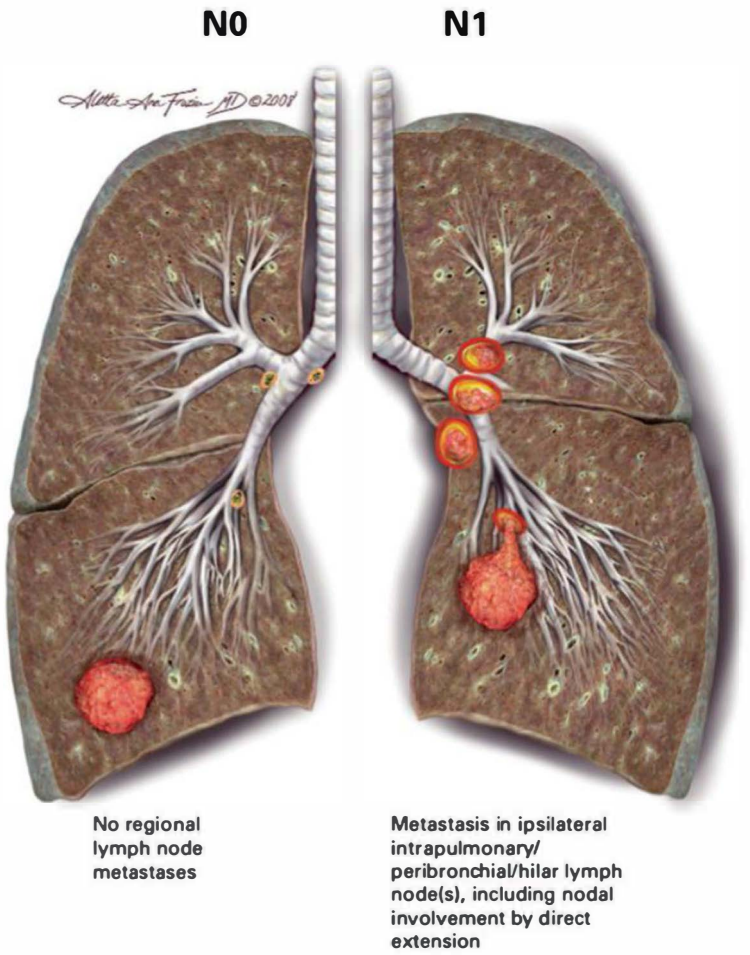

**FIGURE 9-4** Representation of N0 and N1 lung cancer. (Reprinted with permission courtesy of the International Association for the Study of Lung Cancer. Copyright 2008 Aletta Ann Frazier, MD.)

revealed no difference in local and regional recurrence rates or survival between patients who received lymph node sampling and patients who received full mediastinal lymph node dissection.[20] Although the trial did not address the role of mediastinal lymph node dissection in patients with N2 disease, it did suggest that mediastinal lymph node sampling may be appropriate in patients with early-stage lung cancer.

## CHEMOTHERAPY

***Neoadjuvant Therapy.*** Neoadjuvant chemotherapy's role for stage I and II lung cancer was under investigation when studies demonstrating the effectiveness of adjuvant therapy were published. Unfortunately, these findings mandated the closure of the ongoing randomized trials of neoadjuvant chemotherapy for early-stage disease. Still, some clinical situations may derive benefit from a neoadjuvant course of chemotherapy. Dierpierre et al. found that while neoadjuvant therapy provided no overall survival advantage compared with surgery alone in patients with stage I and II lung cancer, neoadjuvant chemotherapy did shrink the tumor and thus facilitate lobectomy in patients who require pneumonectomy at disease onset.[21] His study showed that 62 percent of patients who received neoadjuvant chemotherapy had a decrease in the size of the tumor. A similar finding was seen in the Southwest Oncology Group Trial S9900, phase III study that looked at induction chemotherapy in early stage NSCLC.[22]

***Adjuvant Therapy.*** A meta-analysis performed by NSCLC collaborative group of early adjuvant chemotherapy trials showed that there was a trend toward benefit for patients who are given adjuvant platinum-based chemotherapy compared with patients who had surgery alone. There was a bsolute survival benefit of 5 percent over 5 years.[23] Subsequent trials have shown that adjuvant chemotherapy may benefit patients with resected pathologic stage II NSCLC and the benefits for stage IB were mixed. Staging was based on the 6th edition of the staging system. In patients with good

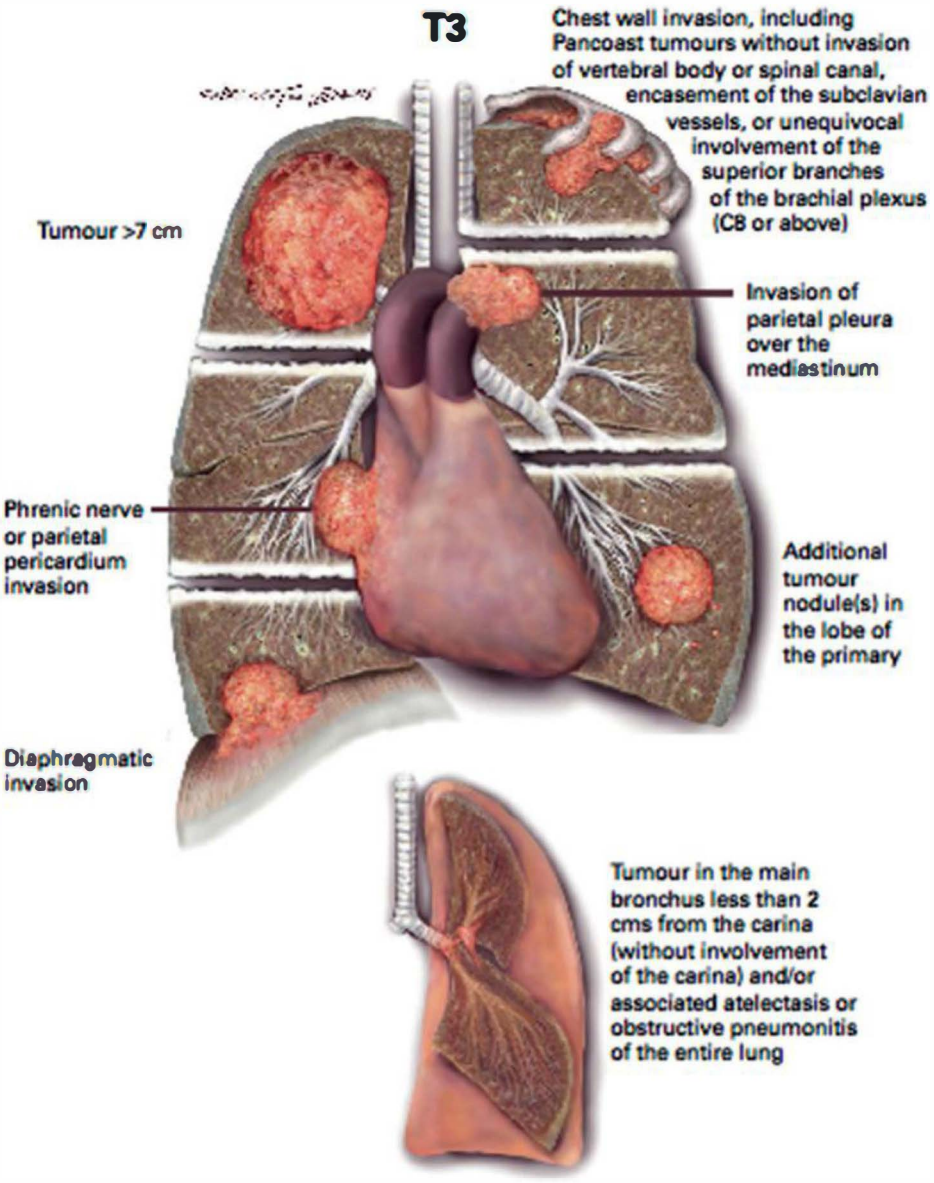

**FIGURE 9-5** Representation of T3 lung cancer. (Reprinted with permission courtesy of t he International Association for the Study of Lung Cancer. Copyright 2008 Aletta Ann Frazier, MD.)

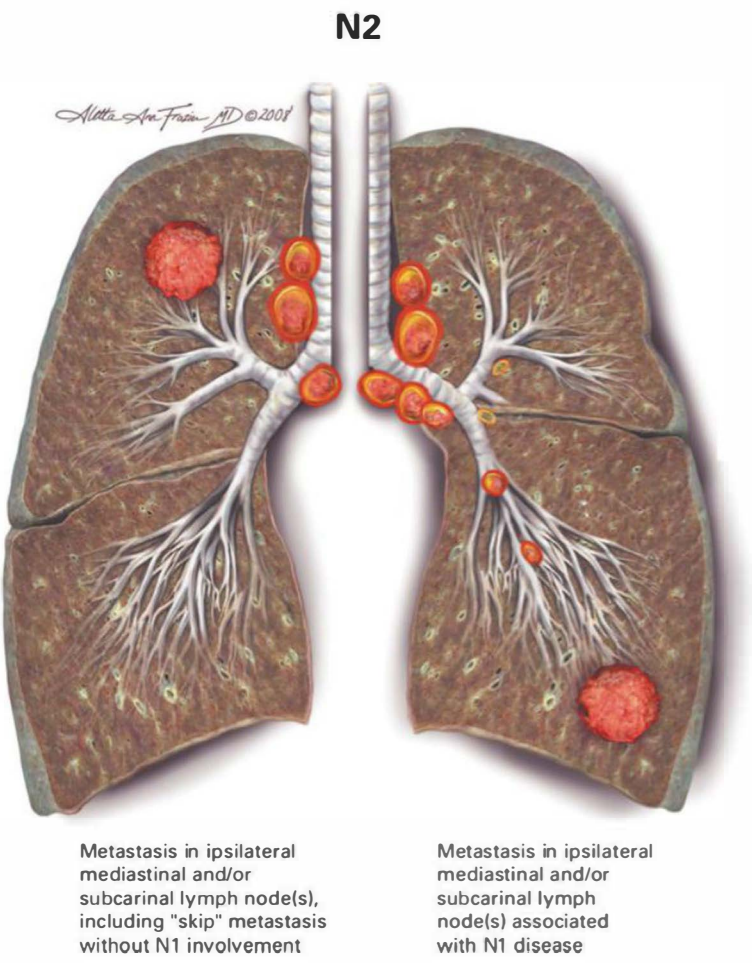

**FIGURE 9-6** Representation of N2 Lung Cancer. (Reprinted with permission courtesy of t he International Association for the Study of Lung Cancer. Copyright 2008 Aletta Ann Frazier, MD.)

performance status, adjuvant chemotherapy is begun within 2 months of curative resection. The most frequently studied adjuvant chemotherapy regimen for stage IB or II lung cancer is cisplatin plus vinorelbine for three or four cycles. Five trials have investigated the use of adjuvant chemotherapy after curative resection in lung cancer patients.

The Adjuvant Lung Project Italy enrolled 1209 patients who underwent curative resection for stage I–IIIA disease and were randomized to receive either placebo or mitomycin, vindesine, and cisplatin for three cycles. The study found no survival benefit with adjuvant chemotherapy. However, critics of the study felt the aggressive triple chemotherapy regimen and the high percentage of patients who received adjuvant radiotherapy (43%) led to the poor outcome in the adjuvant group and may explain the lack of benefit.[24]

Four trials have used cisplatin-based doublets; three were positive whereas one trial showed no difference. The International Adjuvant Lung Cancer Trial (IALT) randomized patients after curative surgery for stages I–IIIA lung cancer to two cycles of cisplatin-based chemotherapy or observation and found a 4 percent absolute increase in overall survival and a 5 percent absolute increase in disease-free survival in the chemotherapy arm.[25] The Adjuvant Navelbine International Trial Association (ANITA) trial, randomized 840 patients with completely resected pathologic stages I–IIIA to four cycles of cisplatin plus vinorelbine or observation and found a significantly higher survival rate in the treatment arm (51%) than in the observation arm (43%).[26] The National Cancer Institute of Canada Adjuvant Study randomized 482 patients with stages IB, IIA, or IIB lung cancer to either observation or treatment with cisplatin and vinorelbine and found markedly improved absolute survival of 15 percent in 5 years in the treatment arm.[27] Subset analyses suggested that the greatest benefit was derived in patients with stage II lung cancer and no benefit in stage IB patients. The role of adjuvant therapy in stage IB patient was studied in a simultaneously performed CALGB trial. CALGB 9633 enrolled

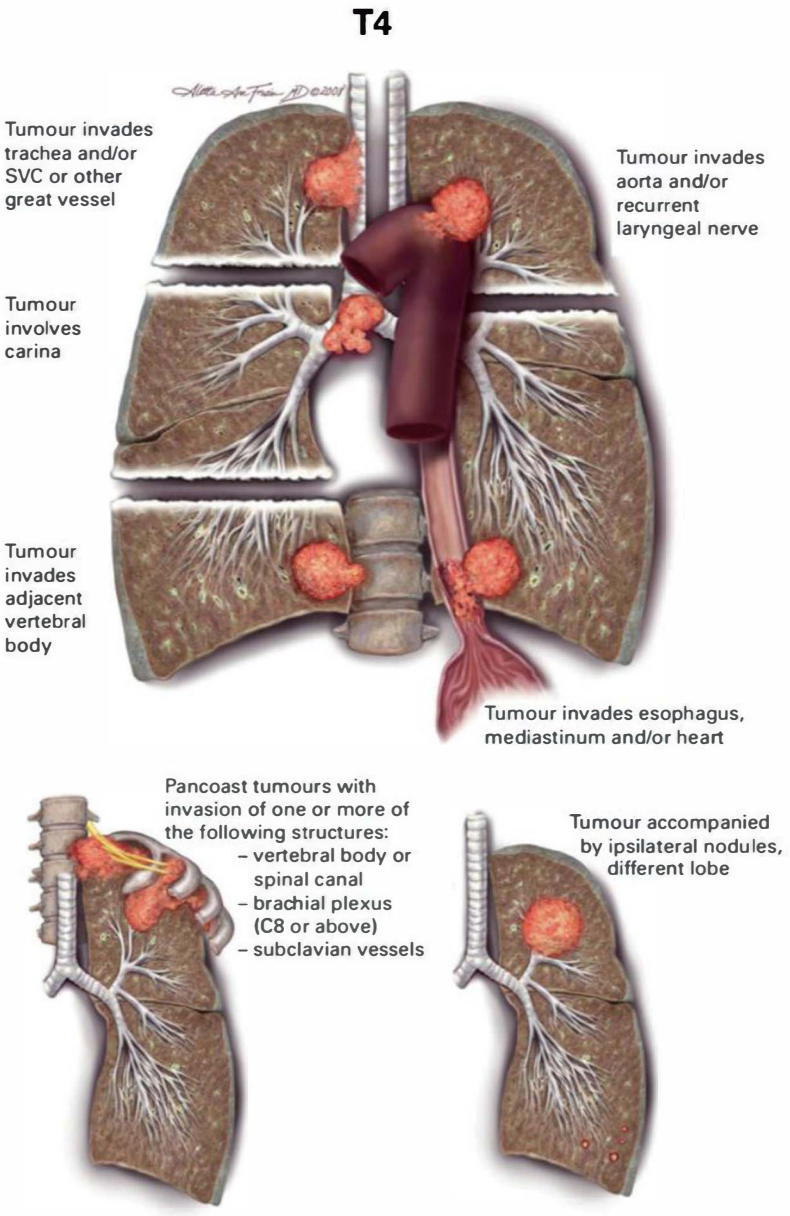

**FIGURE 9-7** Representation of T4 lung cancer. (Reprinted with permission courtesy of the International Association for the Study of Lung Cancer. Copyright 2008 Aletta Ann Frazier, MD.)

344 pathologic stage IB patients and initially found a significant advantage conferred by the use of adjuvant paclitaxel and carboplatin. There was 12 percent absolute survival advantage in the adjuvant chemotherapy arm in 4 years. This finding led to an early closure of the trial. Unfortunately, when updated results were examined, there was no difference in overall survival between the observation arm and the arm that received adjuvant therapy.[28]

The use of adjuvant chemotherapy for completely resected stage II NSCLC should be strongly considered for all patients. Since the subset analyses and CALGB 9633 did not show a significant benefit for adjuvant chemotherapy in pathologic stage IB patients, most oncologists will consider its use only in selected cases such as very large tumors without nodal involvement. Conveniently, the new 7th edition of the staging system has restaged these larger tumors (previously staged IB in the old system) as IIA.

## RADIOTHERAPY

Radiotherapy plays no role in neoadjuvant therapy and plays only a small role in adjuvant therapy for patients with

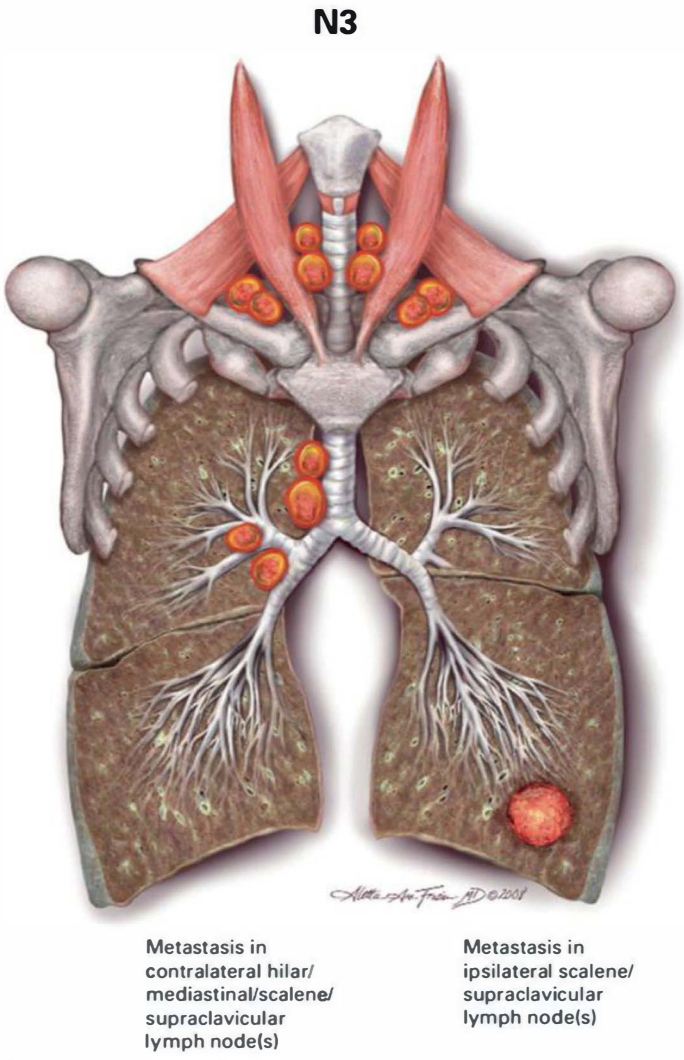

**FIGURE 9-8** Representation of N3 lung cancer. (Reprinted with permission courtesy of the International Association for the Study of Lung Cancer. Copyright 2008 Aletta Ann Frazier, MD.)

stage I or II NSCLC who received an incomplete resection. However, radiotherapy should be considered as a potentially curative option in patients with locoregional disease who may not tolerate surgery because of poor performance status or poor pulmonary function.

***Definitive Radiotherapy for Surgery-Intolerant Patients.*** Generally, chemotherapy and high-dose radiotherapy are used to treat patients with early-stage lung cancer who are not surgical candidates. Standard radiotherapy includes three-dimensional conformal radiotherapy planning and delivery and/or intensity-modulated radiotherapy to limit the radiation dose to normal lung tissue. The Radiation Therapy Oncology Group (RTOG) recommends delivering 60 Gy of radiation in 30 fractions over 6 weeks.[29] Concurrent chemotherapy has been found to improve locoregional tumor control and patient survival although some toxicity is increased.[30]

***Definitive Radiotherapy for Surgery-Tolerant Patients.*** Stereotactic radiotherapy focuses ablative radiotherapy doses to the tumor with less toxicity to adjacent structures by treating only the tumor volume and a rim of surrounding tissue. Although the total dose delivered remains 60 Gy, large fractions of either 15 Gy over 4 fractions or 20 Gy over 3 fractions are used depending on tumor location. This high-dose low-fraction delivery provides a much higher biologic effective dose to the tumor compared with convention radiotherapy. Although only a small lung volume is treated, the local control rates are significantly higher than with conventional radiotherapy. These encouraging results have prompted an international randomized trial comparing

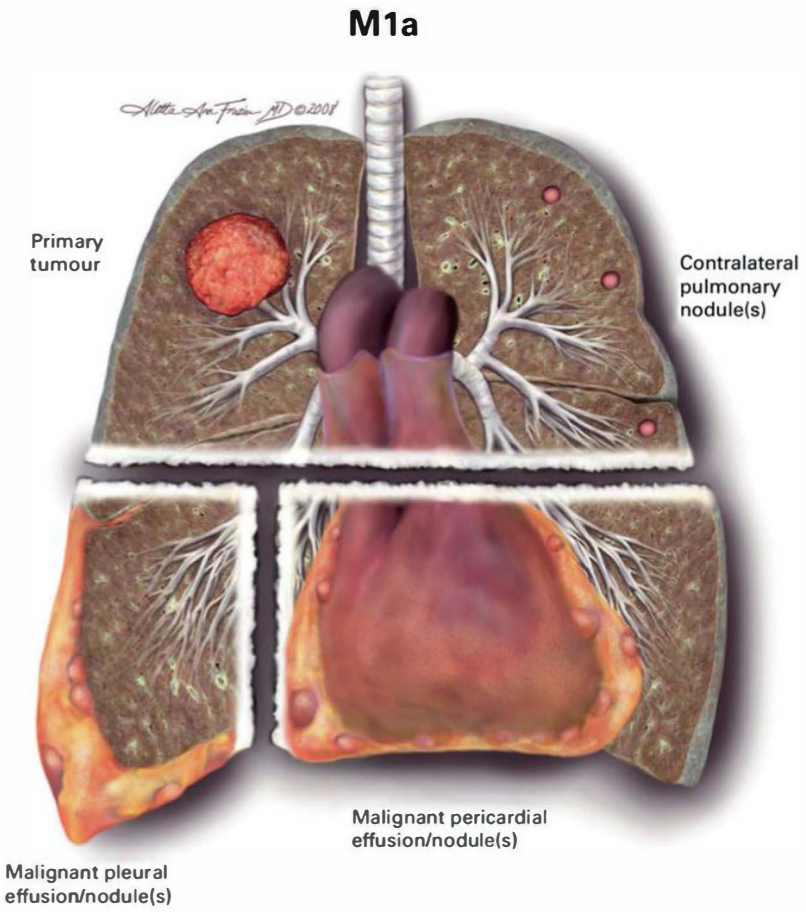

**FIGURE9-9** Representation of M1a Lung Cancer. (Reprinted with permission courtesy of the International Association for the Study of Lung Cancer. Copyright 2008 Aletta Ann Frazier, MD.)

CyberKnife® stereotactic radiotherapy with surgical resection in stage I Nonsmall Cell Lung Cancer (STARS). The trial, to be completed by 2013, will examine survival as the primary endpoint.

***Neoadjuvant Radiotherapy.*** Neoadjuvant radiotherapy has no role in the treatment of patients with stage I or II NSCLC.

***Adjuvant Radiotherapy.*** Adjuvant radiotherapy is recommended only for NSCLC patients with positive surgical margins who cannot tolerate additional pulmonary resection.

## Stage IIIA Nonsmall Cell Lung Cancer

A multimodal approach should be used to treat patients with stage III NSCLC. Patients with unresectable (bulky or multistation) N2 disease should receive definitive chemoradiotherapy. Patients with resectable N2 disease have additional options. One approach is to begin with two to four cycles of neoadjuvant chemotherapy followed by restaging. In the absence of any progression, a complete resection should be performed and if N2 disease persists, radiotherapy can be administered to decrease local and regional recurrences. An alternative strategy is to begin with induction chemoradiation therapy followed by restaging and surgical resection. Finally, if the risk of surgery is deemed to be great (comorbidities, the need for a pneumonectomy, etc.), then definitive chemoradiation therapy can be offered.

### UNRESECTABLE STAGE IIIA DISEASE—N2

Patients with unresectable stage IIIA disease should be treated with definitive chemoradiotherapy. Van Dermmek et al. evaluated patients with unresectable N2 disease at presentation and found that the disease rarely became resectable following neoadjuvant chemoradiotherapy and surgery provided no overall survival benefit.[31]

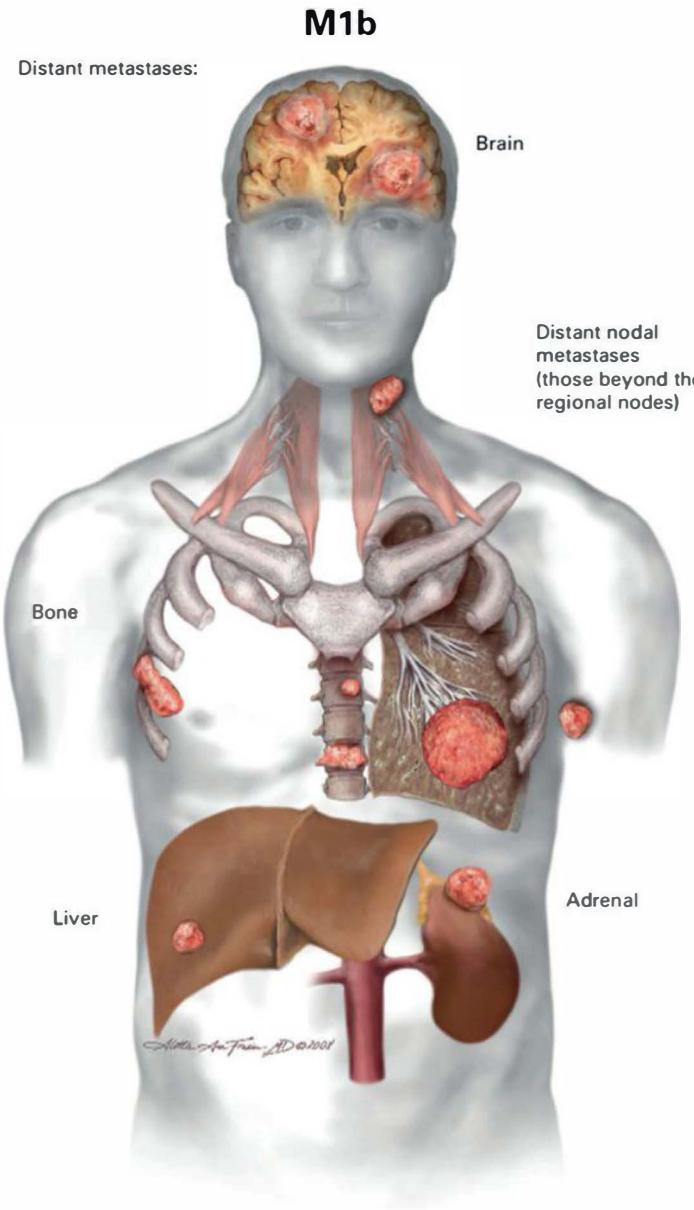

**FIGURE 9-10** Representation of M1b lung cancer. (Reprinted with permission courtesy of the International Association for the Study of Lung Cancer. Copyright 2008 Aletta Ann Frazier, MD.)

## RESECTABLE STAGE IIIA DISEASE—N2

Two strategies are generally used to treat patients with resectable stage IIIA disease. One strategy involves neoadjuvant chemotherapy, and the other strategy involves neoadjuvant chemoradiotherapy.

***Neoadjuvant Chemotherapy, Surgery, and Adjuvant Radiotherapy.*** Roth et al.[32] and Rosell et al.[33] found that neoadjuvant chemotherapy plus surgery impart a survival advantage over surgery alone in patients with stage IIIA disease. However, both studies have been criticized for having a small number of patients, no requirement for pathologic nodal staging, and, in the Rosell study, poorer-than-expected outcomes in the surgery-only group. However, despite these criticisms both studies have continued to remain positive even at late reanalysis. The benefit of adjuvant radiotherapy after neoadjuvant chemotherapy and subsequent surgery for patients with pathologic stage IIIA-N2 disease has also been reported separately and includes fewer local recurrences, fewer distant metastases,

**TABLE 9-2: Lung Cancer Stage Grouping**

| Occult carcinoma | TX | N0 | M0 |

and longer survival than patients who do not receive adjuvant radiotherapy.[34]

***Neoadjuvant Chemoradiotherapy and Surgery.*** At the same time investigators were examining the impact of neoadjuvant chemotherapy for stage IIIA NSCLC other investigators were evaluating the benefit of neoadjuvant chemoradiotherapy followed by surgery compared with surgery alone. Early results appeared promising with survival advantages similar to those seen in the Roth and Rosell studies.[35] Close examination of this data suggested that a new question centered on the additional benefit surgery offered beyond definitive chemoradiotherapy. This prompted a subsequent CALGB trial to see if surgery provided additional benefit for this stage. The study initiated chemoradiotherapy and after completing a preoperative dose of radiotherapy patients were quickly restaged. If there was no progression, patients were randomized to surgery or completion of definitive radiotherapy. The trial began in 1993 and due to slow accrual was finally stopped short of its planned enrollment and published in 2009. Albain et al. found no difference in survival between patients with resectable N2 disease who were treated with neoadjuvant chemoradiotherapy and surgery and patients with resectable N2 disease who were treated with definitive chemoradiotherapy alone. However, a subset analysis of patients in the surgery group revealed that neoadjuvant chemoradiotherapy imparted a survival advantage in patients who underwent lobectomy but no survival advantage in patients who underwent pneumonectomy. Pneumonectomy after chemoradiotherapy was associated with a very high mortality and this increased surgical risk appeared to erode any oncologic benefit derived by the addition of surgery in these patients.[36] Most investigators will therefore still offer surgery after chemoradiotherapy if the tumor resection can be accomplished with a lobectomy. If a pneumonectomy is possible neoadjuvant chemotherapy may be a better alternative.

### STAGE IIIA—T4 N0/N1

Invasion of the carina, superior vena cava, vertebral body, heart, great vessels, and esophagus are considered to be T4 tumors. In these patients with N0/N1 status does seem to have survival advantage with radical surgical resection with negative margin and in the absence of N2 disease surgical resection should be offered is technically and physiologically feasible.[37] The role of neoadjuvant or adjuvant chemotherapy, although not rigorously investigated, does seem appropriate as an extrapolation of results from its use in IIIA disease. The benefit of adjuvant radiation therapy is determined on a case-by-case basis.

## Stage IIIB and IV Nonsmall Cell Lung Cancer

Chemotherapy is the main treatment for patients with advanced lung cancer. A platinum-based doublet is reported to achieve median survival duration of 9 months and an overall 1-year survival rate of 30 percent and is considered first-line therapy for these patients.[38] Targeted therapies may have the potential to cure patients with advanced disease. Local therapy, when appropriate, is performed with radiotherapy.

### CHEMOTHERAPY

***First-Line Chemotherapy.*** Chemotherapy is the mainstay of therapy for stages IIIB and IV disease. Surgery and radiotherapy do not provide significant benefit in this setting. The first-line regimen is a platinum-based doublet such as cisplatin or carboplatin plus docetaxel, paclitaxel, or vinorelbine. Cisplatin and carboplatin trigger apoptosis by crosslinking DNA. Docetaxel and paclitaxel are antimitotic agents that stabilize the microtubule assembly to cause apoptosis. Vinorelbine, also an antimitotic agent, inhibits microtubule depolymerization and triggers apoptosis. Patients with nonsquamous cell histology, no brain metastasis, no significant hemoptysis, and good performance status may benefit from the addition of bevacizumab, an antiangiogenic agent.[39]

***Second-Line or Additional Chemotherapy and Targeted Agents.*** If a patient fails first-line therapy, additional chemotherapy using new agents can be administered based on the patient's status and tumor type. In addition, there are now targeted biologic agents that may be used to treat this group of patients. Erlotinib, an EGFR tyrosine kinase inhibitor, is considered a secondary agent for patients in whom first-line therapy for stage IIIB or IV NSCLC has failed.[40] In one study, patients who received erlotinib had significantly longer progression-free period (2.2 months vs. 1.8 months) and overall survival (6.7 months vs. 4.7 months)

than patients who received placebo. Rash and diarrhea were the two most common side effects of erlotinib. Erlotinib has not shown benefit in patients with K-RAS mutations but it has been found to be effective among patients with high numbers of EGFR gene copies and mutations.[40] In addition, pemetrexed, which inhibits the formation of precursor purine and pyrimidine nucleotides, has been approved for second-line therapy.

### RADIOTHERAPY

***Treatment of Stage IIIB Disease.*** Patients with stage IIIB disease are often treated with concomitant chemoradiation therapy as a curative approach although the 5-year survival for patients with documented stage IIIB disease treated in this manner is 15 percent.[41]

***Treatment of Stage IV Disease.*** The role of radiotherapy in patients with advanced NSCLC is limited to the palliation of symptoms that include superior vena caval obstruction, hemoptysis, neurologic symptoms, and chest, shoulder, arm, and bone pain. Radiotherapy does not effectively relieve bronchial obstruction from atelectasis or vocal cord paralysis due to tumor invasion of the phrenic or recurrent laryngeal nerve. Radiotherapy has been shown to improve symptoms stemming from metastatic disease in the brain and bones and can also reduce or eliminate paraneoplastic syndromes, especially those caused by adrenocorticotropic hormone and antidiuretic hormone overproduction.

Radiation pneumonitis is a potential side effect of radiotherapy in patients with advanced NSCLC. A single radiation dose of 8 to 10 Gy can damage normal lung tissue. The concurrent use of chemotherapeutic agents such as bleomycin, dactinomycin, carmustine, cyclophosphamide, and methotrexate increases the side effects of radiotherapy. Radiation pericarditis occurs in up to 5 percent of patients. Dysphagia caused by radiation-induced inflammation of the esophagus, which rarely leads to obstruction and often resolves after a short period of time, may also occur. The most serious complications of radiotherapy are myelopathy and Brown–Sequard syndrome.

### SURGERY

***Treatment of Stage IV—Oligometastasis to the Brain or Adrenals.*** Surgery has been reported in two unique presentations of stage IV disease. Retrospective studies have demonstrated long-term improvement in survival for patients with surgically resected localized lung cancer and a solitary metastasis to the brain or the adrenal compared with the historical survival of stage IV patients. In lung cancer patients with a solitary brain metastasis, aggressive resection of the lung, and metastasis followed by whole-brain irradiation is offered if the morbidity and mortality associated with the treatment is acceptable. In this nonrandomized study, patients who underwent definitive treatment at both sites had an overall median survival of 26 months, whereas patients who did not receive definitive therapy had overall survival duration of 13 months.[42] In NSCLC patients with isolated adrenal metastasis, the adrenal mass and primary lung cancer should be resected if possible.[43] The 5-year survival rate among patients who undergo resection of both the primary tumor and adrenal mass is 26 percent.[44]

## Special Tumors

### SMALL CELL LUNG CANCER

Patients with limited small cell lung cancer should receive locoregional and prophylactic cranial radiotherapy in addition to chemotherapy. Patients with primary tumors less than 5 cm for whom mediastinoscopy is negative may benefit from a lobectomy with mediastinal lymph node dissection. Patients with large tumors or any lymph node involvement should receive chemotherapy and mediastinal radiotherapy.[45] Chemotherapy is the main treatment for patients with extensive small cell lung cancer.

### PANCOAST TUMORS

Pancoast tumors, which are located at the apical pleuropulmonary groove (superior sulcus), are very difficult to resect because they often involve the vertebral bodies, brachial plexus, and subclavian vessels. Optimal management of these complex tumors does not yet exist. An investigation of the multimodal treatment of Pancoast tumor showed a reasonable survival rate with neoadjuvant chemoradiotherapy and surgery. Patients with T3-4, N0-1 Pancoast tumors received two cycles of cisplatin and etoposide plus 45 Gy of concurrent radiation. Patients were restaged after neoadjuvant therapy; patients who did not have distant metastasis or local progression underwent resection and adjuvant chemotherapy. Patients treated in this fashion had an overall 5-year survival rate of 44 percent. The study showed that a multimodal approach to treating patients with Pancoast tumors is feasible and results in a high rate of complete resection and complete response.[46] An alternative approach was described for Pancoast tumors with vertebral involvement. These patients were treated with surgery followed by adjuvant chemoradiotherapy and had an overall 5-year survival rate of 27 percent.[47]

# SURGICAL THERAPY

## Preoperative Assessment

With any major surgical procedure, one must perform careful assessment of preoperative status to reduce postoperative risks. Accurate assessment of patient's nutritional status, coagulation profile, hemoglobin level, renal function, and hepatic function can provide better understanding of patient's status. In addition to basic factors, it is crucial that

patient undergoes the pulmonary and cardiovascular assessment prior to any surgical resection.

### PULMONARY ASSESSMENT

The most important presurgical evaluation for lung cancer patients is the pulmonary function test. If the forced expiratory volume in 1 s ($FEV_1$) and carbon monoxide diffusion capacity (DLCO) are greater than 80 percent of the predicted values, the patient can tolerate up to a pneumonectomy. However, if the $FEV_1$ and DLCO are below the 80 percent threshold, then the predicted postoperative value of lung function should be assessed by counting the number of segment remaining after removal of the tumor. The right upper lobe has three segments, the right middle lobe has two segments, the right lower lobe has five segments, the left upper lobe has four segments, and the left lower lobe has four segments. For example, if left lower lobectomy is planned then 14 segments (18 segments − 4 segments) or 77.8 percent (14/18) of the lung will be still available postoperatively. For a patient with a preoperative $FEV_1$ of 60 percent, the postoperative predicted value would be 77.8 percent of 60 percent or 47 percent $FEV_1$.[48]

For patients with obstructing tumors resulting in segmental/lobar/or pneumonic collapse, this estimate is no longer adequate since the segments that will be removed are no longer contributing effectively to the patient's overall pulmonary function. A similar situation is seen when resecting lung that is significantly damaged secondary to emphysema. For these patients, measuring the percentage of perfusion and ventilation in the part of the lung to be resected provides a more accurate measure of postoperative lung function. For example, if a tumor involves the distal left lower lobe, bronchus, and pulmonary artery in a patient with an $FEV_1$ of 45 percent, and the perfusion rate is only 5 percent in that lobe, the patient will have an $FEV_1$ of 43 percent after resection or 95 percent of 45 percent.

The usual thresholds above which the planned resection can be performed without a significant increase in perioperative mortality is a postoperative predicted $FEV_1$ and DLCO of 40 percent. When the postoperative predicted values are just above or below 40 percent patients should undergo cardiopulmonary exercise testing to determine whether surgery is appropriate. Patients with a maximal oxygen consumption ($Vo_2$ max) of >15 mL/kg/min are not at an increased risk of complication or death following resection. However, patients with a $Vo_2$ max of <10 mL/kg/min are at a significantly higher risk of complications or death and are not surgical candidates. Patients with a $Vo_2$ max of between 10 and 15 mL/kg/min should undergo pulmonary rehabilitation. Pulmonary function should be reassessed periodically to determine whether these patients are candidates for pulmonary resection.

One exception to this rule is the patients with emphysema. Patients with poor pulmonary function and heterogeneous emphysema with upper-lobe predominance who develop a tumor in the upper-lobe may benefit from lung volume reduction surgery (LVRS) along with the resection of the lung cancer. The criteria for patients who can tolerate LVRS are an $FEV_1$ of <40 percent, a DLCO >20 percent, total lung capacity >120 percent, and residual lung volume >150 percent.[49] Rigorous pulmonary rehabilitation is necessary in patients who are going to undergo LVRS.

### CARDIAC WORK-UP

Patients must have adequate cardiac function to tolerate pulmonary resection. Cardiac work-up including an EKG, a detailed history, and an echocardiogram or a stress test, when indicated, should be performed to ensure that patients can tolerate lung resection. Coronary artery disease is cardiac significant risk factor for myocardial infarction following lung resection. The likelihood of myocardial infarction following resection in patients without coronary artery disease is <0.5 percent, while the likelihood of myocardial infarction following resection in patients with coronary artery disease is about 6 percent.[50]

Arrhythmias are also very common postoperatively and any preexisting arrhythmias will place patients at an even higher risk.

## Technical Considerations

Although posterior lateral thoracotomy with entry through the fifth intercostal space remains the standard incision for anatomic pulmonary resections, complete resections can also be performed through posterior muscle-sparring, anterior muscle-sparing and axillary thoracotomies as well as VATS using two, three, or four incisions. The main advantages of VATS over traditional thoracotomy are reduced postoperative pain, earlier return to normal activity, and an increased likelihood of patients receiving adjuvant chemotherapy.

Upon entry into the thoracic cavity, the surgeon reassesses the clinical stage of the tumor. If there is pleural effusion that is positive for malignancy on cytologic evaluation or if the tumor is invading structures that cannot be resected, the surgeon aborts the surgery. The entire lung and parietal pleura are then inspected and palpated for additional masses. Any suspicious nodules located in lobes other than the tumor bearing lobe are biopsied and the specimens cytologically evaluated; if the nodules are positive for malignancy, the surgeon aborts the surgery. If there are malignant-appearing, broad-based, or dense adhesions to the chest wall the surgeon determines whether the tumor can be resected with negative margins. If the tumor is deemed resectable, the surgeon divides the inferior pulmonary ligament and renders the lung completely atelectatic.

The pulmonary vessels are now dissected along the plane of Leriche. This perivascular plane may be absent in the presence of long-standing granulomatous or tuberculous disease, after major chemotherapy or thoracic radiotherapy, and in cases of reoperation. In these situations, proximal

control of the main pulmonary artery and the two pulmonary veins may be necessary before the more peripheral arterial dissection can be started. During an open operation the pulmonary arterial and venous branches can be ligated in any order. Although there is theoretical concern of pulmonary congestion when the pulmonary vein is ligated first, other collateral vessels between the lobes usually compensate adequately. During a VATS lobectomy the order in which vessels are ligated is more defined with the pulmonary vein often taken first.

Bronchial exposure should not involve stripping the bronchial surface of its adventitia. Aggressive dissection may compromise the vascular supply of the bronchus and lead to impaired healing and bronchial dehiscence. Overlying nodal tissues should be cleared, and major bronchial arteries should be clipped just proximal to the point of division. Bronchial closure has been greatly facilitated by the use of automatic staplers. With the stapler applied but not yet fired, the remaining lung should be ventilated to determine whether there is any impairment of ventilation secondary to stapler placement too close to a proximal lobar bronchus. Only when the absence of ventilatory impairment has been confirmed should the stapler be fired. When bronchial length is limited, the surgeon may perform suture closure of the bronchial stump rather than attempting to force a stapler around the bronchus. A vascularized rotational tissue flap should be used to reinforce the bronchial closure whenever there is a high risk of bronchial stump dehiscence such as in the presence of active infection, steroids, chemotherapy, radiation, or poor nutritional status.

## Right Lung

### RIGHT HILAR DISSECTION

First, the lung is then rotated posteriorly, and the pleura is incised posterior to the course of the phrenic nerve, which usually passes close to the base of the superior pulmonary vein. The phrenic nerve is carefully and gently mobilized anteriorly to expose the superior pulmonary vein and inferior pulmonary vein. Next, the right upper lobe is then rotated more inferiorly to provide a better view of the superior aspect of the hilum and allow complete exposure of the truncus anterior branch. Finally, the lung is rotated anteriorly, and the right main bronchus, right upper-lobe bronchus, and right bronchus intermedius are exposed.

### RIGHT PNEUMONECTOMY

After hilar dissection, the lung is rotated inferiorly and posteriorly, and the main trunk of the right pulmonary artery is exposed as it exits the pericardium posterior to the vena cava. The ligation and division of the right pulmonary artery can be accomplished using a vascular stapler or dividing the vessel between clamps and oversewing with 3-0 nonabsorbable sutures. Next, the lung is rotated posteriorly, and the superior pulmonary vein is mobilized on its superior and inferior aspects with blunt and sharp dissection then encircled, ligated, and divided using a vascular stapler. Division between clamps and oversewing with 3-0 nonabsorbable sutures is also acceptable. The lung is then retracted superiorly, and the inferior pulmonary vein is dissected, ligated, and divided in the same manner as the superior pulmonary vein.

After dividing the major vessels, the lung is retracted anteriorly and the subcarinal lymph nodes are mobilized. The bronchial artery originates at the apex of the carina anteriorly and should be clipped. The remaining peribronchial tissues are then mobilized distally with blunt and sharp dissection so that the bronchus is exposed within 1 cm of the carina. A tick tissue stapler is oriented so as to approximate the anterior cartilaginous and posterior membranous walls and the bronchus is divided distal to the staple line. On the right side, the coverage of the pneumonectomy stump with viable tissue is preferred, especially if the patient has received or will receive chemotherapy and/or radiotherapy. The ideal tissue for coverage is either a rotated intercostal muscle flap harvested during entry into the chest or a pericardial fat pad rotational flap. The flap is secured with carefully placed 4-0 polypropylene sutures.

### RIGHT UPPER LOBECTOMY

Two branches of the pulmonary artery—the truncus anterior and posterior ascending arteries—enter the right upper lobe. The truncus anterior is the first branch of the right main pulmonary artery and is typically a large branch that immediately bifurcates into two or three branches. Once the truncus anterior is exposed, it is either suture-ligated and divided or transected with a vascular stapler. The posterior ascending artery typically originates from the interlobar pulmonary artery opposite the right middle lobe branch. To expose the posterior ascending pulmonary artery, the interlobar fissure is dissected, and the pulmonary artery is exposed at the junction of the major and minor fissures. All the branches are dissected including the middle lobe, posterior ascending, superior segmental, and basilar segmental arteries. The posterior ascending artery is often partially obscured by a level 11 interlobar lymph node and the posterior segmental branch of the superior pulmonary vein, which traverses the fissure towards the superior pulmonary vein. If the exposure is adequate, the posterior ascending branch can be ligated and divided or stapled. If the exposure proves difficult completion of the fissure between the upper lobe and lower lobe can sometimes facilitate this exposure. This is facilitated by dividing the pleura in the posterior hilum along the lateral edge of the bronchus intermedius. A level 11 lymph node located between the right upper-lobe bronchus and the bronchus intermedius is then removed to allow exposure of the posterior ascending branch of the pulmonary artery. A right-angle clamp can be passed from the interlobar fissure between the superior segmental branch of the pulmonary artery and the posterior ascending pulmonary artery to the

posterior hilar dissection. The fissure can then be completed with either a medium or thick tissue stapler.

Next, the superior pulmonary vein is dissected, and the upper- and middle-lobe branches are carefully identified. The branches draining the upper lobe are then ligated and divided or stapled. Attention is now turned to completion of the minor fissure. Dissection continues along the lateral surface of the pulmonary artery until the right middle-lobe artery is identified. A right-angle clamp can be passed from this location posteriorly to the interlobar dissection. The minor fissure is then completed through the serial application of thick tissue staplers.

The upper lobe is retracted superiorly and posteriorly, and the pulmonary artery is gently retracted anteriorly. The bronchus is circumferentially exposed to the right upper lobe, and all nodal tissue surrounding the right upper-lobe bronchus is swept distally so that it can be included with the specimen. Once an adequate length of the right upper-lobe bronchus is exposed, the lung is rotated anteriorly to allow visualization of the course of the bronchus intermedius. The right upper lobe bronchus is compressed within with a thick tissue stapler and the right lung is ventilated to confirm that the bronchus intermedius has not been compromised. Once confirmed, the stapler is fired and the bronchus is divided distally.

### RIGHT MIDDLE LOBECTOMY

The initial steps in a right middle lobectomy can begin with the interlobar dissection described above. There can be one dominant or two smaller middle-lobe arteries. Once the anatomy has been confirmed, the arterial branches to the middle lobe can be individually ligated and divided. If additional exposure is needed before ligation, the minor fissure can be completed to yield added exposure of a proximal middle-lobe artery. Once the arteries are divided, the lung is rotated posteriorly to expose the superior pulmonary vein. The branches to the upper and middle lobes are carefully identified, and the branches to the middle lobe are ligated and divided. The minor fissure is completed as described above. Once complete, the surgeon will have a clear view of the posterior segmental branch of the superior pulmonary vein and the interlobar pulmonary artery coursing posterior and medial to the veins. The fissure between the right middle and lower lobe can be completed using serial application of the thick tissue staplers by keeping the right middle lobe bronchus superiorly and the right lower lobe with the basilar branches of the pulmonary artery and the right lower-lobe bronchus inferiorly.

The middle lobe is then rotated superiorly and posteriorly to expose the right middle-lobe bronchus, which usually arises anterior and inferior to the right middle-lobe branches of the pulmonary artery. The basilar arterial branches to the right lower lobe are gently mobilized posteriorly to expose the bronchus intermedius and the origin of the right middle-lobe bronchus. Peribronchial lymph nodes located in this region should be dissected and removed, with care taken not to injure the bronchial arterial branches. Once the bronchus is free, it is divided and either oversewn or stapled.

### RIGHT LOWER LOBECTOMY

Once again, the interlobar pulmonary artery and its branches are exposed in the major fissure. The pulmonary branches to the superior segment and the basilar segments of the right lower lobe, posterior ascending branch of right upper lobe, and right middle lobe branches are identified. The superior segmental and basilar segmental artery is encircled, ligated, and divided. Next, the fissure between the lower lobe and upper lobe is completed as described above for a right upper lobectomy. Next, the inferior pulmonary vein is then encircled as it exits the pericardium. This step is facilitated by the dissection of the superior edge of the inferior pulmonary vein with the lung rotated first anteriorly and then posteriorly. Once encircled, the pulmonary vein is divided with a vascular stapler. Then, the basilar segmental bronchi and the middle-lobe bronchus are exposed allowing division of the fissure between middle lower lobes. The removal of lymphoid tissue facilitates the application of stapler.

Level 11 and 12 lymph nodes are cleared distally along the bronchi to expose the origin of the superior segmental bronchus. The lung is then rotated anteriorly, and the bronchus intermedius is dissected distally until the origin of the superior segmental bronchus is identified. The branch of the inferior pulmonary vein draining the superior segment of the right lower lobe should be mobilized distally to allow adequate exposure of the origin of the superior segmental bronchus. The superior segmental bronchus is encircled, divided, and oversewn or stapled. Next, the basilar segmental bronchi are encircled at a point where closure will not affect airflow to the middle-lobe bronchus. Appropriate placement is confirmed by ventilating the right lung while the stapler or clamp is applied to the base of the basilar bronchi. If placement is adequate, the basilar segmental bronchi are divided and sewn or stapled.

## Left Lung

### LEFT HILAR DISSECTION

Retract the lung anteriorly and open the hilar pleura to expose the inferior pulmonary vein, and continue superiorly to expose the left main bronchus and the pulmonary artery. Next, with the lung retracted inferiorly, the pleura is incised under the arch of the aorta to expose the left main pulmonary artery. A variable number of small vessels and vagal branches to the lung are encountered and can be ligated and divided. Care is taken not to injure the recurrent laryngeal nerve as it branches from the vagus nerve and courses under the arch just posterior to the ligamentum arteriosum. With the lung now retracted posteriorly, the hilar pleura is opened parallel to and posterior to the course of the phrenic nerve, exposing the main trunk of the left pulmonary artery and the superior pulmonary vein.

### LEFT PNEUMONECTOMY

The superior and posterior surfaces of the main trunk of the pulmonary artery are dissected as it enters the thorax under the aortic arch. Once the perivascular space is entered, the entire vessel can be encircled with blunt dissection. If the superior pulmonary vein limits access to the anterior surface of the pulmonary artery, it may be ligated and divided first to facilitate arterial exposure. Once the pulmonary artery is encircled, the vessel can be divided using vascular stapler or between clamps.

Next, with the lung retracted posteriorly, the superior pulmonary vein is identified, encircled with blunt dissection, and then ligated and divided. The lung is then retracted superiorly to expose the inferior pulmonary vein. Dissection is performed on the anterior and posterior aspects of the inferior pulmonary vein, and blunt dissection is used to completely encircle the vein after which it is ligated and divided. Finally, the lung is retracted anteriorly and superiorly. Complete dissection of the subcarinal lymph nodes is performed and facilitated by dividing one or two pulmonary branches of the left vagus nerve and both bronchial arteries. Gentle traction in conjunction with blunt dissection is applied to allow encirclement of the proximal left mainstem bronchus. An effort should be made to encircle the bronchus within 1 cm of the carina. A thick tissue stapler is then passed around the left main stem bronchus and applied within 1 cm of the carina. If the patient has a left-sided double-lumen tube, ensure that it is pulled back proximal to the carina. The stapler is fired, and the bronchus is divided distal to the staple line. Frequently, the position of the bronchial stump under the aortic arch deep within the mediastinum renders coverage of the stump unnecessary.

### LEFT UPPER LOBECTOMY

The interlobar fissure is developed with a combination of sharp and electrocautery dissection. The posterior aspect of the fissure between the apicoposterior segment of the left upper lobe and the superior segment of the left lower lobe is completed with cautery or GIA stapler to expose the proximal portion of the interlobar pulmonary artery. The left upper lobe is then retracted anteriorly and superiorly to expose the arterial branches supplying the upper lobe. This anatomy varies among patients. Although there are usually three branches—the apico-anterior, posterior, and lingular pulmonary arteries to the left upper lobe—there may be as many as seven vessels. Each vessel should be identified and individually ligated and divided. Although the superior and posterior branches are easily dissected, the anterior-most branch is frequently obscured by an apical branch of the superior pulmonary vein. Division of this venous branch may improve exposure and facilitate control of the arterial branch.

The superior pulmonary vein can then be easily identified in the anterior hilum. If the apical branch was not previously ligated, the surgeon should make every effort not to damage the pulmonary artery branches that lie posterior to this portion of the vein. The majority of the superior pulmonary vein lies anterior to the left upper-lobe bronchus. Once this vein is encircled, it is ligated and divided. The fissure between the lingula and the lower lobe is now completed with serial application of tissue staplers. The left upper-lobe bronchus is encircled and either clamped or ligated with a thick tissue stapler. To prevent inadvertent injury, the pulmonary artery branches to the lower lobe should be gently retracted posteriorly during stapler placement. With the stapler clamped, the left lung is ventilated to verify that air is flowing freely to the entire left lower lobe, and the left-sided double-lumen tube is moved to ensure that the tube is not in the stapler. The stapler is then fired, and the bronchus is divided distal to the staple line.

### LEFT LOWER LOBECTOMY

Dissection begins again within the interlobar fissure. The pulmonary artery is identified, and the branches to the upper and lower lobes are dissected. The superior segmental artery is encircled, ligated, and divided. The basilar segmental arteries are then encircled distal to the origin of the lingular artery and ligated and divided, with care taken to preserve blood flow to the lingular artery. The anterior and posterior fissures are identified and divided with tissue stapler. The lung is rotated superiorly to expose the inferior pulmonary vein. Once the vein is encircled, it is ligated and divided. Attention is then redirected to the interlobar fissure, and the left lower-lobe bronchus is identified. The origin of the bronchus is cleared by dissecting nodal tissue distally with blunt and sharp dissection. The upper-lobe branches of the pulmonary artery are gently retracted superiorly to allow placement of a tick tissue stapler on the bronchus. With the stapler clamped, the anesthesiologist ventilates the left lung to confirm the adequacy of airflow to the upper lobe, and that the stapler is not entrapping the double-lumen tube. The stapler is fired and the bronchus is divided distal to the staple line.

## Complications

### HIGH CHEST TUBE OUTPUT

A chest tube is placed after surgical resection to prevent symptomatic pleural effusion. The amount of pleural fluid output over a 24-h period that is considered safe to allow removal of the tubes has long been debated. However, a single-institution retrospective series recently found that symptomatic pleural effusion occurred after chest tube removal in just 11 of 2077 patients (0.55%) who had their chest tube removed for <450 mL of nonchylous drainage per day.[51]

### PERSISTENT AIR LEAK

Persistent air leak is defined as an air leak that occurs for at least 5 days following surgery. The incidence of persistent air leak is about 10 percent for patients who are undergoing lobectomy based on the Society of Thoracic Surgery

general thoracic surgery database that looked at 4979 cases.[52] A significantly smaller incidence of air leak of 3.2 percent was reported in a single-institution retrospective series when patients undergoing segmentectomy or wedge resections were mixed with lobectomy patients. In that series, the patients with a persistent air leak whose lung remained expanded off suction were discharged with their chest tube in place. At follow-up on an average of 16 days later, 57 of the 199 patients (28%) had persistent air leak and/or pneumothorax. All patients' chest tubes were eventually removed during follow-up. Over the next 3 months, air leaks resolved in all but three patients, who developed empyema.[53]

### PNEUMONIA

About 10 percent of patients develop pneumonia after undergoing pulmonary resection. Pneumonia carries a mortality rate of 19 to 26 percent following lung resection.[54,55] For patients who are undergoing pneumonectomy, pneumonia-associated mortality rates are 40 percent and smoking within 1 month of the operation increases the risk of developing pneumonia nearly threefold.[56] Pneumonia usually develops 2 to 4 days after surgery. Bronchial colonization, male gender, and chronic obstructive pulmonary disease are independent predictors of postoperative pneumonia. Standard treatments used to prevent pneumonia after lung resection includes prophylactic antibiotics, chest physiotherapy to clear secretions, bronchodilator placement, effective pain control, and early ambulation. The standard treatment for postoperative pneumonia is broad-spectrum antibiotics followed by targeted antibiotics selected on the basis of culture results. Repeated bronchoscopies can also be used to facilitate clearance of secretions

### ATRIAL FIBRILLATION

Atrial fibrillation is a common complication following pulmonary resection. The incidence of supraventricular arrhythmias following pulmonary resection is 10 to 28 percent. Although the cause of atrial fibrillation is unclear, contributing factors may include postoperative inflammation, right heart strain owing to right ventricular dilatation, pulmonary hypertension, and/or increased right heart pressures. Alternative explanations include conduction abnormalities from ligation of the pulmonary veins that contain the atrial fibers. The incidence of postoperative atrial fibrillation increases with the amount of lung tissue resected. Patients who undergo pneumonectomy are at the higher risk of developing atrial fibrillation. Curtis et al. found that postoperative supraventricular arrhythmias developed in 46.1 percent of patients who underwent pneumonectomy but only 14.3 percent of patients who underwent lobectomy.[57] Age is the second most important risk factor associated with development of atrial fibrillation. In addition to amount of lung resected and advancing age, male gender, history of congestive heart failure, and history of arrhythmias are risk factors for postoperative atrial fibrillation.[58] Atrial fibrillation often occurs in the first 24 to 72 h following thoracotomy. Although patients who develop atrial fibrillation frequently have a higher incidence of other complication,[59] the atrial fibrillation is usually controlled with medical therapy that is typically discontinued within 4 to 6 weeks of surgery.[60]

### EMPYEMA AND BRONCHOPLEURAL FISTULA

Empyema occurs in 1 to 2 percent of patients after lobectomy and 2 to 12 percent of patients after pneumonectomy. The management of postoperative empyema depends on the timing of its onset, the stability of the patient, and the presence of a bronchopleural fistula. If a bronchopleural fistula develops within the first 2 days after resection, the best option may be an additional surgery that includes debridement of the stump, reclosure at the healthy bronchus, and placement of a muscle flap. The stump should be tested to ensure that no air leaks are present.

If empyema develops more than 2 days after resection, the initial treatment includes administering broad-spectrum antibiotics, draining the space with close-tube drainage, and using flexible bronchoscopy to determine whether a bronchopleural fistula is present. If the patient is medically unstable, Eloesser flap should be performed to provide the best way to sterilize the space. If the patient is stable, treatment depends on whether bronchopleural fistula is present. If bronchopleural fistula is not present, a modified Clagett procedure, in which antibiotic solution is instilled and then drained to sterilize the fluid, can be performed.[61] However, if bronchopleural fistula is present, the treatment will vary based on the operative side, the size of the fistula, the availability of suitable muscle flaps, and a number of other factors. This discussion is beyond the scope of this chapter but muscle flap coverage of the fistula, and vascularized tissue placement to fill the postresectional, or even a thoracoplasty.

## FOLLOW-UP

All patients who complete chemo-, radio-, and/or surgical therapy for lung cancer should be followed with chest imaging for life. The NCCN guidelines recommend that imaging studies be performed every 4 to 6 months for the 2 years to detect potential recurrences and metastases and yearly thereafter to detect potential new primary tumors. After lung cancer resection, patients have a lifetime risk of 1 to 2 percent per year of developing a new primary tumor.[62]

## PROGNOSIS

### Small Cell Lung Cancer

The median overall survival for patients with limited disease small cell lung cancer is 12 to 20 months and 9 months for patients with extended disease.[63] A recent study of patients who underwent resection for small cell lung cancer found

that patients with stage I, II, or IIIA disease had overall 5-year survival rates of 56 percent, 40 percent, and 12 percent, respectively.[64]

## Nonsmall Cell Lung Cancer

The overall 5-year survival rates among NSCLC patients who underwent lung cancer resection at a major cancer center are 75 percent for stage IA disease, 68 percent for stage IB disease, 65 percent for stage IIA disease, 43 percent for stage IIB disease, and 37 percent for stage IIIA disease.[65] Patients with stage IIIB or IV disease have an overall 5-year survival rate of 3.5 percent.[11] NSCLC patients with bronchoalveolar and typical carcinoid tumors tend to have better prognoses than other NSCLC patients.

# CONCLUSIONS

Lung cancer is a leading cause of preventable death attributed to smoking and environmental exposure. It is the result of a series of genetic changes caused by environmental factors that allow cells to grow, proliferate, and metastasize. Most lung cancer patients present with late-stage disease. Patients' clinical symptoms depend on the location and size of the tumor and presence of metastasis. Lung cancer diagnosis is accomplished through the pathologic examination of a biopsied specimen of the mass. Clinical staging is based on a combination of patient history, physical exam, pathologic, and radiographic information. The patients with lung cancer patients are treated using multimodality therapy. Surgery and radiotherapy are used for local and regional disease; surgery remains the primary therapy, and radiotherapy is reserved for patients who cannot tolerate surgery. Chemotherapy is used to treat patients with regional and metastatic lung cancer. Overall, the prognosis for lung cancer is poor. The estimated overall 5-year survival rate for all of the patients with lung cancer is about 16 percent. The type and pathologic stage of the lung cancer is the best predictor for overall survival.

# ACKNOWLEDGMENT

We thank Joe Munch from the Department of Scientific Publications at the University of Texas M.D. Anderson Cancer Center for editing the chapter.

## PRIMARY LUNG CANCER BOARD REVIEW QUESTIONS (CHAPTER 9)

1. Which is the most common growth pattern for adenocarcinoma of the lung?
   A. Central endobronchial tumor
   B. Background of pulmonary fibrosis
   C. Pseudomesotheliomatous carcinoma
   D. Diffuse pneumonia-like consolidation
   E. Peripheral tumor with overlying pleural retraction

2. Which of the following histology patterns is correct?
   A. Squamous: sheets of polygonal cells
   B. Atypical carcinoid: keratin pearls and intracellular bridges
   C. Large cell: two or fewer mitoses and no necrosis
   D. Small cell: ill-defined borders and absent nucleoli
   E. Typical carcinoid: multiple mitoses with necrosis

3. Which is not a risk factor for lung cancer?
   A. Xenon exposure
   B. Smoking
   C. Second-hand smoke
   D. Asbestos exposure
   E. Nickel exposure

4. Which staging is correct according to the 7th edition of the NSCLC staging system?
   A. T3 tumor, N2 disease = stage IIIB
   B. T1 tumor, N3 disease = stage IIIA
   C. T2a tumor measuring 4 cm = stage IB
   D. T2b tumor, N1 disease = stage IIA
   E. T4 tumor of vertebral body = stage IIB

5. Which of the following is true for lung cancer trials?
   A. The ACOSOG Z0030 trials showed no difference in survival between lymph node sampling and formal dissection.
   B. Diespierre et al. demonstrated a survival advantage for neoadjuvant chemotherapy in stage II cancer.
   C. The Adjuvant Lung Project Italy showed decreased survival in the chemotherapy group due to side effects from the aggressive regimen.
   D. The IALT demonstrated improvement in disease-free survival but not overall survival in the chemotherapy arm.
   E. The NCI of Canada study showed greatest survival benefit in stage IB patients.

## ANSWERS

1. **Answer: E.** The most common growth pattern of adenocarcinoma is a peripheral tumor that causes the overlying pleura to retract.
2. **Answer: D.** Small cell cancer is typified by ill-defined borders between cells and absent nucleoli. Sheets of polygonal cells are found in large cell cancers. Keratin pearls and intracellular bridges are found in squamous cell cancers. Typical carcinoids have two or fewer mitoses and no necrosis.
3. **Answer: A.** Radon, not xenon, exposure is associated with lung cancer.
4. **Answer: C.** A T2a tumor measuring between 3 and 5 cm is stage IB.
5. **Answer: A.** There was no difference in survival between lymph node sampling and formal lymph node dissection in the ACOSOG Z0030 trial.

# Pulmonary Metastasis

*DuyKhanh P. Ceppa*
*Betty C. Tong*

**KEY CONCEPTS**

- Metastatic disease to the lung is the second-most common pulmonary malignancy, affecting 20 to 54 percent of patients with cancer. A subset of patients with metastatic disease present with disease confined to the lung. Complete resection of this pulmonary burden of disease can result in 5-year survival rates as high as 40 to 50 percent.
- Pulmonary metastases are typically found on surveillance imaging. Very rarely are patients symptomatic with cough, pain, hemoptysis, or dyspnea.
- Helical, thin-sliced computed tomography is the gold standard for detecting pulmonary metastases. Pulmonary nodules as small as 3 mm can be detected with a sensitivity as high as 75 percent.
- Treatment options for secondary pulmonary malignancies include systemic chemotherapy, isolated lung perfusion or suffusion, radiofrequency ablation, stereotactic body radiation therapy, and surgical resection.
  - Isolated lung perfusion (ILuP) and suffusion are investigational and should be restricted to institutions with active research protocols.
  - The application of radiofrequency ablation (RFA) and stereotactic body radiation therapy (SBRT) is limited by the size and location of the nodule. These modalities are typically reserved for patients who are poor operative candidates or who refuse surgery.
  - Pulmonary metastasectomy is the treatment of choice for patients with metastatic colon cancer, renal cell carcinoma, sarcoma, melanoma, and nonseminomatous germ cell tumor. Surgery should also be considered for select patients with metastatic breast and head and neck cancer.
- Patients considered for pulmonary metastasectomy should meet the following criteria:
  - Primary site of disease is controlled or controllable.
  - Absence of extrathoracic metastases (or, in cases of oligometastases, extrathoracic sites of metastases are controlled or controllable).
  - The patient has the pulmonary reserve to tolerate the appropriate parenchymal loss for a complete resection.
  - Mediastinal and intrathoracic lymphadenectomy is advocated.
- Pulmonary metastasectomy is associated with the following survival rates:
  - Colorectal cancer 40 to 68 percent (5 years), renal cell carcinoma 47 to 74 percent (5 years), sarcoma 40 percent (5 years), melanoma 22 to 27 percent (5 years), and nonseminomatous germ cell tumor (NSCGT) 74 to 94 percent (5 years)
  - Pancreatic adenocarcinoma 40 percent (2 years), hepatocellular carcinoma 41 percent (5 years), breast carcinoma 35 to 80 percent (5 years), and head and neck squamous cell carcinoma 26 to 50 percent (5 years)
  - Disease-free interval, number of pulmonary metastases, and completeness of resection are significant predictors of long-term survival.

## INTRODUCTION

Pulmonary metastases are defined as secondary malignant tumors of the lung parenchyma or pleura. Originating from an entirely separate organ, metastatic disease to the lung is the second-most common pulmonary malignancy. Autopsy studies have demonstrated that 20 to 54 percent of patients who die with a diagnosis of cancer also have pulmonary metastases. A subset of these patients have metastases limited only to the lung. In their study of 162 sarcoma patients, Huth and Eilber reported that of the patients with recurrent disease, 88 percent had pulmonary metastases, with the lung being the sole site of disease in 72 percent.[1] Similarly, Billingsley and associates examined 230 patients with recurrent soft tissue sarcomas treated at Memorial Sloan–Kettering Cancer Center and found that 73 percent of these

patients had recurrences that appeared initially only in the lungs.[2] With a significant proportion of patients with metastatic malignancy confined to the lung, complete resection of the intrathoracic disease burden would render these patients disease-free.

Although the majority of operations for pulmonary metastasectomy can be performed via an open approach, thoracoscopic pulmonary metastasectomy has been demonstrated to be equally efficacious with similar survival rates and has the benefit of fewer adhesions, less pain, and shorter length of stay.

Weinlechner and colleagues published the first report of pulmonary metastasectomy in 1882.[3] In 1927, Tudor Edwards performed a sublobar resection for recurrent sarcoma following an amputation 6 years earlier. Barney and Churchill described a lobectomy after nephrectomy for synchronous metastatic kidney cancer in 1933; the patient subsequently survived for 23 years.[4] Blalock described the first pneumonectomy for metastatic large bowel carcinoma at a "recent advances" lecture in 1944.[5]

In 1947, Alexander and Haight published a case series of pulmonary metastasectomies, proposing the first set of selection criteria for surgery.[6] Since then, pulmonary metastasectomy has become a widely accepted treatment modality for patients with metastatic disease. Recent series have described 5-year survival rates of 40 percent in osteogenic sarcoma,[7] 38 percent in soft tissue sarcoma,[8] 40 percent in colorectal carcinoma,[9] and 50 percent in patients with breast carcinoma.[10]

## PATHOPHYSIOLOGY

Stephen Paget first described his "seed and soil" hypothesis in 1889. He observed that metastatic disease fell in a nonrandom pattern and postulated an affinity of certain primary cancer types (the "seed") toward factors within the metastatic target organ (the "soil"). In 1928, James Ewing challenged this hypothesis, proposing that metastasis was directly related to the anatomy of the vascular system instead. Regardless of which of these two hypotheses holds true, new improvements in cellular, molecular, and imaging techniques have elucidated that the development of metastatic lesions is the result of a complex, multistep process known as the metastatic cascade.[11] In order for a metastatic focus of cancer cells to form, cells from a growing tumor need to escape the local environment (intravasation, resistance to anoikis), travel while avoiding host defenses (evasion of the immune system), leave the bloodstream (extravasation), and begin the process of implantation and growth (dormancy and proliferation).

Recent advances in identifying the gene expression profiles of varying tissues have led to investigations in identifying a signature of genes characteristic of metastatic tumors. Gene expression profiling studies using cDNA microarrays comparing the expression profiles of primary tumors with the expression profiles of metastatic tumors in patients with breast cancer have identified a 70-gene signature that successfully differentiated tumors with poor versus good prognosis.[12] Ramaswamy and coworkers identified a metastatic signature based on gene expression profiling that could predict the presence of metastases across a variety of adenocarcinomas.[13] Lastly, although similar studies in humans are yet to be performed, Minn and colleagues were able to identify an expression signature characteristic of pulmonary metastases in a murine model.[14] Undoubtedly, understanding the metastatic cascade and elucidating the mechanisms of each step will provide insight into potential treatments against metastatic disease.

## CLINICAL FEATURES

Secondary tumors of the lung are most often an occult finding during surveillance imaging after primary tumor resection. Patients are typically asymptomatic. Rarely, patients with pulmonary metastases will present with symptoms of dyspnea, cough, hemoptysis, or pain. Pleural involvement may result in pneumothorax or pain. Thorough history taking may elicit a history of unintentional weight loss, general malaise, or decreased energy. Physical examination is likely to be negative for significant findings.

## DIAGNOSTIC MODALITIES

Although plain chest radiography was previously the mainstay of screening for pulmonary metastases, computed tomography (CT) has emerged as the most commonly used screening imaging modality and is the current standard. On CT imaging, pulmonary metastases appear as single or multiple pulmonary nodules within the lung parenchyma. In general, these lesions are rounded and well circumscribed. Hilar or mediastinal lymphadenopathy may also indicate lymphatic involvement. In some cases, the pulmonary nodule(s) may contain tissue elements consistent with the primary site (e.g., calcification in metastatic osteosarcoma or fatty elements in liposarcoma).

High-resolution CT (HRCT) can detect pulmonary nodules as small as 3 mm. In a study comparing conventional CT with HRCT, Margaritora and colleagues reported a sensitivity of 100 percent for both types of scans for nodules 10 mm in size.[15] The sensitivity of nodules smaller than 6 mm dropped to 62 and 48 percent with conventional CT and HRCT, respectively. Overall sensitivity for pulmonary metastases was 82.1 percent. In examining the sensitivity of thin-slice CT, Pfannschmidt and coworkers found the overall sensitivity of 3- and 5-mm slices to be 88.8 and 83.7 percent, respectively.[16] The sensitivity decreased to 74.7 (3-mm slices) and 64.0 percent (5-mm slices) for nodules smaller than 5 mm.

The use of positron emission tomography (PET) scan in the detection of pulmonary metastasis has also been studied. Fortes and colleagues found an overall sensitivity of 67.5 percent in the detection of pulmonary metastases with

PET imaging.[17] For lesions 10 mm or greater in size, the sensitivity of PET was 87.8 percent; however, for lesions smaller than 10 mm, sensitivity was only 29.6 percent. It is also notable that the sensitivity varied with histology. For metastases with squamous cell carcinoma histology, sensitivity of the exam was 93 percent. For sarcoma, the sensitivity of PET was 44 percent. Although the sensitivity of PET imaging is variable and this modality should not be used solely for the screening of pulmonary metastases, it does serve as an adjunct to CT imaging and is particularly useful in evaluating for the presence of extrathoracic disease.

## MEDICAL THERAPY

### Chemotherapy

Systemic chemotherapy should be used for patients with widely metastatic disease or as an adjunct to surgical therapy in patients with metastatic germ cell tumor or breast cancer. Patients with a solitary pulmonary metastasis or oligopulmonary metastases should be considered for surgical resection, as 5-year survival following resection can be as high as 40 percent.[18] Patients who cannot tolerate surgery or refuse surgery for metastases confined to the lung should be considered for other forms of locoregional therapy such as radiofrequency ablation (RFA), stereotactic body radiation therapy (SBRT), or isolated lung perfusion (ILuP).

### Radiofrequency Ablation

RFA uses an alternating current to create frictional heating of tissue, resulting in tissue necrosis. A radio wave—emitting electrode is inserted into the tumor, which is then heated to 90°C to 100°C to produce coagulation necrosis. Originally used in the treatment of hepatic tumors, the use of RFA was soon extended to the treatment of pulmonary malignancies. Candidates for RFA should have disease confined to the lung(s) or otherwise controlled. In addition, lesions amenable to RFA should be small in diameter (less than 3 cm in diameter) and should not abut mediastinal structures, which may act as a heat sink.[19]

In general, RFA is associated with low morbidity and mortality. Common complications associated with RFA are usually mild and self-limited. Patients should be counseled regarding the possibility of pain during the procedure, pneumothorax (possibly requiring thoracostomy tube management), fever, hemoptysis, cough, pleural effusion, hemothorax, and abscess formation in the ablation bed.

Lesion size is an important consideration of RFA for treatment of metastatic disease. Several authors have demonstrated statistically significant differences in response rates as well as overall survival for lesions greater than 3 cm versus those smaller than 3 cm.[20,21] In a study of RFA for renal cell carcinoma metastases, the 5-year survival of patients with fewer than six nodules that were less than 6 cm in diameter was 100 percent. Recurrence-free survival was 92 percent at 1 year and 23 percent at 5 years. Another study of 22 patients with metastases of varying histology demonstrated a 2-year survival of 68 percent. Lesion size was found to be a significant prognostic factor in both recurrence and survival.[19]

One important aspect to remember regarding RFA is that since there is no pathologic analysis, the treatment margin is unknown. A study of RFA of 18 pulmonary lesions that were subsequently resected for pathologic analysis demonstrated only 39 percent of lesions were completely ablated and only 50 percent of patients had more than 90 percent tumor ablation.[22] More importantly, 11 percent of patients had less than 90 percent tumor ablation. Although the authors contend that early pathologic analysis may have underestimated the effectiveness of tumor ablation, these results are inferior to those achieved with surgical resection. Therefore, RFA should be reserved for treating pulmonary metastasis in patients who are medically inoperable or who refuse surgery.

### Stereotactic Body Radiation Therapy

SBRT is a technique that uses precisely targeted radiation. This technique facilitates the delivery of higher doses of radiation to the target anatomy, resulting in better tumor control, while minimizing harmful effects to adjacent normal tissue. Patients being considered for SBRT should meet the same criteria as those being considered for RFA. Although data regarding SBRT for pulmonary metastases are limited, a multi-institutional Phase I/II trial of SBRT for pulmonary metastases demonstrated local control of 100 and 96 percent at 1 year and 2 years, respectively, and a median survival of 19 months.[23]

Compared with conventional radiotherapy, SBRT has several unique features. First, the doses of radiation administered are high and localized. To reduce treatment toxicity, there are tight dose distributions around the tumor, with rapid dose falloff in the surrounding lung parenchyma. During planning and treatment, the radiation oncologist can account for tumor motion. Finally, there is a reproducible patient immobilization to minimize movement during treatment sessions. Complications associated with SBRT affect up to 5 percent of patients, and most commonly are pneumonitis (grade 2 and higher) and rib fractures.

A significant limitation to SBRT is that the treated lesions should be small in diameter. In addition, the treatment of multiple lesions presents as a challenge while attempting to minimize toxicity to adjacent, normal lung parenchyma. As such, although SBRT should not be the primary modality used in treating secondary pulmonary malignancies, it can serve as a good alternative in treating poor surgical candidates or as an adjunct to surgical therapy in patients with multiple lesions.

## SURGICAL THERAPY

### Surgical Metastasectomy

Surgical resection is the mainstay of therapy for patients with secondary pulmonary malignancies in the absence of extrapulmonary disease and controlled primary disease. Alexander and Haight proposed the first set of selection criteria, listed in Table 10-1, for patients eligible for pulmonary metastasectomy.[6] First and foremost, the site of primary disease must be either controlled or controllable. Ideally, the patients should also have an absence of extrapulmonary disease. For patients with an additional site of metastatic disease outside the lung, the extrapulmonary disease should be controlled or controllable. Finally, the patient should have sufficient pulmonary reserve to tolerate the loss of lung parenchyma required to achieve a complete resection. With the appropriate selection of patients, 5-year survival rates of 20 to 40 percent have been reported.[18]

Patients who are candidates for resection may be treated with either open approach or thoracoscopic approach. Proponents of open resection state that open surgery is mandatory for sufficient manual palpation of the lung parenchyma. However, supporters of thoracoscopic surgery assert that the sensitivity of HRCT obviates the need for manual palpation and that the benefits of a thoracoscopic approach outweigh those of an open approach. Compared with thoracotomy, benefits of thoracoscopy include decreased postoperative pain, decreased chest tube duration, decreased hospital length of stay, faster recovery, and decreased inflammatory response facilitating re-do surgery.

In an attempt to provide guidelines for surgical approach in pulmonary metastasectomy, the European Society of Thoracic Surgeons working group carefully evaluated the considerations involved in decision-making.[24] They narrowed the issue of surgical approach to four questions: (1) What is the evidence for the need for palpation of the lung in the modern era of imaging? (2) Is there evidence of a difference in outcome for an open versus a closed approach? (3) Is there evidence for a difference in outcome for an initial policy of bilateral versus unilateral exploration? (4) In patients with known bilateral disease, is there a difference in outcome with simultaneous versus a staged approach? Each of these topics is an important consideration in the surgical approach to pulmonary metastases.

**TABLE 10-1: Criteria for Surgical Resection of Pulmonary Metastasis**

**Alexander and Haight criteria for resection of secondary pulmonary malignancy**

- Primary tumor is controlled (or is controllable)
- Any extrapulmonary disease is controlled (or is controllable)
- Patient must be fit for surgical resection (patient's pulmonary reserve will tolerate pulmonary resection)

As previously mentioned, HRCT has an overall sensitivity of 88.8 and 83.7 percent for 3 and 5 mm slices, respectively.[16] Although the sensitivity decreased to 74.7 (3-mm slices) and 64.0 percent (5-mm slices) for nodules less than 5 mm in size, it is difficult to argue that manual palpation has a sensitivity superior to HRCT scans currently available. However, in early studies investigating the need for manual palpation of metastatic disease, 10 of 15 patients had additional nodules that were not identified on CT scans or during their video-assisted thoracic surgery (VATS) procedures.[25] More recent studies have similarly reported the identification of additional nodules during thoracotomy that were not recognized either on CT imaging or during thoracoscopy.[26–28]

Although an open approach may identify more nodules than during thoracoscopy, this finding does not translate to improved survival. In a review of seven studies by Molnar, six demonstrated no difference in survival between patients undergoing metastasectomy by VATS versus open surgery.[24] Moreover, patients undergoing thoracotomy experience significantly more complications than those who have similar parenchymal resection by thoracoscopy.[28] In a recent cohort study comparing patients treated with metastasectomy via VATS versus thoracotomy, Carballo and associates demonstrated a 5-year overall survival of 58.8 percent for thoracotomy and 69.6 percent for VATS ($p = 0.03$).[29] There were no statistically significant differences between the two groups in terms of recurrence-free survival.

Finally, there are no data demonstrating a difference in outcome between an initial policy of bilateral versus unilateral exploration and simultaneous versus staged approach in patients with known bilateral disease. Results from the European Society of Thoracic Surgeons working group survey suggested that an initial approach via median sternotomy is reasonable for patients with known bilateral disease.[24] In cases not suitable for median sternotomy, such as posterior lesions or patients with previous pulmonary resection, staged thoracotomy with a 3- to 6-week interval was recommended. Zheng and colleagues recommended a similar approach to pulmonary metastasectomy except that these authors were more supportive of a thoracoscopic approach.[19]

In our experience, complete thoracoscopic resection of pulmonary metastases is possible in 75 percent of cases. We have resected as many as six ipsilateral nodules in a single setting, and have routinely had success in resecting nodules less than 5 mm in diameter. Figure 10-1 depicts an algorithm for managing pulmonary metastasectomy.

Ultimately, the main tenet of surgical resection of pulmonary metastases is complete resection. Peripheral nodules should be treated with wedge resection; more central nodules may require a segmentectomy, lobectomy, or, rarely, pneumonectomy. With regard to open versus thoracoscopy, "there is such evident variation that depends on the particular needs of the patient and the preference of the surgeon that it might well be a situation in which it is a decision for individual craftsmen to do what works best in their hands."[24]

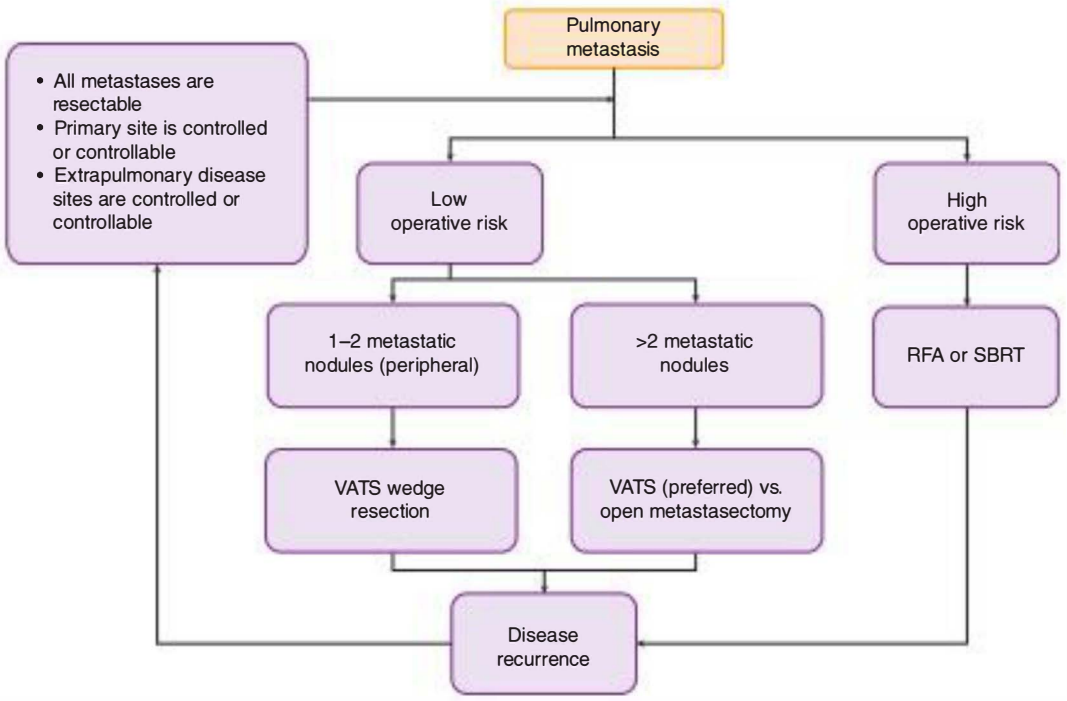

**FIGURE 10-1** Suggested treatment algorithm for management of pulmonary metastases. Patients with pulmonary metastases must first meet the criteria for resection (controlled primary disease, absence of extrathoracic metastases, ability to tolerate resection of lung parenchyma). Patients who are operative candidates with adequate pulmonary reserve should undergo thoracoscopic (preferred) versus open resection. Patients who are at high risk for perioperative morbidity and mortality should be considered for radiofrequency ablation (RFA) or stereotactic body radiation therapy (SBRT). Patients who have recurrent disease should be reevaluated for surgical resection. (From Zheng F, Fernando H (eds). *Surgical and Nonresectional Therapies for Pulmonary Metastasis*. 2010; 90(5):1041–1051. With permission from Elsevier.)

As for any lung resection, preoperative planning should include pulmonary function testing and an evaluation of the patient's ability to tolerate an operation. Patients receiving certain chemotherapeutic agents are at risk for drug-induced lung disease, including interstitial pneumonitis and fibrosis, hypersensitivity pneumonitis, and acute pneumonia. Specific agents implicated in these disorders include bleomycin, mitomycin C, busulfan, cyclophosphamide, carmustine, gefitinib, paclitaxel, and methotrexate. It is mandatory for the surgeon to communicate with the anesthesiologist prior to surgery regarding the patient's prior exposure to chemotherapeutic agents and to attempt to minimize the fractional inspired oxygen ($Fio_2$) to avoid oxygen toxicity. Finally, patients are required to engage in smoking cessation for at least 3 weeks prior to surgery to reduce the risk of postoperative pneumonia and other complications.

## Extended Pulmonary Resection for Metastatic Disease

A small minority (less than 3%) of patients with metastatic disease will require extended resection, defined as pneumonectomy or other lung resection with en bloc resection of chest wall, pericardium, superior vena cava, or other thoracic structures. For these patients, very rigorous consideration of strict preoperative selection criteria, including the probability of complete resection, should be undertaken. Cardiopulmonary bypass may be used in rare instances when tumors involve or invade the great vessels or cardiac structures, and operation is considered for either cure or palliation of symptoms.

Several series of extended resections for metastatic disease have been reported in the literature, with good results. Spaggiari and associates reported a 5-year survival of 16 percent in a series of 42 patients who underwent pneumonectomy for metastatic disease from various primary sites.[30] Similarly, Putnam and colleagues demonstrated a 5-year actuarial survival of 25.4 percent in 38 patients undergoing extended resection, 19 of which had pneumonectomy. Overall mortality was 5.3 percent and occurred in patients undergoing pneumonectomy.

In a review of the International Registry of Lung Metastases, Koong and coworkers reported that 133/5206 (3%) patients underwent primary pneumonectomy for metastatic disease and 38/5206 (1%) underwent completion pneumonectomy.[31] Patients who had complete resection had a 5-year survival rate of 20 percent. Those whose disease

could not be completely resected had a perioperative mortality of 19 percent with a poor 2-year survival rate. Favorable prognostic factors for patients undergoing pneumonectomy for pulmonary metastasis include complete resection, single metastasis, and negative mediastinal lymph node status.

## Recurrent Pulmonary Metastases

In some instances, reoperation is indicated for management of recurrent pulmonary metastases. Patients being considered for reoperation should be selected by the same criteria as for primary operation for pulmonary metastases. That is, the primary and/or other extrathoracic disease site(s) must be controlled and the patient must be physiologically able to tolerate surgery and lung resection.

Most series describing reoperation for pulmonary metastases are small, and consist of patients with primary sarcoma. Median survival for patients with resectable disease ranges from 14.5 to 70 months, depending on the tumor histology.[32,33] The reported 5-year survival after reoperation for sarcomatous lung metastases is 22 percent. Two or fewer nodules, size less than 2 cm, and low-grade primary tumor histology are favorable prognostic factors.

## Lymphadenectomy as an Adjunct to Metastasectomy

The question of whether or not to perform a complete mediastinal lymph node dissection in the setting of pulmonary metastasectomy remains a debate. Most studies evaluating pulmonary metastasectomy have inconsistently included either lymph node sampling or lymph node dissection. As a result, the majority of current reported incidences of lymph node involvement are likely underestimates.

Data from the International Registry of Lung Metastases reported metastasis to hilar or mediastinal lymph nodes in 5 percent of patients.[18] Specific to disease, 11 percent of germ cell tumors, 8 percent of melanomas, 6 percent of epithelial tumors, and 2 percent of sarcomas harbored lymph node metastases. However, more recent studies that included systematic lymph node dissections have reported lymph node involvement in up to 32 percent cases, including a study on patients with metastatic sarcoma, of whom 19 percent had lymph node involvement.[34]

The involvement of regional, hilar, or mediastinal lymph nodes is an important prognostic factor. In a series of 245 patients with lung metastases of various primary sites, Pfannschmidt reported a median survival of 63.9 months in patients without lymph node involvement (N0 disease), compared with 32.7 months and 20.6 months for patients with N1 disease and N1 + N2 disease, respectively.[35] Similarly, Welter and associates reported a 5-year survival of 78.5, 0, and 0 percent in patients with colorectal cancer and pulmonary, hilar, and mediastinal lymph node metastases, respectively.[36] As such, a formal and systematic evaluation of hilar and mediastinal lymph nodes should routinely be performed during pulmonary metastasectomy.

## Isolated Lung Perfusion

ILuP allows the selective delivery of a chemotherapeutic agent into the lung while diverting the venous effluent. With this technique, higher and more toxic doses of chemotherapy can be delivered with fewer adverse effects as compared with intravenous chemotherapy. Drug metabolism by the liver or kidneys to inactive forms is avoided, as are high drug levels in critical organs.

Unilateral ILuP is performed by first cannulating the pulmonary artery and pulmonary veins. These cannulas are then connected to an extracorporeal circuit. The vessels are clamped centrally, and the chemotherapeutic agent is injected into the circuit. Perfusion of both lungs simultaneously requires two extracorporeal systems to completely separate the systemic and pulmonary circulation.

Although several animal studies on ILuP demonstrated promising results, studies in humans thus far have been limited to Phase I/II clinical trials with mixed results. In a thorough review of ILuP, Van Schil et al. described seven studies using various chemotherapeutic agents on metastatic sarcoma, melanoma, Ewing sarcoma, renal cell carcinoma, adenoid cystic carcinoma, and colon carcinoma.[37] Out of 32 patients with metastatic sarcoma treated with doxorubicin, only 1 had a major response, 1 patient had stabilization of disease on the treated side (with progression of disease on the untreated side), and the remainder of the patients had neither a partial nor a complete response. Complications included pneumonia ($n = 2$), lung injury ($n = 1$), paradoxical tumor embolus ($n = 1$), and sternal nonunion ($n = 1$). Two of the three studies using doxorubicin identified a significant decrease in pulmonary function ($FEV_1$, FVC, or DLCO) following treatment. A decrease in pulmonary function was also noted in six patients with metastatic sarcoma who were treated with cisplatin. Of 10 patients treated with cisplatin, 6 developed pulmonary edema, one of whom required prolonged mechanical ventilation. Three patients were disease-free at 12 months, and one patient was disease-free in the chest but succumbed to cerebral metastases at 13 months. In a study using TNF-α as the chemotherapeutic agent, only 3 of 16 patients treated demonstrated short-term partial response and ultimately had progression of disease 6 to 9 months following therapy. Lastly, of 23 patients treated with melphalan, 8 were disease-free at 25 months while 14 patients had recurrent disease.

To date, studies on ILuP are limited to Phase I/II trials and the studied involved a variety of chemotherapeutic agents and target histology. As such, it is difficult to interpret the results and make any generalizations on the application of ILuP. Although experimental data support the use of ILuP, these techniques remain experimental and their use should be restricted to centers with special interests in regional therapy for lung metastases.

### Isolated Lung Suffusion

Similar to ILuP, lung suffusion involves the injection of a chemotherapeutic agent into a pulmonary artery. The artery is clamped proximal to the injection site. In contrast to ILuP, however, lung suffusion involves isolation and clamping of the pulmonary veins. This allows for uniform distribution of the chemotherapy through the entire lung, with slow leakage into the systemic circulation. Lung suffusion can be achieved using minimally invasive techniques. To date, the use of lung suffusion in humans has been restricted to Phase I clinical studies.

## OUTCOMES AND PROGNOSIS

Although resection of secondary pulmonary malignancies had been performed for many decades, data in support of this practice were lacking. Therefore, in 1991, the International Registry of Lung Metastases was established to establish the long-term results of pulmonary metastasectomy. The results of this effort, an analysis of 5206 cases of epithelial cell, sarcoma, germ cell, and melanoma metastasectomies, were published in 1997.[18] In this study, actuarial 5-, 10-, and 15-year survival was 36, 26, and 22 percent (median 35 months), respectively, for patients who underwent complete resection of metastases. In contrast, those who had incomplete resections had an actuarial survival of 13 percent at 5 years and 7 percent at 10 years (median 15 months). In addition, 5-year survival was significantly greater for patients with a longer disease-free interval (DFI; 45% for DFI longer than 36 months vs. 33% for DFI up to 11 months) and a single focus of metastasis (43% for single lesion vs. 27% for >4 lesions). Multivariable analysis demonstrated a more favorable prognosis based on histology, with germ cell tumor being the best and melanoma being the worst. These findings were further supported in a more recent single-institution study of 708 pulmonary metastasectomies.[38]

### Colorectal Carcinoma and Other Gastrointestinal Epithelial Cell Carcinomas

Secondary pulmonary malignancies of epithelial cell origin are the most common metastatic pulmonary disease. Of these malignancies, thoracic surgeons most frequently encounter pulmonary metastases from a colorectal primary malignancy. Resection of these pulmonary metastases has become a common practice. Surgical resection is associated with low morbidity and mortality as well as long-term survival rates up to 40 to 68 percent in a select population of patients.[39] In a review of 378 patients undergoing pulmonary metastasectomy of colorectal malignancies at Duke University and Memorial Sloan–Kettering Cancer Center, 3-year overall survival was 78 percent and 3-year disease-free survival (DFS) was 28 percent.[40] Independent predictors of recurrence were a DFI of less than 1 year and more than three pulmonary lesions at the time of presentation.

For colorectal carcinoma, there are conflicting data regarding whether a history of a previously resected hepatic metastasis is of prognostic value. Zabaleta and colleagues concluded that a prior history of a hepatic metastasis predicted a poorer prognosis while Jarabo and associates reported otherwise.[41,42] In both studies, however, multivariable analysis identified the presence of metastatic disease in mediastinal or pulmonary lymph nodes as a predictor of poorer prognosis. In addition, prognosis did not decrease with repeated pulmonary resection. No randomized trials investigating the validity of surgical resection of colorectal pulmonary metastases exist. To this end, the Pulmonary Metastasectomy in Colorectal Cancer (PulMiCC) trial is currently underway.[43]

Data regarding pulmonary metastasectomy of other gastrointestinal epithelial cell cancers are fewer and limited to case series and anecdotal information. In a study of 31 Stage I/II pancreatic adenocarcinoma patients, Arnaoutakis and coworkers reported no morbidity or mortality following pulmonary metastasectomy, an increase in median cumulative survival (51 months vs. 23 months; $p < 0.04$), and a trend toward improved overall 2-year survival (40% vs. 27%; $p = 0.02$).[44] For metastatic hepatocellular carcinoma, Kitano et al. reported a 5-year survival of 40.9 percent and a 2-year DFS of 19.5 percent in 45 patients.[45]

### Renal Cell Carcinoma

Data regarding pulmonary metastasectomy for renal cell carcinoma typically are included in large studies on pulmonary metastasectomy, without focusing on outcomes specific to renal cell carcinoma.[18,38] However, in a large series of 191 patients, Pfannschmidt and colleagues reported that the length of the DFI, the number of pulmonary metastases, and the involvement of lymph node metastases were all independent predictors of survival following metastasectomy for renal cell carcinoma.[46] Overall 5-year survival was 42.1 percent in patients without lymph node metastasis and who underwent complete resection. Similarly, Alt et al. from the Mayo Clinic reported a 5-year cancer-related survival rate of 73.6 percent with complete resection in 49 patients with metastases confined to the lung.[47] Moreover, they supported resection in the setting of multiple-site renal cell carcinoma metastases, demonstrating prolongation of median cancer-related survival in patients who underwent complete resection (4.8 years complete resection vs. 1.3 years incomplete resection; $p < 0.001$).

Kanzaki and associates reported long-term outcomes in a single-institution 25-year experience on pulmonary metastasectomy for renal cell carcinoma.[48] Of 48 patients who underwent 59 resections (8 of whom had additional resections for pulmonary recurrence), the 3-, 5-, and 10-year overall survival rates were 60, 47, and 18 percent, respectively. On multivariate analysis, DFI greater than 2 years and complete resection were identified as positive prognostic factors.

## Osteogenic Sarcoma

When considering pulmonary metastasectomy, one must distinguish soft tissue sarcoma from osteogenic sarcoma. Osteogenic sarcoma may develop pulmonary metastases in up to 80 percent of patients after initial treatment.[1] Because the lung is often the only site of metastatic disease in patients with osteogenic sarcoma, pulmonary metastasectomy may render these patients disease free. Both Snyder and Putnam, in their series of 21 and 39 patients, respectively, reported 5-year survival rates of nearly 40 percent in patients with osteogenic sarcoma who underwent pulmonary metastasectomy.[7,49] The presence of three or fewer nodules on preoperative imaging, longer DFI, and the presence of resectable metastases were associated with longer postthoracotomy survival. Conversely, lack of primary tumor control, incomplete excision of metastases, and disease progression during treatment have all been shown to be negative prognostic indicators.[50]

## Soft Tissue Sarcoma

Soft tissue sarcomas are nonossifying tumors arising from connective tissue elements. Approximately 23 percent of patients with soft tissue sarcoma will develop distant metastases.[2] As with osteogenic sarcoma, the majority of distant recurrences present initially within the lungs; median survival after the development of lung metastases is approximately 1 year.

Pulmonary metastasectomy may be useful in selected patients with metastatic soft tissue sarcoma. In a large series of 255 patients, Van Geel and colleagues reported a 5-year survival of 38 percent for patients with soft tissue sarcoma undergoing pulmonary metastasectomy.[8] In a more recent study, Sardenberg reported a 7.5-year survival rate of 34.7 percent.[51] As with other primary sites, a longer DFI (greater than 6 months) and fewer than three nodules are associated with a higher overall 5-year survival.

The role of adjuvant chemotherapy following resection is unclear and currently under investigation. What is clear, however, is that some patients benefit from repeat resection. In several series of patients with recurrent pulmonary metastases from soft tissue sarcoma, patients whose tumors were completely resected in repeat surgical procedures had significantly longer overall survival compared with those whose tumors were either incompletely resectable or unresectable.[32,52]

## Melanoma

Thirty percent of patients with previously treated melanoma will develop metastatic disease, and approximately 40 percent of these patients will have isolated pulmonary metastases. Patients with Stage IV melanoma have a median survival of 6 to 8 months and a 5-year survival of less than 5 percent. In their review of pulmonary metastasectomy for melanoma, Oliaro and coworkers reported 5-year survival rates of 22 to 27 percent, which is consistent with other published results.[53] Petersen and colleagues estimated 13, 17, and 23 percent risk of developing pulmonary metastases at 5, 10, and 20 years, respectively, in a large longitudinal database of melanoma patients.[54] Multivariable analysis demonstrated that nodular histologic type, DFI shorter than 1 year, more than two pulmonary metastases, and the presence of extrathoracic metastases were predictors of poor prognosis. Conversely, completion of pulmonary metastasectomy was identified as an independent predictor of improved prognosis and associated with a survival advantage. There was no significant difference in survival between patients undergoing single metastasectomy and those undergoing repeated pulmonary metastasectomy (median survival 17 vs. 15 months; $p = 0.9$). As such, pulmonary metastasectomy should be considered for patients with Stage IV melanoma who have fully controlled primary disease, a limited number (2 or fewer) of pulmonary metastases, absence of extrathoracic disease on PET or CT imaging, and a long DFI between the diagnosis of the primary and metastatic disease.

## Breast Carcinoma

Although the minority of patients with metastatic breast cancer has disease confined to the lung, there is evidence of benefit to pulmonary metastasectomy in selected patients. In a recent review of the International Registry of Lung Metastases, Friedel and colleagues examined outcomes of 467 patients who underwent lung resection for metastatic breast cancer.[55] In this series, 5-, 10-, and 15-year survival rates were 38 percent, 22 percent, and 20 percent, respectively. Other studies on pulmonary metastasectomy in patients with breast cancer have reported similar survival, with 5- and 10-year survival rates as high as 35 to 80 percent and 8 to 60 percent, respectively.[56] DFI greater than 36 months, complete resection, and solitary metastasis were associated with improved outcomes.

## Squamous Cell Carcinoma of the Head and Neck

Experience with pulmonary metastasectomy for malignancies of the head and neck is limited, and most reports describe experience with small case series. However, the data suggest that pulmonary metastasectomy for patients with head and neck squamous cell carcinoma may result in good long-term outcomes. In a study of 25 patients undergoing pulmonary metastasectomy, Haro and colleagues reported 3- and 5-year survival rates of 53.3 and 50 percent, respectively.[57] The largest case series in the literature, a retrospective review of 237 patients by the Metastatic Lung Tumor Study Group of Japan, reported a lower 5-year survival of 26.5 percent.[58] Favorable prognostic factors include the presence of a solitary metastasis, early stage of head and neck primary, complete resection, and longer DFI.

Many authors have written that pulmonary metastases from squamous cell carcinoma originating in the oral cavity

and oropharynx portend a worse prognosis. For example, Mochizuki and associates found that 21 of 23 patients with an oral tongue primary undergoing pulmonary metastasectomy died of their malignancy within 2 years of metastasectomy.[59] They concluded that even for patients with solitary pulmonary metastasis of oral tongue cancer, surgical metastasectomy is not a recommended treatment option. Other predictors of poor prognosis include age greater than 60 years, male sex, lymph node metastasis, and incomplete resection.

## Nonseminomatous Germ Cell Tumor

Approximately 8 percent of patients with clinical Stage I nonseminomatous germ cell tumor (NSCGT) will develop pulmonary metastases. For patients with NSCGT, resection of residual masses in either the lung or mediastinum after chemotherapy is indicated. Large published series have reported excellent long-term outcomes with low morbidity and mortality. A review of the literature by Pfannschmidt reported an overall 5-year survival between 74 and 94 percent following complete resection of pulmonary and/or mediastinal metastases.[60] Complete resection was achievable in 78.5 to 87 percent of the cases. The number of metastases is of prognostic significance, as is the presence of viable malignant cells in the completely resected masses.[61] Older age at the time of diagnosis and the presence of nongerm cell cancer in testicular specimens are favorable prognostic indicators.[62]

## Gynecologic Tumors

The lung is an uncommon site of metastasis for uterine and cervical carcinoma. However, pulmonary metastasectomy has been described in several series. Depending on the histologic type, 5-year survival may range from 37.9 (leiomyosarcoma) to 86.5 percent (choriocarcinoma).[63] As with other primary sites, a longer DFI and complete resection are favorable prognostic factors. Conversely, primary cervical tumor has been shown to be a negative prognostic factor.[64]

# SUMMARY

Up to 54 percent of patients with cancer may develop pulmonary metastases. In many of these cases the lung is the single focus of metastatic disease. For these patients, pulmonary metastasectomy should be considered and can result in 5-year survival rates as high as 40 to 50 percent. For most primary tumors, a longer DFI, complete resection, and solitary site of metastasis are favorable prognostic factors. The surgeon should aim to achieve complete resection while sparing as much lung parenchyma whenever possible. Although median sternotomy and thoracotomy may be used as surgical approaches, a thoracoscopic approach is more efficient with regard to postoperative pain, chest tube duration, and hospital length of stay, with comparable long-term survival outcomes. Only rarely is an extended resection indicated for management of pulmonary metastases. For patients who refuse or are unable to tolerate surgery, RFA or stereotactic body radiotherapy should be considered.

## PULMONARY METASTASIS BOARD REVIEW QUESTIONS (CHAPTER 10)

1. Which of the following is not a criterion for pulmonary metastasectomy?
   A. Primary malignancy is controlled
   B. Fewer than three pulmonary nodules
   C. Absence of extrathoracic metastases
   D. Sufficient pulmonary reserve to tolerate proposed resection

2. Which of the following is the most important factor during resection of pulmonary metastases?
   A. Number of metastases
   B. Disease-free interval
   C. Tumor doubling time
   D. Completeness of resection

3. Which of the following patients is the best candidate for immediate pulmonary metastasectomy?
   A. A 79-year-old patient with COPD and bilateral pulmonary nodules identified 2 months following radiation therapy for oral tongue cancer.
   B. A 56-year-old female with a history of breast cancer 5 years ago with a PET positive left internal mammary node and a peripheral single pulmonary nodule in the right upper lobe.
   C. A 25-year-old male 3 years after systemic therapy of nonseminomatous germ cell tumor with two ipsilateral pulmonary nodules and elevated serum markers.
   D. A 50-year-old male with a history of Stage II colon cancer 4 years ago and two pulmonary nodules, one in either hemithorax.

4. Which of the following is not a treatment option for a patient with pulmonary metastases and poor pulmonary function?
   A. Isolated lung perfusion
   B. Systemic chemotherapy
   C. Radiofrequency ablation
   D. Stereotactic body radiation therapy

5. The gold standard for imaging pulmonary metastases is
   A. Plain chest radiography
   B. Computed tomography
   C. Positron emission tomography
   D. Combined computed/positron emission tomography

## ANSWERS

1. **Answer: B.** Criteria for surgical resection of pulmonary metastases are that both the primary malignancy and any extrathoracic metastases (if present) are controlled or controllable. Ideally, there would be an absence of extrathoracic disease. Lastly, the patient must be able to tolerate the proposed surgery. The number of pulmonary metastases is not a factor in the selection of patients as long as a complete resection is achievable.
2. **Answer: D.** Completeness of resection is the single most important predictor of outcome following pulmonary metastasectomy. Long disease-free interval and slow tumor doubling time are also predictors of improved prognosis, but number of metastases is an inconsistent predictor of survival.
3. **Answer: D.** Criteria for pulmonary metastasectomy are that both the primary malignancy and any extrathoracic metastases (if present) are controlled or controllable. The patient must be able to tolerate the proposed surgery. Predictors of improved prognosis following metastasectomy are long disease-free interval, slow tumor doubling time, and complete resection. Malignancies with the best surgical outcomes are nonseminomatous germ cell tumor, colon cancer, renal cell carcinoma, and sarcoma. Option A depicts a poor operative candidate with a disease with poor outcomes (oral tongue cancer). Option B presents a patient with contralateral, extrathoracic disease and a malignancy of moderate outcomes following pulmonary metastases. Although option C describes a patient with a long disease-free interval and a malignancy with favorable outcomes following pulmonary metastasectomy, the patient has elevated serum markers and ought to be treated with systemic therapy first to attempt normalization of serum markers prior to proceeding with resection. Bilateral and repeated resections have not been demonstrated to negatively impact outcome in patients with metastatic colon cancer.
4. **Answer: A.** Isolated lung perfusion requires a thoracotomy, which may result in significant morbidity in patients with poor pulmonary function. In addition, ILuP has not been investigated in Phase III trials and should be restricted to institutions of specialization with active research protocols.
5. **Answer: B.** Computed tomography is the current standard for imaging pulmonary nodules. Plain radiography is not as sensitive as CT for small nodules; PET has poor sensitivity for nodules smaller than 10 mm and for certain histologies. Although PET/CT shows promise, its role has not been sufficiently studied yet.

# Lung and Heart–Lung Transplantation

*Ashish S. Shah*

## KEY CONCEPTS

- Epidemiology
  - To date, more than 30,000 lung and 2600 heart–lung transplantations have been reported to the International Society of Heart and Lung Transplant Registry. Since 2005, bilateral lung transplant has been the most commonly performed procedure.
- Pathophysiology
  - Lung and heart–lung transplantation is performed for patients who have end-stage cardiopulmonary disease with no contraindications and have the potential to be rehabilitated completely. Most lung transplants are done for chronic obstructive pulmonary disease (COPD), cystic fibrosis, idiopathic pulmonary fibrosis, and pulmonary hypertension. Primary pulmonary hypertension and Eisenmenger syndrome are the most common indications for heart–lung transplantation.
- Clinical features
  - Candidates typically experience severe dyspnea, cyanosis, hemoptysis, or multiple hospitalizations and have New York Heart Association functional class III and IV status. Lung transplant candidates typically have a life expectancy of 24 to 36 months and are usually less than 75 years of age. Patients with COPD generally have a forced expiratory volume in 1 second ($FEV_1$) of less than 20 percent predicted, whereas patients with cystic fibrosis usually have an $FEV_1$ of less than 30 percent predicted, an increasing oxygen requirement, nutritional decline, and an increasing requirement for hospitalization. Patients with interstitial lung diseases may have a rapidly progressive decline with increasing oxygen requirements and reduced vital capacity. Candidates for heart–lung transplant have both pulmonary and cardiac disease and are typically under 65 years of age.
- Diagnostics
  - Candidates for lung and heart–lung transplants undergo an extensive workup to evaluate underlying cardiopulmonary function and exclude malignancy, active infection, end-organ dysfunction, and vascular disease. Diagnostic modalities include pulmonary function tests, endoscopy (especially bronchoscopy), echocardiography, cardiac catheterization, duplex ultrasonography, computed tomography and/or magnetic resonance imaging, serologic screens, and metabolic panels.
- Treatment
  - *Lung transplantation:* COPD, cystic fibrosis, idiopathic pulmonary fibrosis, and pulmonary hypertension.
  - *Heart–lung transplantation:* Eisenmenger syndrome, sarcoid with both cardiac and pulmonary involvement.
- Outcomes
  - Lung transplant survival rates are 82, 55, and 30 percent at 1, 5, and 10 years, respectively; best survival rates are among patients with cystic fibrosis. Significant spirometric improvement is immediate and plateaus at 6 to 12 months. For heart–lung transplantation, survival rates are 71 percent at 1 year. Early morbidity and mortality stem from technical complications, infections, and graft failure. Late complications are usually manifestations of bronchiolitis obliterans and malignancy.

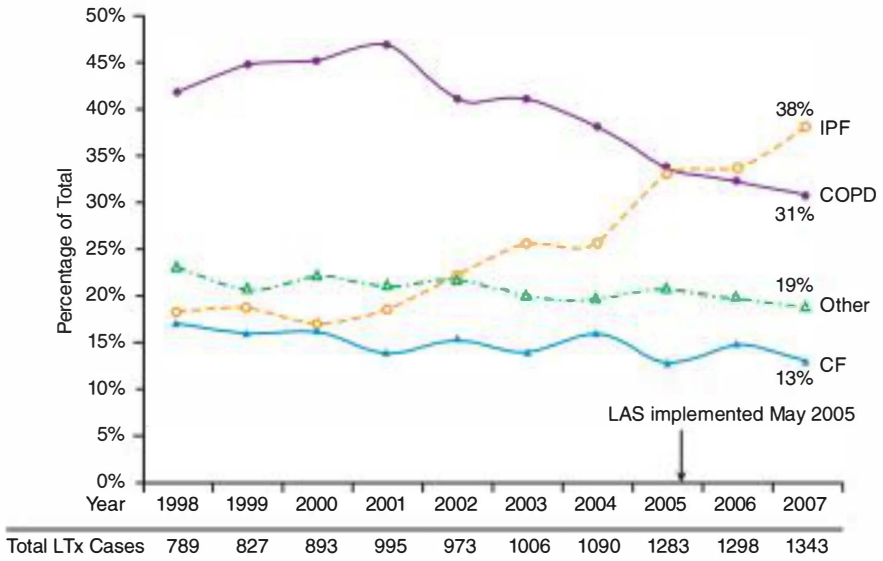

**FIGURE 11-1** Changing indication for lung transplant in the United States. Following implementation of the Lung Allocation Score system in 2005, there has been an increase in patients transplanted with the diagnosis of IPF. Survival after single versus bilateral lung transplantation for high-risk patients with pulmonary fibrosis. *Ann Thorac Surg* 2009; 88:1616–1625. Copyright Elsevier.)

## INTRODUCTION

Lung and heart–lung transplantation has emerged over the past several decades as an acceptable therapy for end-stage lung disease. Despite significant progress, lung transplantation remains a complex therapy that requires a multidisciplinary approach for successful outcomes. Moreover, it is increasingly clear that early postoperative events are associated with long-term complications. There are currently approximately 1800 and 70 patients awaiting lung and heart–lung transplant, respectively. In 2009, 1599 adult lung transplants were performed in the United States. In 2005, a new allocation policy was adopted in the United States. Patients are now assigned a Lung Allocation Score (LAS) based on clinical parameters. The score emphasizes transplant utility rather than wait-list time. It allows rapid allocation of organs to critically ill patients and decreasing allocation to less sick patients. As a result, patients are no longer listed just to accrue time. This has led to a significant reduction in the size of the active wait list (Fig. 11-1). The number of heart–lung transplant procedures has also declined.[1] Bilateral lung transplant has supplanted many of the indications. Nonetheless, a small group of patients remain excellent candidates for this unique procedure.

## HISTORY

In 1963, James Hardy performed the first human lung transplant.[2] This right single-lung transplant recipient died in 18 days with a functioning allograft. After the introduction of cyclosporine, Reitz and colleagues at Stanford performed the first combined heart–lung transplant.[3] In 1983, Joel Cooper successfully performed single-lung transplants in three patients.[4] By 1992, bilateral sequential lung transplantation supplanted en bloc double lung transplant, marking the modern era of lung transplantation.

## RECIPIENT SELECTION

Simply stated, lung transplant is indicated in patients with end-stage lung disease, with the purpose of increasing survival and improving quality of life. Recipient selection is critically important and may be complex, given the range of pathologies in candidates.

## ABSOLUTE CONTRAINDICATION

There are a number of absolute contraindications to lung transplantation as defined by the International Society of Heart and Lung Transplantation (ISHLT).[5] Patients should not have had a malignancy in the last 2 years, except for certain skin cancers. In patients with a history of cancer, a disease-free interval of at least 5 years is recommended. Candidates should not have untreatable end-organ dysfunction. This would include uncorrectable coronary artery disease, significant left-ventricular dysfunction, and end-stage liver disease. Patients with renal failure or significant insufficiency should not be considered unless combined with kidney transplant. Active viral infections are a contraindication and include hepatitis B, C, and HIV. Patients who are actively

using tobacco or abusing other drugs or alcohol should not be considered for transplant and should be abstinent for at least 6 months. Finally, significant psychosocial problems preclude transplantation.

## RELATIVE CONTRAINDICATIONS

With improving results, several centers have been emboldened to offer lung transplantation to a wider spectrum of patients. As a result, there are several relative contraindications to lung transplantation, and each center must decide the importance of each. Initially, an age cutoff for lung transplant had been proposed; however, several centers have transplanted patients over the age of 70 years with reasonable results. The national experience in this age group, however, is poor. Nonetheless, the ISHLT guidelines have set 65 years as the upper limit, and advanced age as a relative contraindication. Severely limited functional status and obesity lead to poor outcomes, and patients should actively participate in rehabilitation programs if possible, maintaining a body mass index (BMI) <30. Long-term steroids after transplant make severe osteoporosis a relative contraindication.[5]

## DISEASE-SPECIFIC INDICATIONS FOR TRANSPLANT

The ISHLT has established disease-specific guidelines summarized in Table 11-1. Controversy exists in transplantation for bronchoalveolar cell carcinoma. Since the disease recurs locally, lung transplantation has been used to treat these patients. Limited series have demonstrated acceptable short-term survival.[6] Primary, diseases do not recur except in sarcoid.

## DONOR SELECTION

There has been a significant liberalization of donor criteria over the past decade. The original criteria for what is considered a standard donor have given way to a more realistic set of criteria (Table 11-2). Ultimately, centers can accept or decline any organ for various reasons, but it is increasingly clear that donor characteristics have less to do with outcome than previously thought. Large database studies have found only donor tobacco use greater than 20 pack-years and age to be important risk factors.[7,8] Nonetheless, there are special considerations in lung transplantation. First, matching donor and recipient size is important. Oversized lungs can compromise hemodynamics early after transplant and have a long-term propensity of atelectasis. Height is clearly more important than weight, and gender is relevant when considering female recipients with fibrotic lung diseases. There are many ways to judge size matching ranging from simple height and weight ranges to estimating total lung capacity.[9] A simple rule is to use

### TABLE 11-1: Disease-specific Guidelines for Listing for Lung Transplantation

**Chronic obstructive pulmonary disease**
BODE index of 7 to 10 or at least one of the following:
- History of hospitalization for exacerbation associated with acute hypercapnia ($P_{CO_2}$ exceeding 50 mm Hg)
- Pulmonary hypertension or cor pulmonale, or both, despite oxygen therapy
- $FEV_1$, 20% and either DLCO, 20% or homogenous distribution of emphysema

**Idiopathic pulmonary fibrosis**
Histologic or radiographic evidence of UIP and any of the following:
- A DLCO, 39% predicted
- A 10% or greater decrement in FVC during 6 months of follow-up
- A decrease in pulse oximetry, 88% during a 6-min-walk test
- Honeycombing on HRCT (fibrosis score 0.2)

**Cystic fibrosis**
$FEV_1$, 30% of predicted, or rapidly declining lung function if $FEV_1$, 30% (females and patients, 18 years of age have a poorer prognosis; consider earlier listing) and/or any of the following:
- Increasing oxygen requirements
- Hypercapnia
- Pulmonary hypertension

**Idiopathic pulmonary arterial hypertension**
Persistent NYHA Class III or IV on maximal medical therapy
- Low (350 m) or declining 6-min-walk test
- Failing therapy with intravenous epoprostenol, or equivalent.
- Cardiac index of <2 L/min/m²
- Right atrial pressure >15 mm Hg

**Sarcoidosis**
NYHA functional class III or IV and any of the following:
- Hypoxemia at rest
- Pulmonary hypertension
- Elevated right atrial pressure >15 mm Hg

Definition of abbreviations: BODE 5 body mass index, airflow obstruction, dyspnea, and exercise capacity; HRCT 5 high-resolution computed t omography; NYHA 5 New York Heart Association; UIP 5

### TABLE 11-2: Donor Criteria

**Standard**
Age <55
ABO compatible
Clear chest X-RAY
Arterial oxygen pressure >300 on inspired oxygen of 100% and positive end-expiratory pressure of 5 cm $H_2O$.
<20-pack-year smoking history
Absence of chest trauma
Absence of aspiration
Gram stain free of bacteria

**Realistic**
Age <65
>20-pack-year smoking history with clear Chest CT and no functional impairment
Positive donor sputum culture (pansensitive organism)
Unilateral infiltrate

donors who are no more than 4 inches in recipient height for most lung diseases. However, cystic fibrosis and chronic obstructive pulmonary disease (COPD) can usually accommodate much larger donor sizes (as much as 12 inches in difference). Moreover, oversized donors may be trimmed with multiple wedge resections or even anatomic resection ex vivo to allow transplantation in small recipients.

There has been growing interest in using non-heart beating donors (DCD) for lung transplant. Lungs remain metabolically stable without circulation for up to an hour when ventilated. As a result, DCD donors may yield functional lungs without brain death-related injury. The initial experience is acceptable but the number of actual donors added to the pool may be limited.[10] Similarly, there is a growing experience with ex vivo perfusion of potential donors to rehabilitate unacceptable lungs.[11,12]

## DONOR ASSESSMENT

When the recovery team arrives at the donor hospital, review of the imaging and documentation should be performed as well as the mechanics on the ventilator. Bronchoscopy should be performed by the recovery team to assess for intraluminal masses and secretion quality. Purulent secretions that cannot be cleared bronchoscopically represent a relative contraindication to donation.

After median sternotomy and opening of the pleural spaces, the lungs should be palpated for masses and the compliance assessed by simple observation. Frequently, obese donors will have much better mechanics when the chest is opened. The pericardium is then opened. The superior vena cava (SVC) should be mobilized completely to prevent injury to the right pulmonary artery. We prefer separation of the aorta and main PA as well. In donors with small atria, modest dissection of Sondergaard's groove can help the right-sided left atrial cuff. A final arterial blood gas is obtained under these ideal conditions. If single-lung transplantation is planned, then blood gases may be obtained from individual pulmonary veins to asses each lung.

The main pulmonary artery should be cannulated with an angled 20-F aortic cannula. Some institutions strongly feel to direct the cannula toward the pulmonary valve to evenly distribute preservation solution, but we have not found this to be clinically important. Prior to cross-clamping, the teams should decide where venting of the left atrium should occur. If the heart is to be recovered, then the left atrial appendage is preferable. To preserve left atrial appendage function, some centers will rather incise along Sondergaard's groove. The SVC is ligated. Prostaglandin is injected into the main pulmonary artery. The inferior vena cava (IVC) and left atrium are then vented. The aorta is cross-clamped, and the preservation solution is delivered. When a heart–lung bloc is recovered, both cardioplegia and pulmonary preservation solution are used.

During infusion of the preservation solution, we continue gentle ventilation with inspired oxygen and monitor the effluent from the left atrial venting site. We infuse 4 L antegrade in all donors. The donor heart is then removed. Special attention should be made to the left atrial cuffs. These may be taken as two discrete cuffs or one single. The right-sided cuff can be compromised, and dissecting Sondergaard's groove prior to recovery can help prevent this problem.

Once the heart is out, we proceed with retrograde perfusion of the donor lungs via the pulmonary vein orifices (500 $cm^3$ in each). Low-potassium dextran has emerged as the most common and currently best preservation solution. This is particularly true for high-risk lung transplant recipients.[13] The maximal acceptable ischemic time for lungs is between 6 and 8 hours.

The dissection then proceeds outside the pericardium and anterior or ventral to the esophagus. The left and right pleura are then incised along the esophagus as far cephalad as possible. On the right, the azygous vein is transected, and on the left, the aorta is transected. The airway is then isolated between the aorta and SVC and tissue cleared laterally. The final attachments are usually at the level of the carina, and the airway is stapled with a modest level of inflation. We have never found it necessary to take the esophagus with the bloc but some centers work in this plane to prevent injury to the allograft.

The lungs are then inspected for damage and packed in iced saline and preservation solution. In the case of single-lung transplantation, the bloc should be divided prior to packaging.

## PROCEDURE SELECTION

### Single Versus Bilateral Lung Transplant

Bilateral lung transplant is necessary in suppurative lung diseases and in pulmonary hypertension. Single-lung transplantation can be used in patients with interstitial or fibrotic lung disease and emphysema. However, there is some evidence that bilateral lung transplant may have advantages in COPD and IPF. Although patients with IPF have similar outcomes with single or bilateral lungs, high-risk IPF patients may benefit from bilateral lung transplant.[14–16] For COPD, there is a modest survival and potential immunologic advantage. Certainly, bilateral lung transplant in emphysema eliminates complications of the native lung including hyperinflation, pneumothorax, differential compliance, and long-term risk of malignancy.

### Heart–Lung Transplant

Patients with end-stage heart and lung disease are candidates for combined heart–lung transplant. Although primary or secondary pulmonary hypertension is no longer an exclusive indication for heart–lung transplant, patients with biventricular failure or unreconstructable heart disease are reasonable candidates. Occasionally, cystic

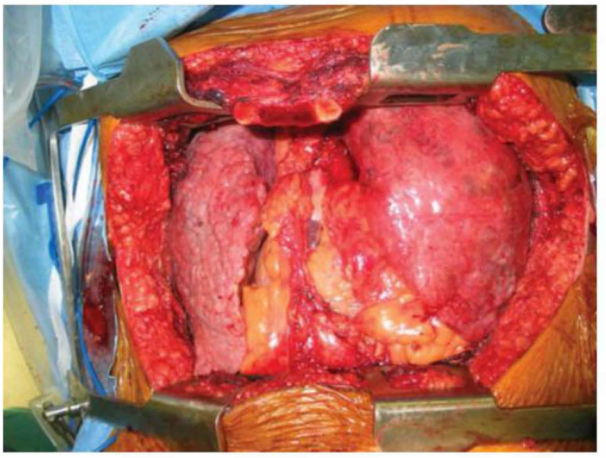

**FIGURE 11-3** Exposure after clamshell or bilateral trans-sternal thoracotomy.

fibrosis, primary pulmonary hypertension, and sarcoid patients will have biventricular failure.

## OPERATIVE TECHNIQUES

### Bilateral Sequential Lung Transplantation

After the induction of anesthesia, the recipient is intubated with a double-lumen endotracheal tube whenever possible. Even when cardiopulmonary bypass (CPB) is planned, double-lumen tubes allow for flexibility in dissection and reperfusion management. Pulmonary artery catheters are routinely as well as radial and femoral arterial lines. The femoral arterial line allows more consistent blood pressure measurement. It also allows access to place intra-aortic balloon pumps and extracorporeal circulation cannulae. The arms are placed over the head in arm stirrups (Fig. 11-2). Bilateral anterolateral thoractomies are performed through the fourth or fifth interspace and across the sternum (Fig. 11-3). Some centers have used sternal-sparing techniques or bilateral posterolateral thoractomies. Median sternotomy may also be used; however, access to pleural adhesions may be limited.

Once the retrosternal mediastinal adhesions are cleared cephalad and caudad, the intercostals muscles are incised with cautery generously. Two retractors are placed and the exposure is excellent. Attention is turned to the right lung first to isolate the inferior and superior veins, and then the pulmonary artery. The left lung is similarly dissected. In the presence of dense adhesions or severe bleeding, an intrapericardial dissection may allow safer isolation, and an extrapleural dissection may cause less bleeding. When the donor lungs have arrived, the less perfused lung (based on preoperative ventilation/perfusion scan) is removed first using vascular staplers. The bronchus is finally stapled. The hilar structures are further dissected into the pericardium to allow for maximal length and minimal cardiac manipulation.

The donor lung is placed in the chest, wrapped in an iced sponge. The airway is then anastomosed with running prolene or PDS. This may be done with a telescoping or end-to-end technique. The membranous trachea may be approximated with a continuous suture and the cartilaginous with an interrupted technique. We use a simple running, end-to-end technique with satisfactory results.

The pulmonary artery is approximated next, followed by the pulmonary veins. The allograft is deaired through the atrial anastomosis with partial opening of the pulmonary artery clamp. With good hemostasis, the lung is inflated with room air and reperfusion performed in a controlled manner over 10 minutes.

The left lung is implanted in a similar fashion. However, exposure to the left hilum may be more difficult due to the heart and small left atrium found in women and fibrotic lung disease patients. Several techniques can be used to improve exposure. The pericardium may be opened and the left ventricular apex displaced medially similar to off-pump techniques. Alternatively, the surgeon may decide to go on CPB centrally to safely implant the left lung with stable hemodynamics. CPB may also be used if the first lung is overcirculated or not functioning adequately to support the patient.

The left lung may also be implanted first if necessary to maintain cardiopulmonary stability. It is critically important to identify the phrenic nerves on both sides and not to injure them. Less concerning is injury to the recurrent nerve on the left. Both vagus nerves may also be injured as they run dorsal to the airways.

With both lungs reperfused and the cardiopulmonary status stable, the wound is closed with several chest tubes and three sternal wires. The endotracheal tube is exchanged for a single-lumen tube, and final bronchoscopy is performed to make sure that there is no intraluminal obstruction, anastomotic problems, or lobar torsion.

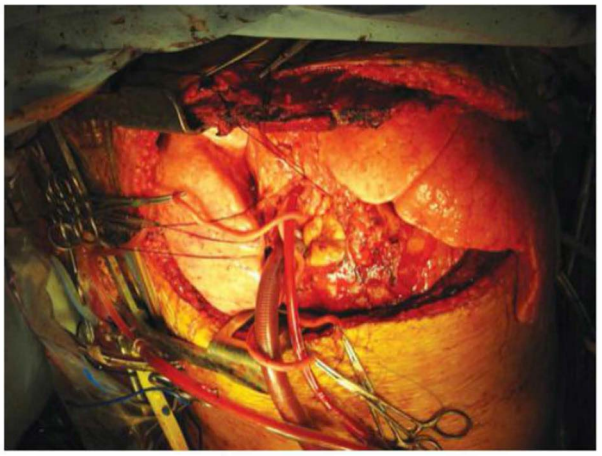

FIGURE 11-4 A patient following lung transplant using cardiopulmonary bypass. The patient is centrally cannulated.

## USE OF CARDIOPULMONARY BYPASS

CPB may be used selectively (pulmonary hypertension and patients unable to tolerate single-lung ventilation) or routinely. Typically, the aorta and right atrium are cannulated, and the patient is placed on normothermic bypass (Fig. 11-4). If concomitant cardiac surgery is necessary, this may be done prior to lung implant. Reperfusion on CPB is even more controlled where the goal is to keep the mean pulmonary artery pressure low during the 10-minute period. We use a period of modified ultrafiltration as well. In this technique, after separation from bypass, the patient's blood is withdrawn from the aorta and reinfused into the venous cannula after running through a hemoconcentrator. The purpose is to remove extravascular fluid and inflammatory cytokines. Alternatively, there is some evidence that CPB use is associated with increased risk of primary graft dysfunction and blood product usage, but less lung manipulation and soilage in suppurative lung disease.[17,18] Our center uses CPB selectively, but with a low threshold. We initiate CPB for one lung when the first allograft is overcirculated or functioning poorly, and when the left atrium on the left side is small.

### Single-Lung Transplant

Single-lung transplant uses similar anastomoses (bronchus, PA, and LA) and may be performed through posterolateral thoracotomy or anterolateral approach.

### Heart–Lung Transplant

Heart–lung transplant involves the following connections: trachea, aorta, SVC, and IVC. As a result, either median sternotomy or clamshell may be used. In patients with potential pleural adhesions or previous sternotomy, we prefer the clamshell incision. The recipient explants may be difficult, but the patient is cannulated via the aorta, SVC, and IVC. The cross-clamp is applied, and the heart is removed as in heart transplant. The phrenic nerves are identified and windows created dorsal to both. The pulmonary artery and vein may be divided with staplers or simply transected with the cautery, but the airway should be stapled to limit contamination. The airways are then dissected back to the trachea and then transected well below the innominate vein. The remaining cardiac structures may be resected or left behind. Care should be taken in the area of the recurrent nerve, and we usually leave posterior or dorsal wall of the pulmonary artery near the ligamentum to minimize the risk. Special attention should be paid to hemostasis at this point before proceeding with implantation. The allograft is then brought to the field, and both lungs are placed in anatomic position. The tracheal anastomosis constructed first with 4-0 prolene or PDS, followed by the IVC and the aorta. The cross-clamp is then removed and the SVC reconstructed. The lungs are inflated with room air during reperfusion and separation from bypass. We use a period of modified ultrafiltration prior to reversing the heparin. Typically, the cardiac function is good, and the patient may be managed as a standard lung transplant patient.

## POSTOPERATIVE CARE

Managing the postoperative lung transplant patient demands a unique focus on protecting the allograft while supporting the patient. Transplanted lungs do not have lymphatic drainage, are susceptible to excess extra vascular fluid, and have a propensity for oxidative injury. Moreover, a significant percentage of lungs will have varying degrees of graft dysfunction that need to be managed carefully. From a ventilatory perspective, the recipient is maintained at the lowest fraction of inspired oxygen ($Fio_2$) possible. The purpose is to minimize oxidative stress, but to also provide an early warning system for graft dysfunction. Keeping the $Fio_2$ low will lead to desaturation if there is a problem and direct an evaluation in a timely manner. We use a pressure-control mode of ventilation, maintain a positive end-expiratory pressure (PEEP) of 8, and try to achieve tidal volume of 8 $cm^3/kg$. Ventilator settings are adjusted to maintain a $Pao_2$ >70 and pH >7.3. After a period of stabilization, the patient may be extubated within 24 hours. Some patients, particularly after single-lung transplant, may be extubated in the operating room. Alternatively, some allografts need prolonged positive pressure and can develop severe pulmonary edema after extubation. Anecdotally, this is a bigger problem in patients with primary pulmonary hypertension, and we are much slower to wean these patients. We also liberally place tracheostomy tubes and use noninvasive ventilation when patients are at risk for prolonged ventilation or reintubation. Pain control is critical and we place an epidural catheter in *all* patients postoperatively. This is done while intubated and when any coagulopathy is resolved. Patients are extubated after toilet

bronchoscopy and when meeting conventional criteria for extubation. Volume status is maintained with central venous pressure (CVP) <8 as tolerated, with liberal use of adrenergic agents and diuretics. We used dopamine, vasopressin, and epinephrine preferentially. Patients with poor respiratory effort, allograft dysfunction, and phrenic nerve dysfunction undergo early tracheostomy. Noninvasive ventilation is also used liberally in the early postoperative period if the mechanism of respiratory failure is easily reversible.

Once extubated, vigilance is critical. The allograft is denervated and mucociliary clearance is impaired. As a result, patients need to work hard on pulmonary toilet. We liberally use bronchoscopy to clear airways. Since pharyngeal dysfunction is common postoperatively, all of our patients undergo formal video fluoroscopic swallow studies. Many patients will aspirate thin liquids for 1 to 2 weeks postoperatively.[19] Patients with preoperative malnutrition, severe swallowing problems, or gastroparesis receive percutaneous gastrojejunostomy feeding tubes.

**TABLE 11-3: Rejection Table**

**Acute rejection**
Grade 0—none
Grade 1—minimal
Grade 2—mild
Grade 3—moderate
Grade 4—Severe

**Airway inflammation**
Grade 0—none
Grade 1R—low grade
Grade 2R—high grade
Grade X—ungradable

**Chronic airway rejection—obliterative bronchiolitis**
0—absent
1—present

**Chronic vascular rejection—accelerated graft vascular sclerosis**

## IMMUNE SUPPRESSION

Standard immune suppression for clinical lung transplantation includes a calcinuerin inhibitor (CI), purine synthesis inhibitor, and steroids. Cyclosporine and tarcrolimus have similar efficacy, but tacrolimus is the most commonly used CI in the United States. Azathioprine and mycophenolate (MMF) seem to have similar efficacy as well. MMF does have some advantages in patients with preformed anti-HLA antibodies[20] and is the most commonly used agent in the United States. Induction agents, such as Thymoglobulin, Basiliximab, and Azulatamab, are also commonly used in 60 percent of US transplant patients.[1] There is some evidence that these agents reduce acute rejection episodes in the first year, but with no long-term benefits. Azulatamab has been used to limit immune suppression in a series from the University of Pittsburgh.[21] A small series of patients have also benefited from inhaled cyclosporine.[22]

## POSTOPERATIVE COMPLICATIONS

### Infection

There are four broad categories of postoperative infections. The first is bacterial. Patients may develop pneumonias from donor-acquired organisms or native pathogens particularly in CF patients. Perioperative antibiotics should be directed toward such organisms for a prolonged period (at least 2 weeks). Surveillance bronchoscopy postoperatively should also include cultures. The second is viral. The most common is cytomegalovirus, and patients receive prophylactic ganciclovir for donor and recipient mismatch. The rare CMV naïve donor and recipient may receive Valcyte. Other respiratory viruses should be cultured in all BALs. Fungal infections are the third troublesome pathogen. CF patients in particular are at high risk; however, in the setting of immune suppression, any patient can be infected or colonized. We use inhaled amphotericin in all recipients during their hospitalization and oral antifungals as directed by cultures. Finally, patients are at risk for pneumocystis infection and receive lifelong bactrim for prophylaxis.

## REJECTION

### Acute Rejection

Acute rejection is unfortunately common after lung transplantation. The incidence in the first year is typically 30 to 50 percent depending on the definition and severity.[23] Cellular rejection is far more common, and the diagnosis is made by transbronchial biopsy. Symptoms may be similar to infection and include fever, dyspnea, and decline in spirometry. Less common is antibody-mediated rejection that may manifest in similar ways or fulminant vasculitis and capillary leak syndrome. Table 11-3 summarizes the current ISHLT rejection criteria. For cellular rejection (A2 or greater) treatment is high-dose steroids. For humoral rejection, plasmapheresis, rituximab, and IVIG are all used at JHH. Patients with refractory rejection may have campath or thymoglobulin. Multiple episodes of acute rejection have been implicated in the development of chronic allograft function. Figure 11-5 is a representative specimen of severe A3 acute cellular rejection.

### Chronic Rejection

Chronic rejection and chronic allograft dysfunction are likely the final common pathway of multiple injuries and agents. Acute rejection, viral infection, antibody-mediated injury, and, more recently, gastroesophageal reflux have all been postulated to cause a narrowing of small airways leading to

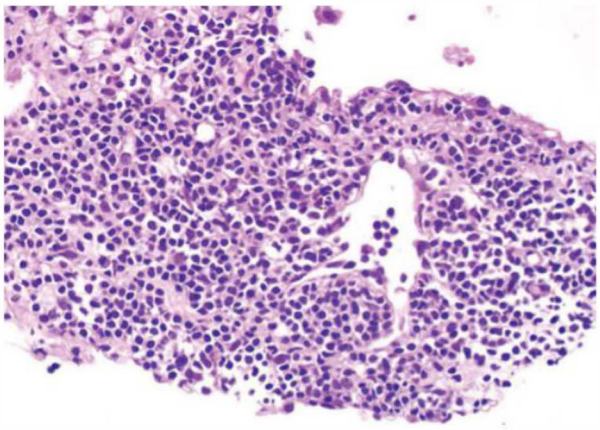

FIGURE 11-5 Representative histology of severe A3 acute cellular rejection.

airflow obstruction and allograft failure. Failing allografts with a decline of $FEV_1$ >20 percent are considered as having the bronchiolitis obliterans syndrome (BOS); histologic confirmation may be done with biopsy. At 5 years, nearly 50 percent of recipients have BOS.[23] Treatment is limited and includes azithromycin, fundoplication, or retransplantation. It is currently impossible to predict which patients will improve or stabilize their allograft function with any of these therapies and studies are ongoing. The Washington University group has postulated that early primary graft dysfunction leads to anti-HLA antibodies that in turn injure the allograft and ultimately lead to BOS.[24]

### AIRWAY COMPLICATIONS

The early surgical experience in human lung transplant was plagued with airway complications. In particular, airway dehiscence was a dreaded and common complication leading to death. With surgical and medical refinements, dehiscence in uncommon but stenosis has emerged as a persistent problem. Patients can present with anastomotic problems or distal airway disease. The etiology remains unclear and is likely a spectrum of problems that may be technical or microvascular in nature. Fortunately, a number of techniques exist to remedy airway problems. Simple balloon dilatation, stents (covered and uncovered), brachy, cryo, and antineoplastic therapies are all used. Many patients will require multiple interventions, and it is important to maintain a close follow-up (Fig. 11-6).[25]

## SPECIAL CONSIDERATION FOR HEART–LUNG TRANSPLANT

Heart–lung transplant patients are managed like lung transplant patients. The cardiac function is consistently good, although some patients may experience brady arrhythmias. Interestingly, the lungs may be rejected without synchronous cardiac rejection. Both organs are typically biopsied in the follow-up period. Heart–lung patients appear to have the same risk of BOS and coronary vasculopathy as isolated lung transplant patients.[26,27]

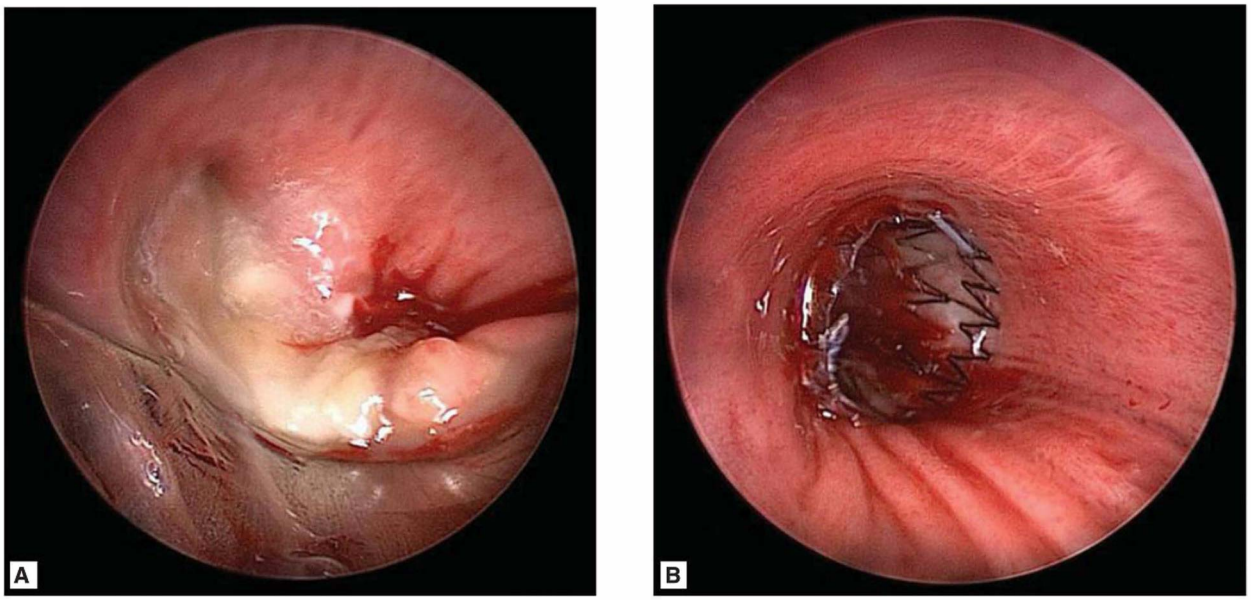

FIGURE 11-6 **A.** Bronchoscopic appearance of posttransplant airway stenosis. **B.** Results of dilatation and stenting.

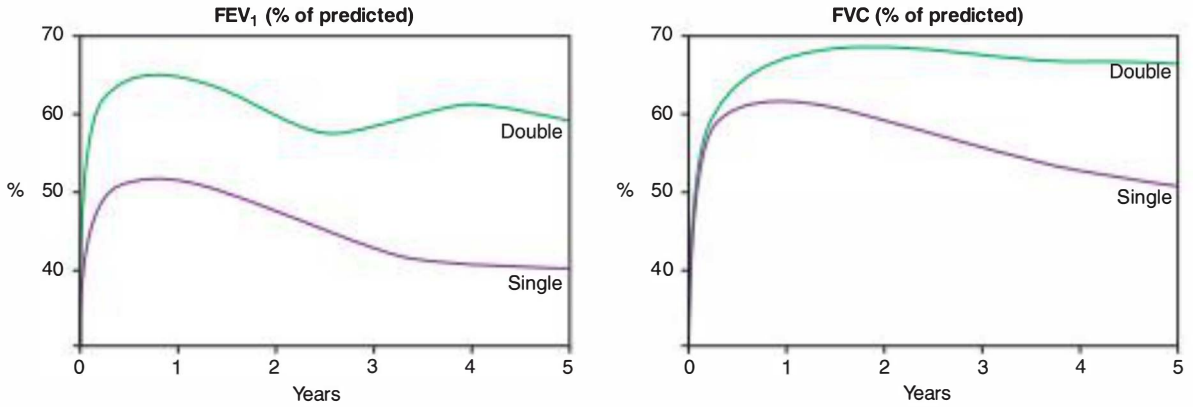

**FIGURE 11-7** Actual spirometric outcomes following double- or single-lung transplant over time. (Reproduced with permission from Mason DP, Rajeswaran J, Murthy SC, et al. Spirometery after transplantation: How much better are two lungs than one? *Ann Thorac Surg* 2008;85:1193–1201. Copyright Elsevier.)

## OUTCOMES/RESULTS

Short-term outcomes have improved significantly over the past 20 years. Current unadjusted 90-day survival is 90 percent and 1-, 5-, and 10-year survival is 83, 54, and 29 percent, respectively.[1] In the short term, patients with pulmonary hypertension have worse outcomes than other diseases. However, over time, pulmonary fibrosis emerges with worse outcomes and then at 10 years, emphysema has the lowest long-term survival. Patients with higher LAS appear to have higher 1-year mortality posttransplant.[28] Moreover, patients on mechanical ventilation and extracorporeal membrane oxygenation have significantly worse postoperative outcomes.[29] This should be kept in context with the high likelihood of death without transplant. Survival after heart–lung transplant is similar.

Spriometry is currently the basic measure of lung performance, and patients achieve maximal function after 6 months to 1 year. Bilateral lung transplant patients have better spirometric lung function than single lung (Fig. 11-7).[30]

## BRONCHIOLITIS OBLITERANS SYNDROME

BOS is the long-term form of allograft dysfunction. The pathologic lesion is obliteration of bronchioles with airflow obstruction and decline in spirometry. The exact cause is unknown, but there are a number of putative mechanisms including CMV, chronic aspiration, and reflux, as well as antibody-mediated injury. It represents the final common pathway of airway injury leading to a maladaptive reparative response.[24,31–35] Treatment is limited to augmenting immune suppression, surgical correction of reflux, and azithromycin. There is likely a spectrum on BOS that may or may not be responsive to therapy, and certainly timing of therapy and onset of BOS will determine efficacy. Retransplant is also an option in properly selected patients.

## SPECIAL ISSUES

### Sensitized Patients

Preformed antibodies against HLA loci create challenges both pre- and posttransplant. These antibodies form the basis of prospective crossmatching, but with modern laboratory techniques, centers are moving away from tissue crossmatching. Current flow cytometric methods allow for sensitive detection and specification of the antibodies. All donors are typed, and a comparison is made between antibodies and antigens. This is virtual crossmatching. Without the need for actual tissue crossmatching, recipients have shorter wait times.[36] Since 1997, the presence of anti-HLA antibodies is no longer a risk factor for early death in lung transplantation.[37] However, there appears to be a relationship with the de novo development of antibodies and risk of chronic rejection.[38] Sensitized patients are managed with multiple therapies including IVIG, plasmapheresis, and rituximab.[39,40]

## REFLUX AND ASPIRATION

As surgical challenges have been overcome, attention has turned to long-term failure. Patients with significant gastroesophageal reflux appear to have worse outcomes. Moreover, posttransplant, reflux worsens in a subset of patients. This is likely a consequence of vagal injury, immune suppression, and postoperative changes. Led by work at Duke University, an aggressive approach to correcting reflux with fundoplication has proven to be safe, effective, and, in many patients, to stabilize and even improve allograft function. Unfortunately, the results with posttransplant fundoplication have been inconsistent, and future studies are needed to better define timing of the procedure.[19,41–45]

**TABLE 11-4: International Society for Heart and Lung Transplantation Primary Graft Dysfunction Grading Schema**

| Grade | $Pao_2/Fio_2$ | Radiographic Infiltrates Consistent with Pulmonary Edema |
|---|---|---|
| 0 | >300 | Absent |
| 1 | >300 | Present |
| 2 | 200–300 | Present |
| 3 | <200 | Present |

## PRIMARY GRAFT DYSFUNCTION

Early postoperative allograft failure is formally described as primary graft dysfunction. There is a range of failures that is defined by the $Pao_2/Fio_2$ ratio (Table 11-4). The injury has all the hallmarks of acute respiratory distress syndrome (hypoxemia, pulmonary hypertension, and poor compliance) but differs in that it usually improves within 72 hours. Support includes protective ventilation strategies and extracorporeal membrane oxygenation. It is important to rule out mechanical problems including pulmonary vein thrombosis or stenosis and immunologic injury. Severe PGD has a mortality of 30 to 40 percent, and survivors are at increased risk of long-term allograft dysfunction. There have been several studies looking at risk factors for PGD and include clinical and biochemical variables.[46–48] Clinically, important variables include pulmonary hypertension, prolonged ischemic time, and blood product transfusion.

## RETRANSPLANTATION

When allograft dysfunction is irreversible and other end-organ dysfunction is absent, retransplantation may be the only option. It accounts for approximately 5 percent of all transplants and has an unadjusted 1-year survival of 70 percent. In the United States, most retransplants are bilateral lung transplants, and 60 percent are done for BOS. A small percentage of patients with early allograft failure may undergo retransplant, but with inferior results. Mean time to retransplant in the United States is 1500 days.[1]

## LUNG ALLOCATION SCORE

Since 2005, donor lungs in the United States have been allocated by the LAS. The score is generated from several clinical variables and prioritizes patients (Table 11-5). The score (0–100) was designed to maximize utility-minimizing wait list mortality and maximizing posttransplant survival. After implementation, waiting time has decreased and mortality has remained unchanged or slightly lower. Postoperative survival is unchanged in most patients; however, patients with LAS >44 appear to have worse 1-year survival. The score is revised periodically.[28,49–51]

**TABLE 11-5: Components of LAS**

| |
|---|
| Age |
| BMI |
| FVC % predicted |
| Functional status |
| Diagnosis |
| PA systolic pressure and mean |
| Diabetes |
| Mechanical ventilation |
| Oxygen requirement |
| 6-min-walk distance |
| Serum creatinine |
| Change in $CO_2$ |

## CONCLUSION

Lung and heart–lung transplantation is a complex, but effective therapy for patients with end-stage lung disease. Future work in the field will continue focusing on improving early allograft performance and further understanding long-term allograft dysfunction.

## LUNG AND HEART–LUNG TRANSPLANTATION BOARD REVIEW QUESTIONS (CHAPTER 11)

1. Which of the following is not a contraindication to lung transplantation?
   A. Disease-free interval of at least 10 years from malignancy
   B. Uncorrectable coronary artery disease
   C. Significant left ventricular dysfunction
   D. Renal failure
   E. Current tobacco use

2. Which is correct regarding lung procurement?
   A. Prostaglandin is injected after aortic cross-clamping.
   B. Gentle ventilation is continued during infusion of lung preservation solution.
   C. Retrograde perfusion of the lungs is discontinued before the heart is removed.
   D. The maximal acceptable ischemic time is 8 to 12 hours.
   E. The lungs are deflated prior to airway division.

3. Which is correct regarding donor selection criteria?
   A. Greater than 20 pack-year tobacco history is an absolute contraindication
   B. Severe multilobar contusion is acceptable
   C. Active non-central nervous system malignancy is acceptable
   D. Sputum culture positive with multidrug resistant organism
   E. Greater than 20 pack-year tobacco history is associated with increased long term risk of death

4. Which is true regarding outcomes after lung transplantation?
   A. Survival at 5 years exceeds 50 percent
   B. Patients with pulmonary hypertension have the best short-term outcomes.
   C. Patients with pulmonary fibrosis have the best long-term outcomes.
   D. At 10 years, those patients with emphysema have the best survival.
   E. Patients requiring mechanical ventilation prior to transplantation have equivalent survival.

5. Which grade is correct?
   A. Acute rejection, minimal = 2
   B. Acute rejection, severe = 5
   C. Airway inflammation, high grade = 1R
   D. Airway inflammation, ungradeable = X
   E. Chronic airway rejection, minimal = 1

## ANSWERS

1. **Answer: A.** A disease-free interval of at least 5 years from malignancy is required for listing for lung transplantation. Uncorrectable coronary artery disease, significant left ventricular dysfunction, renal failure or severe renal insufficiency, and active tobacco use are all absolute contraindications.

2. **Answer: B.** Gentle ventilation is continued during infusion of lung preservation solution. Prostaglandin is injected into the pulmonary artery prior to aortic cross-clamping. Retrograde perfusion of the lungs is continued after the heart is removed. The lungs are inflated prior to airway division. The maximal acceptable ischemic time is 6 to 8 hours.

3. **Answer: E.** Modern lung transplantation has seen a dramatic liberalization of donor criteria. Essentially any donor regardless of age with reasonable compliance, size matching, and $Pao_2$ >200 on an $Fio_2$ of 100% may be utilized for transplant. There are several relative contraindications such as active malignancy, Hepatitis C and HIV. Donor tobacco use is not an absolute contraindication, though heavy smoking is associated with long term risk of death particularly in patients with fibrotic lung disease.

4. **Answer: A.** Overall, a 5-year survival for lung transplantation is about 54 percent. Patients with pulmonary hypertension have the worst short-term outcomes. At midterm, patients with pulmonary fibrosis have the worst outcomes, and at 10 years, those with emphysema have the lowest survival. Patients requiring mechanical ventilation or ECMO have significantly worse outcomes.

5. **Answer: D.** Ungradeable airway inflammation is grade X. Minimal acute rejection is grade 1 and severe acute rejection is grade 4. Chronic airway rejection is either absent or present.

# Esophageal Physiology, Function Tests, and Endoscopic Techniques

*Daniela Jodorkovsky*
*John O. Clarke*
*Kerry B. Dunbar*

**KEY CONCEPTS**

- Physiology
  - The basic function of the esophagus is to propagate a bolus from the oropharynx to the stomach.
  - The coordination of esophageal muscle contractions, vagal innervation, and sphincter relaxation allows this event to occur.
- Function tests
  - Primary esophageal motility disorders can be diagnosed using conventional- or high-resolution manometry.
  - Various systems are available for reflux testing including 24-hour catheter-based pH monitoring, wireless capsule pH testing, and combined pH impedance.
- Endoscopic techniques
  - High-resolution endoscopy, chromoendoscopy, narrow band imaging, and confocal endomicroscopy are techniques that enhance the esophageal mucosa, improving diagnostic yield in Barrett's esophagus (BE) and early esophageal cancer.
  - Endoscopic ultrasound adds imaging from adjacent structures, and is useful for staging and fine-needle aspiration.
  - Multiple ablative techniques are now available for BE and early esophageal cancer, and include endoscopic mucosal resection, photodynamic therapy, radiofrequency ablation, cryotherapy, and endoscopic mucosal dissection.

## PHYSIOLOGY

Although the basic function of the esophagus is to simply propagate a bolus of food from the oropharynx to the stomach, the execution of this function remains complex. Ultimately, the swallow mechanism is a dynamic process between the muscles of the esophagus and its neural innervation, and involves the interplay between the upper esophageal sphincters (UESs) and lower esophageal sphincters (LESs).

The esophagus is a hollow tube, usually between 17 and 30 cm but averaging 23 cm.[1] At the proximal end is the UES, which is approximately 1 cm in length. The UES is composed of striated cervical esophageal muscle, the cricopharyngeus, and the inferior pharyngeal constrictor muscles. The superior and inferior hyoid muscles and superior pharyngeal muscles also help facilitate UES opening. Innervation of the UES arises from branches of the vagus nerve stemming from the nucleus ambiguus. Tonic closure of the UES functions to prevent insufflation of air during inspiration and esophagopharyngeal reflux. Intermittent relaxation of the UES allows bolus transit and venting (belching).

The esophageal body is composed of two different types of myocytes. Although somewhat variable, in general, the proximal third of the esophagus is striated muscle and the distal two-thirds composed of smooth muscle. The transition is not abrupt, and thus there is a short segment in which the muscles fibers are mixed. The arrangement is such that there is an outer longitudinal muscle layer and an inner circular muscle layer. This arrangement facilitates peristalsis, which will be discussed below.

Between the longitudinal and circular muscle layers lies the myenteric or Auerbach's plexus. This network of neurons

contains ganglia arising from the vagus nerve, although the concentration of ganglia affecting the smooth muscle portion is higher than the striated muscle portion. Ganglia innervating striated muscle stem from the nucleus ambiguus while ganglia innervating smooth muscle stem from the dorsal motor nucleus of the vagus. The neurotransmitter acetylcholine plays a role in activation of both striated and smooth muscles in the esophagus. Acetylcholine released by nerve endings activates the esophageal striated muscle. Postganglionic neurons in the distal esophagus activate smooth muscle cells by releasing acetylcholine. Inhibitory innervation of esophageal smooth muscle, which induces relaxation, is achieved by the release of nitric oxide (NO) and vasoactive intestinal polypeptide (VIP) from postganglionic nerve endings. The myenteric plexus is interconnected with Meissner's plexus, which is located in the submucosa and is responsible for innervation of the circular muscle layer and muscularis mucosa.

Sensory information is relayed in a dual manner via both vagal and spinal nerves. Esophageal sensation is extremely complex and beyond the scope of this chapter. In short, sensory information in the esophagus is relayed from either muscular afferent receptors or mucosal afferent receptors. In general, muscular afferent fibers respond to intraluminal distention. The pressure threshold leading to sensory nerve firing, and the rate of spontaneous firing, differs among vagal and spinal afferent neurons. In contrast, mucosal afferent fibers do not respond to distention but rather touch and chemical irritation by acid, bile, and other agents.[2]

The LES is a 2- to 4-cm high-pressure zone that provides a barrier between the distal tubular esophagus and stomach, composed of intrinsic circular muscles of the esophagus and extrinsic muscles from the crural diaphragm. Motor innervation again stems from the vagus nerve with preganglionic nerves releasing acetylcholine. The LES contracts in response to postganglionic excitatory neurons releasing acetylcholine. The LES relaxes with postganglionic inhibitory neurons releasing NO or VIP. The LES is tonically contracted and relaxes via reflex mechanisms in response to a swallow. The LES also relaxes in response to vomiting, belching, rumination, and transient LES relaxations (TLESRs). TLESRs are seen in normal patients and are increased in patients with gastroesophageal reflux disease (GERD). TLESRs also increase in response to gastric distention via reflex pathways.

Bolus transport occurs with peristalsis of the esophagus. Voluntary oropharyngeal deglutition triggers UES relaxation. Once the bolus enters the esophagus, the UES closes and the esophageal phase of swallowing takes over. The swallow event triggers primary peristalsis, or sequential esophageal muscle contractions, which occlude the esophageal lumen. Primary peristalsis propels the bolus forward down the esophagus, and a pressure of at least 20 mm Hg is needed to propel the bolus forward. Contraction of the longitudinal muscles also occurs, shortening the esophagus by approximately 2 cm. The peristaltic wave has a velocity of 3 cm/s in the upper esophagus, 5 cm/s in midesophagus, and 2.5 cm/s in the lower esophagus. With multiple rapid swallows, peristalsis remains inhibited until the last swallow. The control of primary peristalsis is centrally mediated.

Secondary peristalsis is triggered with luminal distention for the purpose of clearing residual bolus material due to ineffective primary peristalsis or reflux events. Pharyngeal contraction and UES relaxation are not seen in secondary peristalsis. The control of secondary peristalsis is intrinsic to the esophagus and is not centrally mediated. Local afferent sensory neurons respond to luminal distention and trigger contractions above the area of distention and relaxation below, moving the bolus forward.[3]

## ESOPHAGEAL FUNCTION TESTS

### Barium Studies of the Esophagus

A barium esophagogram, also called a barium swallow, is a radiology test with the ability to help diagnose structural lesions of the esophagus as well as to assess function. In a double-contrast esophagogram, the patient ingests an effervescent agent to distend the esophagus. Next, high-density barium is swallowed in the upright position to obtain full views of the esophagus. Structural lesions may be seen including strictures, diverticula, webs, masses, and even esophagitis. Fluoroscopic views of the patient swallowing barium boluses while prone are used to evaluate esophageal motility.[4]

Certain features identified on barium esophagogram are indicative of primary esophageal motility disorders. The classic esophagogram in achalasia shows a dilated esophagus with a "bird's beak" narrowing of the distal esophagus. In advanced cases, the esophagus may appear massively dilated or tortuous, hence called sigmoid esophagus.[5] With this classic barium study appearance and an EGD to rule out pseudoachalasia, some argue manometry studies are not needed to diagnose achalasia[4]; however, this remains controversial. A barium esophagogram performed in patients with diffuse esophageal spasm (DES) will show a classic "corkscrew" esophagus. DES manifests as repetitive nonperistaltic contractions that may obliterate the lumen. However, this classic finding is seen in less than <15 percent of patients with DES.[4]

The addition of a dynamic recording using video, called a "video fluoroscopic swallow study" or "cine-esophagogram," evaluates the pharyngeal phase of the swallow. Therefore, patients with symptoms of oropharyngeal dysphagia should have a cine-esophagogram instead of just a barium swallow.

### Esophageal Scintigraphy

Another noninvasive image-based modality used to evaluate esophageal function is esophageal scintigraphy. This nuclear medicine study uses a radiolabeled meal to evaluate esophageal transit and clearance. The study uses a gamma camera, also called a scintillation camera, to image ingested radioisotopes. Although a variety of protocols are available, the basic premise of the study includes ingestion of a technetium-99m–labeled

substance, like water, cornflakes, or applesauce, by the patient. Events are recorded at short intervals to assess bolus transport from the oropharynx to stomach. The test can be performed upright, which is more physiologic, or supine, which eliminates the force of gravity and potentially may pick up more subtle defects. The major parameter measured is total esophageal transit time, calculated from time point of entry of radioactivity into the esophagus until <10 percent of radioactivity remains in the esophagus. The test is easy to perform, quick, and usually tolerable for patients.

When the technology first emerged, many proposed esophageal scintigraphy as a useful screening test for esophageal dysmotility. One study measured esophageal scintigraphy and conventional manometry in 16 controls and 34 patients with established esophageal motility disorders.[6] An abnormal study was defined as prolonged esophageal transit greater than 15 seconds. Results were significant for lack of false negative scintigraphy results and a 96 percent agreement between conventional manometry and scintigraphy. All patients with disorders of peristalsis due to achalasia, scleroderma, and DES had an abnormal scintigraphy. Of note, only two of ten patients with esophagitis had a prolonged esophageal transit time, making scintigraphy a poor test for reflux disease.[6] In contrast to the results of some earlier studies, a more recent study found a greater number of false negatives using scintigraphy.[7] Radionuclide studies were performed on 49 patients with established esophageal dysmotility disorders and 14 controls. Although esophageal transit was prolonged in the patients with achalasia, DES, and nonspecific peristaltic disorders, only a minority of the patients with nutcracker esophagus and hypertensive LES had a prolonged esophageal transit time. This led the group to conclude that scintigraphy is useful in disorders with abnormal peristalsis but a poor study in motility disorders or cases where peristalsis is preserved.[7]

The main limitation of esophageal scintigraphy is the limited number of swallows evaluated. As some motility disorders are intermittent, they could be missed by this test. This has led some groups to advise repeat scintigraphy in those patients with a high clinical suspicion for disease.[6] Another limitation is that the presence of a hiatal hernia, particularly if a significant amount of stomach lies above the diaphragm, may be confused with distal esophagus leading to false positive results as radioactivity will persist in the hernia sac.

## Esophageal Manometry

### CONVENTIONAL ESOPHAGEAL MANOMETRY

Esophageal manometry is performed by passing a flexible catheter transnasally down the esophagus and into the stomach. Conventional esophageal manometry relies on either a multilumen water perfusion catheter (attached to a pressure transducer) or a catheter with a few discrete solid-state pressure sensors. When the information from the pressure transducers is transmitted to the computer and analyzed, continuous pressure information from the esophagus is obtained.[8] The channels on the catheter are usually spaced 3 to 5 cm apart for a total of six channels. Unfortunately, this constraint does not allow for the simultaneous recording of pressure spanning the entire esophagus including UES and LES. Therefore, the catheter has to be repositioned during the study to record from all points, starting in the stomach and slowly moving the catheter proximally, called the "pull-through" technique. Not all patients tolerate transnasal placement of the manometry catheter, and occasionally the catheters may need to be placed endoscopically.

Data from the study are displayed on a 2-D graph. The *X*-axis displays time and the *Y*-pressure on the left. There are 6 line tracings corresponding to each channel, displayed in order from least distance from nares at the top to greatest distance from nares at the bottom, the LES (Fig. 12-1).

### HIGH-RESOLUTION MANOMETRY

In the last decade, major developments in manometry technology have occurred. Newer catheters have more sensors that are closely spaced together (1 cm), which adds the ability to measure pressures within the entire esophagus, simultaneously spanning pharynx to stomach.[8] This system of monitoring pressures can allow the investigation of the full mechanics of swallow and bolus transport. Smaller segments of the esophagus not previously able to be evaluated by conventional manometry can also be analyzed.

The large volume of data acquired from the high-resolution manometry system is displayed on a 3-D color topographic map (Fig. 12-1). As in conventional manometry, the *X*-axis displays time. The *Y*-axis displays distance from nares, again with the UES at the top and LES and stomach at the bottom. Pressure is denoted by color on the *Z*-axis, with warmer colors denoting high pressure and bluer colors denoting low pressure. This topographic representation makes it easier to evaluate the full dynamics of peristalsis and bolus transport from UES to stomach.[9]

Although theoretically the high-resolution manometry system provides more data, it is unclear at this time whether it translates to greater clinical utility. However, it does appear to have a logistical benefit. The high-resolution manometry system is less operator dependent, as the pull-through technique is not needed. Furthermore, the study is now shorter for the patients and may be more tolerable. Finally, the high-resolution system may be beneficial in those challenging cases where manometric subtleties are found.

### USES OF ESOPHAGEAL MANOMETRY

As a research tool, manometry has helped clarify the intricacies of esophageal physiology. However, its clinical value is most useful when evaluating absent, weak, or abnormal peristalsis, and abnormalities in LES pressure and relaxation. With its closely spaced sensors, high-resolution manometry can also more easily define UES function and dysfunction compared with conventional manometry, as the UES only spans 1 cm in length.[9] Symptoms prompting

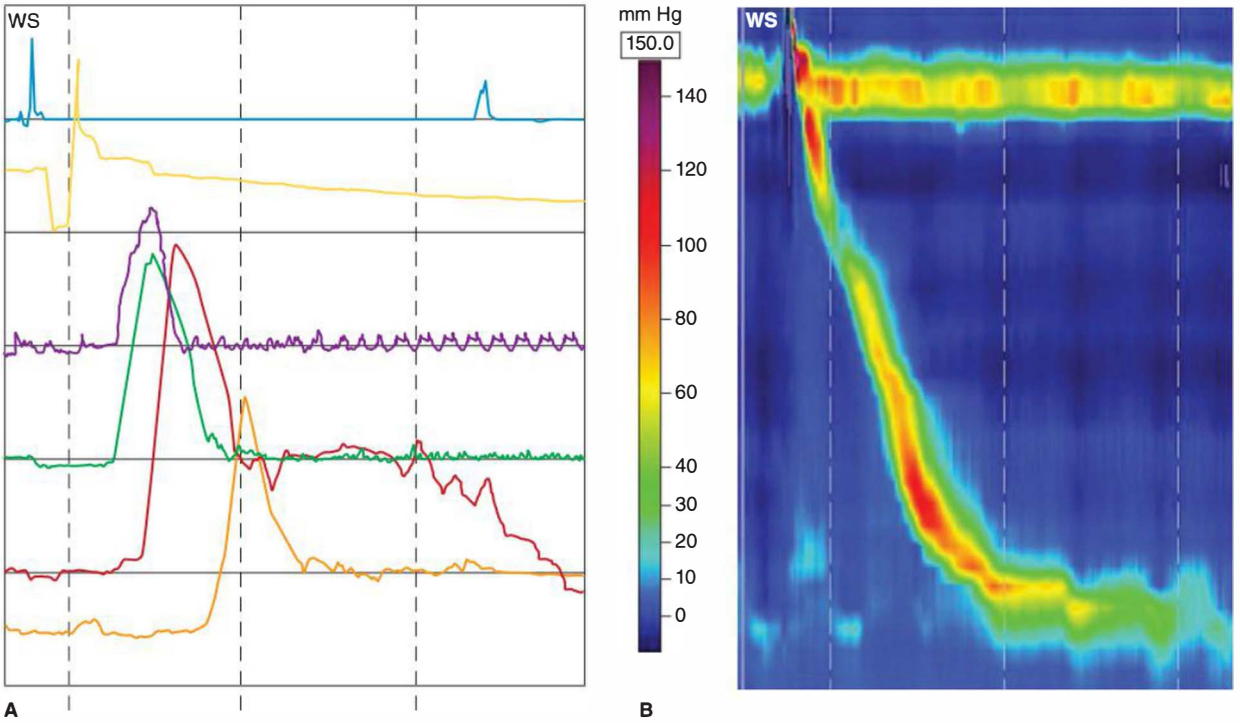

**FIGURE 12-1** Side-by-side comparison of a normal wet swallow (WS) induced peristaltic wave in conventional and high-resolution manometry. **A.** Peristaltic wave is depicted in conventional manometry as a 6-line tracing corresponding to six sensors placed in esophagus. The *X*-axis is time, and the *Y*-axis is position in esophagus. **B.** In a high-resolution manometry depiction, the *X*-axis represents time, the *Y*-axis represents position in esophagus, and *Z*-axis (color) represents pressure. Warm colors represent higher pressures.

manometry testing include dysphagia, reflux and regurgitation, and chest pain.

Mechanical causes of dysphagia such as strictures or rings are far more common than motility disorders of the esophagus. Thus, manometry usually follows radiographic and endoscopic inspection of the esophagus in the evaluation of dysphagia.[10] Unfortunately, many manometric abnormalities can be seen in asymptomatic healthy controls, and thus it is sometimes difficult to equate findings with motor disorders. However, there are certain manometric patterns of peristalsis and disordered LES function that correlate with specific disorders that lead to dysphagia. Ineffective peristalsis or complete aperistalsis on manometry can be seen in a variety of systemic disorders such as diabetes, connective tissue diseases like scleroderma, and amyloidosis. Specific patterns of peristaltic abnormalities and LES dysfunction also help diagnose primary esophageal motility disorders such as achalasia and DES.

The use of esophageal manometry for symptoms of reflux is not as straightforward. Certainly, ineffective esophageal peristalsis can be seen in patients with GERD; however, this is neither sensitive nor specific for GERD. Reduced LES pressure seen on manometry can contribute to an impaired antireflux barrier leading to GERD. However, the manometry study may be too short to pick up the TLESRs that are fundamental to the pathophysiology of GERD. Further discussion of reflux testing is described below.

Preoperative manometry for antireflux surgery is important for ruling out motility disorders in which antireflux surgery would be detrimental. Specifically, fundoplication in a patient with scleroderma, achalasia, or DES could worsen their symptoms. Postoperative manometry can be used in the evaluation of recurrent dysphagia after the fundoplication once mechanical obstruction is ruled out.

Use of preoperative manometry in prognostic determination of response to surgical treatment for GERD is more controversial. Some nonrandomized studies found that preoperative peristaltic dysfunction could lead to postoperative dysphagia with a classic 360 degree Nissen fundoplication. One group used a laparoscopic Toupet fundoplication in patients with peristaltic dysfunction on manometry and found lower rates of postoperative dysphagia compared with those with esophageal dysmotility who had a Nissen fundoplication.[11] However, a more recent randomized prospective study found no correlation between preoperative esophageal dysmotility on manometry and postoperative dysphagia in either a Nissen or a Toupet fundoplication.[12] Therefore, there is no consensus how to optimally use preoperative manometry in reflux patients.

Chest pain of esophageal origin may be due to esophageal hypersensitivity from chemical irritants, distention, or muscular contractions. Therefore, noncardiac chest pain can be due to GERD or primary motility disorders like achalasia, DES, and nutcracker esophagus. As GERD is the most

common cause of esophageal chest pain, manometry would not be a high-yield study for those limitations described above. Therefore, manometry in the evaluation of chest pain usually follows thorough investigation and treatment of GERD.[10]

Aside from diagnosis, manometry can be used in the management of some of these disorders. There are emerging data that suggest that high-resolution manometric subtypes of achalasia may have different responses to treatment, and high-resolution manometry in these patients may have prognostic information.[13] Manometry can also identify residual high GE junction pressures that may be amenable to further therapy in those patients with recurrent dysphagia following endoscopic or surgical therapy for achalasia.

## Esophageal Reflux Testing

### CATHETER-BASED pH TESTING

Ambulatory pH monitoring is used for diagnosis of GERD, evaluation of treatment failure, and preoperative evaluation. The test involves placement of a transnasal catheter 5 cm above the LES. Patients are instructed to continue daily activities and diet. A 24-hour test will record pH events, with acid reflux events defined as a pH <4.0 for 5 or more seconds. Patients also employ event buttons to record meals, postural changes, and symptoms. The most important recorded measurements include percentage of time when pH <4, percent of upright time when pH <4, percent of supine time when pH <4, number of reflux episodes, number of reflux episodes >5 minutes, and the longest reflux episode. Using these six parameters, the DeMeester score is calculated to estimate global acid exposure. The sensitivity and specificity of ambulatory pH catheter testing for GERD reach 77 to 100 percent and 85 to 100 percent, respectively, in patients with endoscopically proven esophagitis. However, the sensitivity of pH testing ranges from 0 to 71 percent in endoscopy-negative reflux disease (NERD).[14]

### WIRELESS CAPSULE pH TESTING

Now available is a wireless pH recording capsule, the Bravo system (Medtronic, Minneapolis, MN, USA). This system was devised to avoid the limitation of patient intolerance of the transnasal catheter pH testing. The capsule is attached to the esophageal mucosa using a flexible introducer, positioned 6 cm above the GE junction as determined by endoscopy or esophageal manometry. pH data are recorded onto an external receiver by radio telemetry. The wireless system is equivalent to the catheter-based system in recording accurate pH data.[15] The capsule naturally falls off several days after placement. The advantage of the wireless system is better patient tolerability. Patients are more likely to go about their normal routines including diet and exertion, which may avoid false negative results. Furthermore, increased tolerability may translate to extension of study time. Forty-eight hours of data increase the diagnostic accuracy for GERD. Disadvantages include greater cost of the test and the rare risk of chest pain requiring endoscopic removal of the capsule.[14]

### IMPEDANCE TESTING

Broadly defined, GERD is the exposure of the esophagus to gastric contents causing symptoms. Wireless and catheter-based ambulatory pH monitoring can measure the acidity of the refluxate but does not evaluate weakly acidic or non-acidic reflux events, which may still cause symptoms. Thus, a system was devised to detect all types of liquid movement in the esophagus using intraluminal electrical impedance. Intraluminal impedance monitoring uses a cylindrical catheter-containing multiple metallic electrodes. It is passed transnasally and swallowed by the patient to be placed within the esophagus above the GE junction.

The principle behind measurement of impedance is that the current flow between two electrodes will depend upon the conductivity of the surrounding environment. A liquid bolus has high electrical conductivity, and thus the resistance (or impedance) between the two electrodes will drop. On the other hand, an air bolus has low conductivity and impedance will increase. The sequence of impendence changes between the different segments of electrodes can establish directionality to determine whether the flow is related to swallowed material or esophageal reflux.[16]

Impedance is measured with at least three electrodes spaced 2 cm apart. The placement of the most distal electrode should be 1 to 2 cm above the LES. A number of studies have evaluated gas, liquid, and acid reflux in animals, asymptomatic controls, and patients with reflux using impedance monitoring compared with fluoroscopic exam, manometry, and pH monitoring. The sensitivity for detecting reflux using impedance ranged from 92 to 99 percent.[16–18] Therefore, the technical recommendations from a workshop led by 11 GERD specialists advise that appropriate electrode placement should detect at least 90 percent of reflux events.[16] Sensitivity may be affected by conditions that lead to low baseline impedance values. Esophagitis and Barrett's esophagus (BE) are two such conditions; therefore, it is important to be aware of these entities prior to analysis of impedance studies.

Impedance monitoring is often combined with pH monitoring to increase diagnostic accuracy and determine the specific type of reflux causing symptoms. One study measured pH and impedance events in 60 patients with heartburn or regurgitation and established the statistical relationship between symptoms and reflux events. The combination of impedance and pH yielded a higher proportion of patients with a positive symptom association probability (SAP) compared with either test alone.[19]

### USES OF pH MONITORING

Whether to perform pH monitoring on or off proton pump inhibitor (PPI) therapy is debated, but it primarily depends on the purpose of the study. If the purpose is to define

whether the patient's symptoms are stemming from GERD as opposed to another etiology, ambulatory pH monitoring should be performed off PPI therapy. Should the patient continue taking PPIs in this case, the study may be falsely negative. If the purpose of the study is to define whether PPI therapy is effectively reducing acid exposure in patients with known GERD, the study would be useful with continuation of PPI therapy.

### BILITEC

Another element of symptomatic reflux disease may stem from reflux of duodenal contents into the esophagus, hence called "Duodenogastroesophageal reflux disease" (DGER). The Bilitec 2000 (Synectics Medical, Enfield, UK) monitoring system uses measurement of bilirubin concentration as a marker for duodenogastric reflux. The probe that is inserted transnasally into the esophagus is a fiber optic spectrophotometer that can identify presence of bile. Recording takes place over a 24-hour period.[20] There are several limitations to the Bilitec system. Notably, the sampling rate is once per 8 seconds; therefore, it is unlikely to accurately evaluate timing of DGER events. In addition, solid material may become trapped in the sensor at the probe tip, impairing accurate measurement and increasing artifact.[16] Thus, testing is most accurate when patients are on a liquid diet, but unfortunately this does not reproduce normal physiologic settings. Despite its limitations, the Bilitec system is the only system that evaluates the presence of bile in reflux events.

## ENDOSCOPIC TECHNIQUES

### Endoscopic Imaging

#### HIGH-RESOLUTION AND HIGH-MAGNIFICATION ENDOSCOPY

Endoscopy is used to visually inspect esophageal mucosa and may be used to inspect dysplastic or malignant tissue. The image quality depends upon magnification and resolution. Resolution is the ability to distinguish two closely spaced pixels and is expressed as pixel density. Standard endoscopes carry chips that capture images with a resolution of 640 to 700 pixels wide × 480 to 525 pixels high.

There are three high-resolution endoscope systems available in the United States. The chips in these systems capture images with resolutions of 1280 × 1024 and 1280 × 960, over a million pixels. These high-resolution endoscopes must be used with a high-definition compatible system including processor and monitor. A standard endoscope displays an image that is magnified 30 to 35 times. High-magnification endoscopes use a combination of digital and optical zoom to magnify up to 150 times.[21]

Higher resolution and magnification improves the quality of the image captured and displayed (Fig. 12-2). Theoretically, this increases the detection of abnormal esophageal tissue like BE or malignancy. However, the majority of studies of high-resolution or magnification endoscopy are also comparing other techniques that are discussed below.

**FIGURE 12-2** High-resolution endoscopy image of abnormal BE mucosa.

#### CHROMOENDOSCOPY

Chromoendoscopy refers to the application of stains or dyes via spray catheter to the gastrointestinal mucosa at the time of endoscopy. Stains available include Lugol's solution, methylene blue, toluidine blue, and crystal violet, classified as absorptive stains. These stains preferentially absorb in specific cells, allowing for distinction of cell types. Indigo carmine is a contrast dye that absorbs in mucosal defects and can thus identify mucosal irregularities. Finally, reactive dyes such as congo red chemically react under certain conditions like low pH. Acetic acid is an agent that can be sprayed topically during endoscopy but does not dye the mucosa and thus is not technically considered chromoendoscopy. However, it temporarily denatures glycoproteins in the mucosa and will help detect dysplastic or abnormal tissue.[22] The major limitation of chromoendoscopy is that it increases procedure time. A high interobserver variability also limits this technique.

Chromoendoscopy can be used throughout the GI tract to detect inflammatory, dysplastic, or neoplastic tissue. In the colon, it is predominantly used for dysplasia surveillance in inflammatory bowel disease. In the esophagus, chromoendoscopy is predominantly used for detection of dysplasia in BE or early cancer, either adenocarcinoma or squamous cell carcinoma.

In methylene blue chromoendoscopy, normal epithelial cells absorb the dye while dysplastic or malignant cells do not. Although several studies showed an increase in diagnostic yield to detect dysplasia in BE using methylene blue as compared with random biopsies, a recent meta-analysis of nine studies failed to show a significant increase in diagnostic yield. However, this result may be an effect of

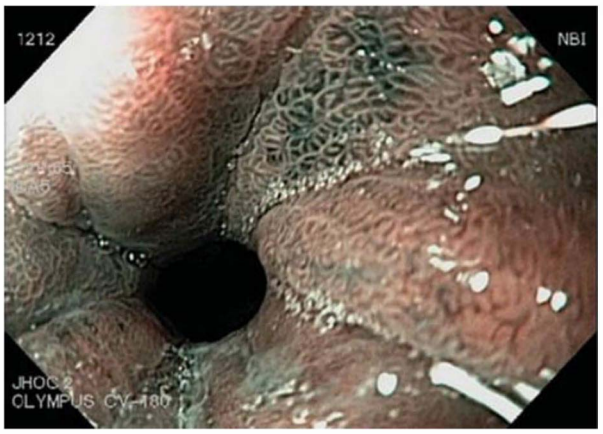

**FIGURE 12-3** Narrow-band imaging of BE mucosa.

differences in inclusion criteria and application techniques in various studies.[23]

## NARROW-BAND IMAGING

A digital-based technique to enhance the contrast of mucosal changes may overcome these limitations. To illuminate mucosa, standard endoscopy uses a white light that passes through a rotary RGB filter to separate wavelengths corresponding to red, green, and blue. Narrow-band imaging (NBI) uses a filter with a narrower range that predominantly allows blue (415 nm) and green (540) wavelengths to pass, while blocking red (650 nm) wavelengths.[24] Given that longer wavelengths of light penetrate deeper layers of mucosa, the shorter blue and green wavelengths enhance the contrast of the superficial mucosa (Fig. 12-3). As hemoglobin absorbs blue light, NBI is also particularly helpful in assessing microvasculature of the GI mucosa. The narrow-band filter can be switched on and off by the endoscopist, facilitating ease of use with standard white light endoscopy.

As in chromoendoscopy, NBI can be used throughout the GI tract, particularly for detection of early gastric cancer and colonic polyps or dysplasia. In the esophagus, NBI has most been studied in BE. Several classification systems have been devised to characterize NBI findings in BE. One group simplified a classification system into A to D. Grade A was characterized by round pits with regular microvasculature; grade B, villous/ridge pits with regular microvasculature; grade C, absent pits with regular microvasculature; and grade D, distorted pits with irregular microvasculature. This classification was validated in a study where grade A had a high predictive value for columnar mucosa without BE, grades B and C were predictive for nondysplastic BE, and grade D predicted BE with high-grade dysplasia. Low-grade dysplasia could not easily be distinguished from nondysplastic without dysplasia.[25]

Detection of high-grade dysplasia is important for determining management of BE. Current surveillance guidelines use random four quadrant biopsies every 1 or 2 cm of BE for dysplasia detection, but they may be suboptimal. A recent meta-analysis of eight studies with close to 500 patients examined the accuracy of NBI in detection of high-grade dysplasia with histological confirmation. The pooled sensitivity and specificity was 96 and 94 percent, leading the authors to conclude that NBI has a high diagnostic accuracy for detection of high-grade dysplasia.[25]

Few studies have directly compared NBI with chromoendoscopy to determine which, aside from endoscopist preference, would be more beneficial in detection of dysplasia. The only randomized prospective study included 28 patients with known Barrett's and high-grade dysplasia or early esophageal cancer. Each patient was randomized to high-resolution endoscopy with adjunct NBI or high-resolution endoscopy with adjunct chromoendoscopy. Six to eight weeks later the patients crossed over to the other modality performed by a separate endoscopist. Although the majority of high-risk lesions were detected on high-resolution endoscopy alone, both NBI and chromoendoscopy picked up several additional lesions equally well.[26]

## CONFOCAL ENDOMICROSCOPY

Confocal laser endomicroscopy (CLE) is a tool that enables gastroenterologists to obtain real-time in vivo histology at the time of endoscopy. In CLE, tissue is illuminated with a low-power laser. The laser light is reflected back and focused through the same lens, the size of a pinhole. The images obtained have a high enough resolution (up to 1000×) that histologic information is available (Fig. 12-4). This technique requires administration of an intravenous or topical fluorescence agent. The most commonly used agent is intravenous fluorescein sodium, which is a renally excreted agent that is distributed within 7 to 14 seconds across the vasculature to GI tissue. Various topical sprays that stain either nuclei or cellular cytoplasm may be used as well.[27]

CLE is available in a probe-based system or an integrated endoscopic system. In the latter, the confocal microscope is integrated into the distal end of a white light endoscope. Images from the integrated scope are displayed on two monitors, concomitantly showing both video and endomicroscopy views. Probe-based CLE systems use a stand-alone confocal probe that can pass through the accessory channel of a standard endoscope.[27]

CLE has been used to classify colon polyps, determine diagnosis of or direct celiac disease biopsies, detect early gastric cancer, or *Helicobacter pylori* infection. In the esophagus, CLE is useful in detection of BE and early neoplasia. As in NBI and chromoendoscopy techniques, CLE can distinguish BE from early neoplasia. Confocal endomicroscopy features of high-grade dysplasia include irregular cells with loss of normal cellular pattern, distorted subepithelial capillaries, and leakage of fluorescein.

A clinically relevant outcome using CLE technology is that fewer mucosal biopsies may be needed to detect

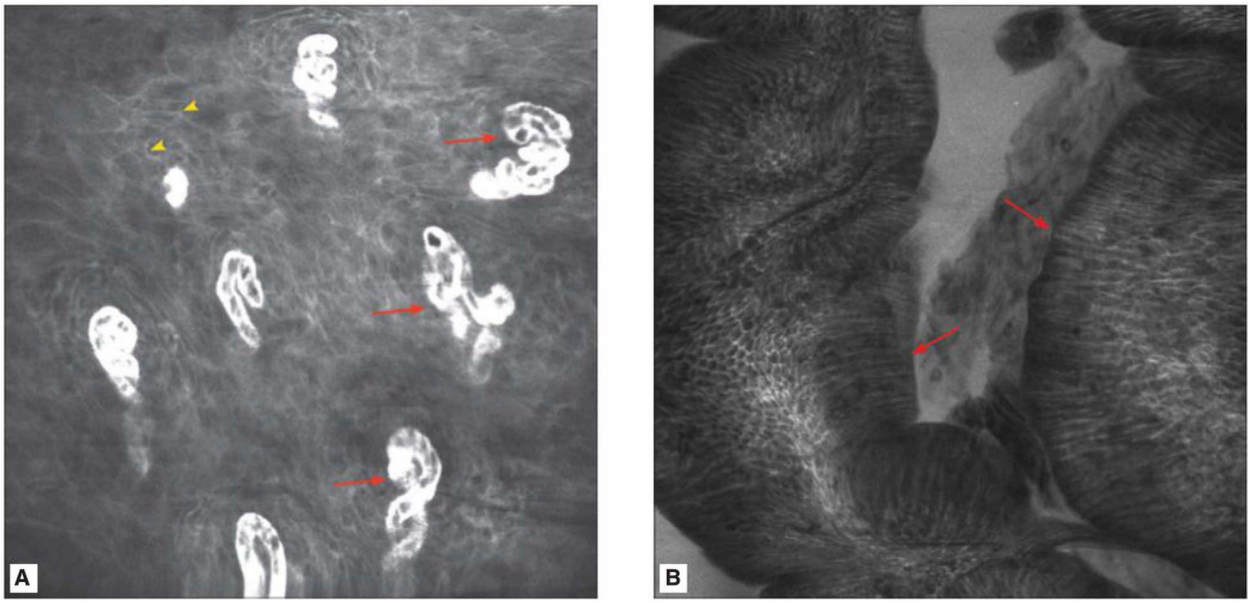

**FIGURE 12-4** Confocal endomicroscopy images of esophagus. Image **A** shows confocal endomicroscopy image of the squamous esophagus (1000× magnification). The arrows point to intrapapillary capillary loops. Arrowheads point to the intracellular spaces between epithelial cells. Image **B** shows an image of Barrett's esophagus. The arrows point to the cells in a villiform, glandular pattern.

high-grade dysplasia or early neoplasia. One study randomized 39 patients to standard endoscopy with four-quadrant random biopsies or CLE with four-quadrant optical biopsies as well as targeted biopsies. Several weeks later, the patients were crossed over. The diagnostic yield for high-grade dysplasia or cancer was higher in the confocal endomicroscopy procedures. In those 16 patients who were considered high risk, with suspected but unlocalized neoplasia, there was an almost 60 percent reduction in the number of biopsies needed to obtain the diagnosis. In the remaining 23 patients who were undergoing routine BE surveillance, 65 percent did not require any mucosal biopsies based on confocal images, and no neoplasia was identified.[28]

## ENDOSCOPIC ULTRASOUND AND FINE-NEEDLE ASPIRATION

Endoscopic ultrasound (EUS) adds high-frequency sonographic information via an ultrasound transducer at the tip of the endoscope to provide imaging of the GI wall and surrounding structures. Echoendoscopes are available in three types of designs: radial array, curvilinear array, and probe based. Radial array echoendoscopes provide a 270- to 360-degree view of the surrounding structures whereas curvilinear echoendoscopes provide a 180-degree view parallel to the scope. Some systems have Doppler capabilities to visualize blood vessels.

The curvilinear echoendoscope is ideal for fine-needle aspiration (FNA). The needle, passed through the accessory channel, will be seen in the plane of the ultrasound, allowing for accurate and safe biopsies or other therapies. Needles available range from 19 to 25 gage and can penetrate up to a depth of 10 cm. The risks of EUS without FNA are equal to that of standard endoscopy. Although still quite low at 1 percent, EUS–FNA has a slightly greater risk than EUS without FNA.[29] Notably, risk of infection during aspiration of cystic lesions is higher, and antibiotic prophylaxis is warranted.

EUS can be used for diagnosis and management of luminal GI, pancreatic, or biliary disorders. In the esophagus, EUS produces images corresponding to the five histologic layers of the GI tract. The endosonographic images appear as alternating hyper and hypoechoic bands. The innermost band is hyperechoic and corresponds to the lumen or superficial mucosal layer. The second layer corresponds to the lamina propria, the third corresponds to the submucosa, the fourth corresponds to the muscularis propria, and the fifth corresponds to the adventitia. Beyond the adventitia, adjacent structures such as lymph nodes can be visualized (Fig. 12-5). This makes EUS suitable for evaluation of submucosal lesions and staging esophageal cancer.

Locoregional TNM staging is vital in determination of surgical or medical management of esophageal carcinoma. EUS has a greater diagnostic accuracy for staging compared with computed tomographic (CT) scanning.[30] Furthermore, using cost-effectiveness analysis models, EUS may be more cost effective than other strategies by detection of celiac lymph nodes that would prevent unnecessary surgery.[31]

## Therapeutic Procedures

### ENDOSCOPIC MUCOSAL RESECTION

Advanced endoscopic therapies may obviate the need for surgery in certain cases. Endoscopic mucosal resection (EMR) is one such therapy that pertains to esophageal pathology, particularly in BE with dysplasia and very early esophageal cancers that have not extended into the submucosa. Although a variety of techniques have been described, the two major methods include EMR with a cap (EMRC) or EMR with ligation (EMRL). The first step to mucosal resection includes injection of a substance, usually normal saline with or without epinephrine, to lift the lesion in question off the muscularis propria. Other solutions like hypertonic saline, 10 percent glycerol/5 percent fructose, 50 percent dextrose, and sodium hyaluronate have also been used.[32]

EMRC uses a transparent cap fitted to the endoscope. Once the lesion has been lifted, a snare is passed through the accessory channel and opened inside the cap. The lesion is then suctioned into the cap where it can be excised with the snare. EMRL uses a single-band or multiband ligation device similar to those used for treating esophageal varices. The band ligator is deployed, grasping the lesion into a polypoid configuration. This allows for resection via snare and retrieval (Fig. 12-6).

The risks of EMR include perforation, bleeding, and stricture formation with large areas of EMR. It appears that EMRC and EMRL have similar safety profiles. Despite these adverse risks, EMR is generally safe in experienced hands and can be done in an outpatient setting.

Esophageal indications for EMR include early esophageal cancer and BE with dysplasia. Accepted criteria for EMR as proposed by the Japanese Society for Gastroenterological Endoscopy (JSGE) include esophageal cancer lesions less than 2 cm in diameter and involvement of less than 1/3 of the esophageal circumference. EMR for lesions extending into the submucosa is contraindicated, and thus relevant investigations like EUS can be considered prior to EMR.

Traditionally, patients with high-grade dysplasia in BE were offered esophagectomy, especially in light of possible concomitant carcinoma. However, now with ablative techniques such as EMR, patients may be offered endoscopic therapy instead. One study found a curative rate of 96.6 percent when treating 279 patients with either high-grade dysplasia

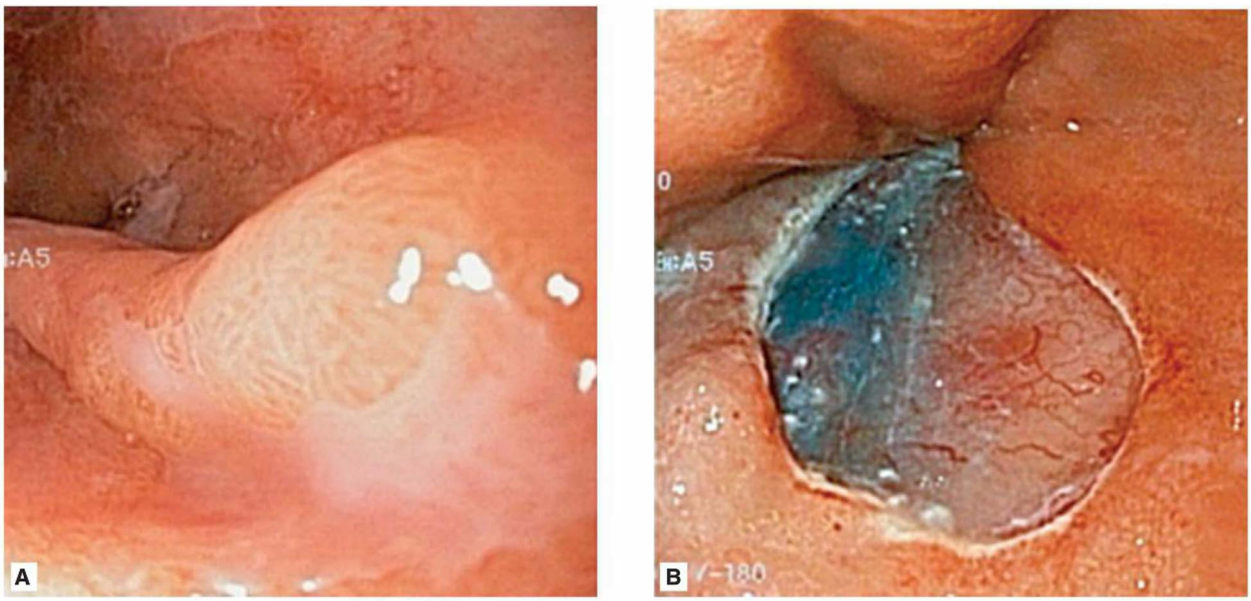

**FIGURE 12-6** **A.** BE with nodule **B.** After endoscopic mucosal resection and submucosal injection of indigo carmine.

($N = 61$) or early neoplasia. Patients required an average of two EMR sessions to achieve complete response. Risk factors associated with local recurrence included piecemeal resection, long-segment BE, lack of post-EMR ablative therapy (see the sections below), time to complete response greater than 10 months, and multifocal neoplasia.[33]

## PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) is another ablative technique for BE and early esophageal cancer. PDT can be used alone or may follow EMR to ablate residual dysplastic tissue after resection of focal lesions. The principle behind PDT is that when exposed to intense light, certain photosensitizing chemicals produce oxygen and other radical species. These radical species cause nonthermal cellular necrosis and vascular thrombosis. The only systemic photosensitizer approved by the FDA is porfimer sodium. It is given as an intravenous infusion over 3 to 5 minutes. Porfimer sodium is absorbed by most tissues but is selectively retained in neoplastic tissue. After approximately 48 hours, the photosensitizer is only retained in neoplastic tissue and has cleared normal tissue. Thus, PDT endoscopic therapy is usually scheduled 48 hours after infusion.

Porfimer sodium becomes activated in response to light at 515 and 630 nm wavelengths. Therefore, a specific light source has to be used at endoscopy, in contrast to standard white light endoscopy. The FDA-approved 630 nm red light source that is available also contains an automatic feature to change power and duration of treatment based on indication of procedure (e.g., BE vs. carcinoma). A variety of catheters and balloon catheters are available to deliver light to pretreated tissue in a circumferential fashion. Treatment is delivered for 8 to 12 minutes depending on indication.[34]

The major risk of PDT is stricture formation. Risk factors for this complication include long-segment BE, multiple PDT treatments, preceding EMR, history of chemoradiation, and history of prior stricture. As some residual photosensitizer remains in the patient's skin for up to 30 days, they are advised to avoid direct sunlight as severe sunburns can result.

## RADIOFREQUENCY ABLATION

Radiofrequency ablation (RFA) is another technique used in BE and other conditions. RFA can be performed circumferentially or focally. Circumferential RFA in the esophagus uses a 3-cm balloon ablation catheter in which resides a coiled electrode array. Two pulses of electric current at an energy level of 10 to 12 J/cm$^2$ are sufficient for ablation of full-thickness epithelium, without damaging the submucosa. Prior to placement of the balloon catheter, the esophageal luminal diameter has to be measured. The balloon ablation catheter's outer diameter must not be greater than the esophageal luminal diameter. The balloon ablation catheter is introduced via guidewire, followed by the endoscope.

Focal RFA is usually performed after circumferential ablation, if residual Barrett's tissue remains or when small amounts of BE are present. Instead of a balloon ablation catheter, focal RFA uses an electrode array that is mounted at the tip of the endoscope and seen in the 12 o'clock position.

As in EMR and PDT, RFA can be used for BE with high-grade dysplasia. However, it also has a role in low-grade dysplasia to prevent progression to high-grade dysplasia and cancer. Although more controversial, RFA can also be used in BE without dysplasia. Recently published was the longest running study, AIM-II, which followed 50 patients who had RFA of nondysplastic BE. At 2.5 years, 98.4 percent of patients had complete eradication of all metaplastic tissue. At 5 years, 92 percent still had complete eradication, while the remaining patients obtained complete eradication with further treatment with focal RFA.[35] Complications of RFA include bleeding, strictures, and postprocedure pain.

## CRYOTHERAPY

Cryotherapy is a nonthermal noncontact ablative technique that, when applied via endoscopy, causes freezing of the mucosa and induction of necrosis. The technology is based on the Joule–Thomson effect that dictates that the temperature of a liquid gas will drop when the surrounding pressure drops. There are currently two cryoablation systems available, one based on liquid nitrogen and the other on carbon dioxide. The cryoablation system includes a pressurized canister of compressed gas or liquid nitrogen. This cryospray is delivered to esophageal tissue via a single-use side or end-firing catheter that passes through the standard endoscope accessory channel. Once the gas is released from the tip of the catheter, tissues sprayed freeze in the context of decreased pressure. A suction tube is affixed to the tip of the endoscope or passed separately next to the scope to simultaneously remove evacuated gas that would distend the GI tract. Each application lasts 10 to 20 seconds and multiple applications can be performed to one area, with 10 to 30 seconds in between each to allow for thawing.

Cryotherapy can ablate tissues throughout the GI tract and has been studied in gastric antral vascular ectasia (GAVE) and radiation proctopathy. In the esophagus, cryotherapy is another ablative technique for BE and early carcinoma. Early data for cryotherapy suggest that it can eradicate high-grade dysplasia in a high proportion of patients.[36]

## ENDOSCOPIC SUBMUCOSAL DISSECTION

Endoscopic submucosal dissection (ESD) is a technique used to remove esophageal lesions that are flat and greater than 2 cm. This provides the pathologist the opportunity to examine the tissue en bloc. The lesion is not removed via a modified "polypectomy" as in the EMR technique. The initial step of ESD involves marking the margins with electrocautery. Next, the lesion is lifted with submucosal injection as described in the EMR section. An incision is then made in a circumferential manner with a special endoscopic electrocautery knife. A variety of electrocautery knives have been

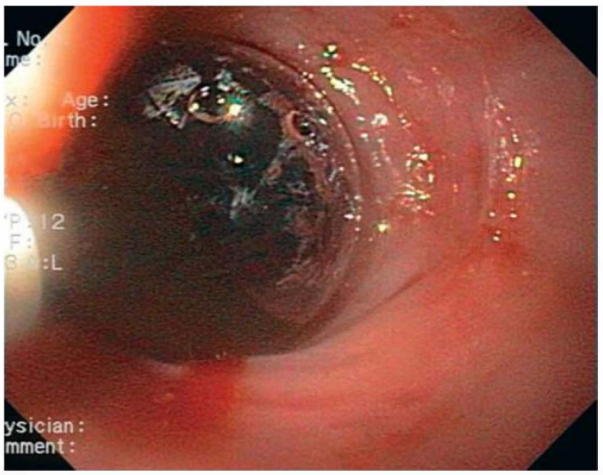

**FIGURE 12-7** Through the scope (TTS) balloon dilation o f esophageal stricture.

developed for use. Once the lesion is dissected off the deeper layers, it can be removed en bloc.

ESD can be a time-consuming procedure, lasting over an hour for one lesion. Complications include acute or delayed bleeding, perforation, and stricture. Perforation rates for ESD are higher than those of EMR.[37] The most experience with ESD comes from resection of early gastric cancer in Asia. However, ESD can be applied to high-grade dysplasia or early esophageal cancer as well.

## ESOPHAGEAL DILATION

Esophageal dilation can be used to manage benign and malignant esophageal strictures, postsurgical anastomotic strictures and is a mainstay of therapy for achalasia. There are two basic kinds of esophageal dilators: balloon-based dilators and mechanical (Bougie) dilators. Balloon dilators are typically passed through the scope and through the stricture (Fig. 12-7). For narrow strictures, wire-guided balloons are available. There are several types of mechanical dilators, such as Maloney dilators, which are not wire-guided, and Savary dilators that are wire-guided. Fluoroscopy is helpful for guiding dilation of difficult or proximal esophageal strictures. Balloon dilators disrupt strictures by exertion of radial force, while mechanical dilators exert force radially and longitudinally. Potential complications of esophageal dilation include esophageal perforation and bleeding. The "rule of threes" for esophageal dilation suggests that no more than three dilators of increasing size should be used in each dilation session, which allows increasing the lumen of the stricture by about 3 mm.[38]

With mechanical dilators, the amount of resistance of a stricture can be felt by the endoscopist passing the dilator, which also helps guide therapy. Achalasia dilation is performed with 30- to 40-mm pneumatic balloons, typically with fluoroscopic guidance. Symptomatic improvement in dysphagia is as high as 85 percent, but dysphagia returns in one-third to half of patients.[39] Complications of dilation can include bleeding and esophageal perforation, with rates of 0.1 percent for simple dilations and 3 percent for large pneumatic dilations.[40]

## ESOPHAGEAL STENTS

Esophageal stents are used to maintain the lumen in a variety of benign and malignant conditions. Stents are either self-expanding metal stents (SEMS) or self-expanding plastic stents (SEPS). SEMS are composed of woven metal meshes that expand to exert radial force until the maximum diameter is reached. Multiple sizes and diameters are available. Certain metals are more flexible and are thus more appropriate for stenting across angulations. SEMS have flares on one end to prevent migration. SEMS can be wholly or partially covered with a polymer membrane to prevent tumor infiltration. This allows for future repositioning or removal. In contrast, ingrowth of tissue prevents the ability of uncovered SEMS to be removed or repositioned.

SEPS are completely covered with a silicone membrane to prevent tissue ingrowth. They were designed to facilitate ease of repositioning and removal. However, SEPS have high rates of migration and may not have long-term clinical efficacy for malignant conditions. Decision to use a SEPS as opposed to a covered SEMS has to be carefully made.

Esophageal stents are deployed over a guidewire, generally with fluoroscopic guidance. Esophageal lumens less than 12 mm require dilation prior to successful placement of SEMS. Complications of esophageal stent placement include bleeding and perforation. Particularly with bulky upper esophageal tumors, airway compression as the stent expands can be life threatening and simultaneous bronchoscopy with tracheal stent placement should be considered. Another complication of stent placement is pressure necrosis with subsequent fistula formation.

Indications for esophageal stenting includes palliation for unresectable esophageal cancer. Dysphagia may be relieved in a high proportion of patients, improving quality of life. Esophageal stents have also been used in benign esophagotracheal fistulas, anastomotic leaks, or perforations. Although results have been favorable in multiple case series and observational studies for these conditions, there are no randomized control trials comparing stents to surgical therapy. Esophageal stents for benign esophageal stricture are used occasionally, but much less frequently than in malignant disease and with careful patient selection.[41]

## ESOPHAGEAL PHYSIOLOGY, FUNCTION TESTS, AND ENDOSCOPIC TECHNIQUES BOARD REVIEW QUESTIONS (CHAPTER 12)

1. Which of the following contribute to the lower esophageal sphincter pressure?
   A. Circular smooth muscle of the distal esophagus alone
   B. Longitudinal smooth muscle of the distal esophagus alone
   C. Striated muscle of the right crus of the diaphragm alone
   D. Circular and longitudinal smooth muscle of the distal esophagus
   E. Circular smooth muscle of the distal esophagus and striated muscle of the right crus of the diaphragm

2. A 47-year-old female presents with a 5-year history of substernal burning. Proton pump inhibitor (PPI) therapy is ineffective and upper endoscopy is unremarkable. A 24-hour pH study demonstrates 12 reflux events. Four of these events were associated with symptoms. What is the next appropriate step in management?
   A. Increase PPI regimen
   B. Surgical referral for fundoplication
   C. Initiate antidepressant therapy
   D. Perform esophageal manometry
   E. Perform esophageal scintigraphy

3. A 72-year-old man with newly diagnosed adenocarcinoma of the esophagus presents for evaluation. What is the most sensitive test for locoregional staging of his cancer?

   A. CT scan
   B. PET scan
   C. Endoscopic ultrasound
   D. Barium esophagogram
   E. Chromoendoscopy

4. A 20-year-old male presents with chest pain associated with eating. His upper endoscopy is normal. Which is the next most appropriate test?

   A. Esophageal manometry
   B. Barium esophagogram
   C. CT scan of chest
   D. 24-hour pH test
   E. Capsule endoscopy

5. A 64-year-old man is found to have early adenocarcinoma on endoscopic surveillance for Barrett's esophagus. Which is of the following is not an acceptable form of management?

   A. Esophagectomy
   B. Endoscopic mucosal resection of lesion followed by photodynamic therapy
   C. Endoscopic mucosal dissection of lesion
   D. Cryotherapy
   E. Continued endoscopic surveillance every 6 to 12 months

## ANSWERS

1. **Answer: E.** A combination of the circular smooth muscle of the distal esophagus and striated muscle of the right crus of the diaphragm comprises the lower esophageal sphincter.
2. **Answer: C.** A 24-hour pH testing is quite sensitive and specific and the patient's symptoms do not correlate with significant reflux. Further testing with manometry and scintigraphy is not warranted.
3. **Answer: C.** Endoscopic ultrasound will provide staging for tumor size and lymph nodes. Barium esophagography and chromoendoscopy do not provide staging information. CT and PET scanning are useful for regional as well as distant disease, but cannot provide detail on depth of local tumor invasion.
4. **Answer: D.** The most likely diagnosis is gastroesophageal reflux, and 24-hour pH testing is the appropriate study.
5. **Answer: E.** This patient has established and documented malignancy and needs some form of resectional or ablative therapy. Continued surveillance without initiation of treatment is inappropriate.

# 13 Congenital Esophageal Anomalies

*Nishant D. Patel*
*Avedis Meneshian*

**KEY CONCEPTS**

- Epidemiology
  - Esophageal atresia and tracheoesophageal fistula (EA–TEF) occurs in 1 in 3400. Esophageal duplication cysts represent 10 to 15 percent of foregut duplication cysts and 5 to 10 percent of mediastinal cysts. The true incidence of esophageal duplication cysts is unknown. Congenital esophageal stenosis and webs occur in 1 in 25,000 to 50,000 live births.
- Classification
  - Anatomic variations of EA–TEF include isolated EA, EA with distal TEF, EA with proximal TEF, EA with distal and proximal TEF, or N-type TEF. EA with distal TEF is the most common. Esophageal duplication cysts can be cervical, thoracic, or abdominal. Esophageal stenosis and webs can be characterized on the basis of etiology into fibromuscular thickening, trachobronchial remnants, and membranous web.
- Clinical features
  - EA–TEF is suggested by polyhydramnios, and infants present with drooling, rhonchi, aspiration with subsequent respiratory distress. Esophageal duplication cysts are often asymptomatic. Symptoms due to esophageal duplication cysts are secondary to mass effect and include dysphagia and respiratory insufficiency. Congenital esophageal stenosis and webs present in infancy with dysphagia and vomiting of solid food.
- Diagnosis
  - EA–TEF is readily diagnosed with passage of a 10-F esophageal tube and gentle insufflation, and plain chest radiograph. The presence of air in the stomach confirms a distal TEF, and its absence suggests isolated EA. Esophageal duplication cysts are also diagnosed on plain film and confirmed with esophagography and CT. Esophageal stenosis and web are diagnosed with esophagography and endoscopy.
- Treatment
  - Surgical repair of EA–TEF consists of a single-layer primary anastomosis of the proximal and distal esophageal segments and ligation of any TEF. Esophageal duplication cysts are resected. Esophageal stenosis and webs are initially managed conservatively with dilatation. Surgical treatment is reserved for stenosis refractory to dilatation and consists of resection of the stenotic segment and primary anastomosis.
- Complications
  - Outcomes following repair of EA–TEF are good. Early complications include anastomotic leak and subsequent sepsis. Mid-to-late-term complications include stricture, recurrent fistula, and gastroesophageal reflux.

## ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA

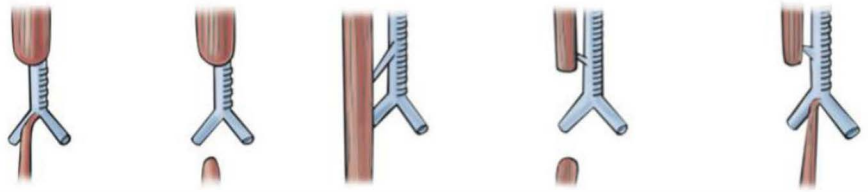
### Epidemiology

The incidence of esophageal atresia (EA), with or without tracheoesophageal fistula (TEF), is approximately 1 in 3400.[1] There is a reported slight preponderance in males and children of diabetic or older mothers.[2] Chromosomal anomalies have been reported in 6 to 10 percent of cases.[3] Although EA–TEF can be an isolated finding, epidemiologic studies suggest that up to 60 percent will have other anomalies.[2] Some will present with other anomalies that lead to a specific genetic diagnosis, whereas others will present with a nonrandom association of other defects. These other defects include coloboma, heart, atresia choanae, retarded development,

genital hypoplasia, and ear abnormalities (CHARGE associations), as well as vertebral, anal, cardiac, tracheoesophageal fistula, renal, and limb defects (VACTERL).

## Embryology

EA constitutes a spectrum of incomplete esophageal development, which arises from interruptions in endoderm–mesoderm interactions. Although the exact embryologic mechanism of EA–TEF is not well characterized, some of the mechanisms have been recently discovered. Most studies on EA–TEF have used intraperitoneal Adriamycin injections in pregnant rodents, which reproduces the VACTERL association that is identical to the defects found in humans.[4] In this model, the esophagotracheal foregut tube fails to divide into ventral and dorsal parts, and a fistula develops. Several molecular pathways seem to play an important role. Some studies have shown that when genes for the retinoic acid receptors were deleted in mice, the foregut tube failed to separate.[5] The hedgehog signaling pathway has also been implicated.[6] Targeted deletion of the sonic hedgehog gene resulted in mice embryos with severe TEF malformations.[6] The Hox genes are thought to play a role in endodermal patterning and are expressed in the endodermal and mesodermal germ layers. Mice that are null mutant for Hoxc4 develop a partially or completely blocked esophageal lumen.[7] In another study, T-box transcription factor 4 misexpression resulted in failure of tracheoesophageal septum formation in chicks.[8,9] Despite these studies, the exact pathogenic mechanism behind EA–TEF remains elusive.



## Classification, Clinical Presentation, and Diagnosis

EA is characterized using the Ladd[10] or Gross[11] classification system. In general, the different variants include isolated EA, EA with distal TEF, EA with proximal TEF, EA with proximal and distal TEF, and N-type TEF. EA with distal TEF (gross class C or Ladd III/IV) is the most common EA anomaly, seen in approximately 87 percent (Table 13-1). Infants with N-type EA and those weighing less than 2000 g are more likely to present with associated anomalies.[12] The most common associated anomalies are cardiovascular malformations, seen in up to 30 percent infants with EA.[13] These include atrial and ventricular septal defects, patent ductus arteriosus, tetralogy of Fallot, and anomalies of the aortic arch.

The diagnosis of EA–TEF is usually made in the first 24 hours of life, but can be made antenatally or delayed.[14,15] Prenatal ultrasound detects EA by the presence of polyhydramnios (amniotic fluid index >97.5 percentile) with a small or absent stomach.[16] Polyhydramnios occurs because of the fetus' inability to swallow amniotic fluid. If an EA is detected on ultrasound without polyhydramnios, a distal TEF allows the amniotic fluid to pass into the stomach.

In early postnatal life, infants with EA–TEF will accumulate excess saliva, drool, develop rhonchi with mild-to-moderate respiratory distress, and demonstrate inability to feed. Workup of EA–TEF is used to confirm diagnosis, plan for surgical intervention, and look for associated anomalies. On workup, infants with EA–TEF will fail to have a 10 F tube pass beyond 10 cm from the lips. On gentle insufflation of the esophageal tube, the size and shape of the

**TABLE 13-1: Gross and Ladd Classification Schemes for Esophageal Atresia and Tracheoesophageal Fistulas**

| Description | EA with distal TEF | Isolated EA | "N-type" TEF | EA with proximal TEF | EA with proximal and distal TEF |
|---|---|---|---|---|---|
| Gross Classification | C | A | E | B | D |
| Ladd Classification | III/IV[a] | I | | II | V |
| Frequency (%) | 86.5 | 7.7 | 4.2 | 0.8 | 0.7 |

EA, esophageal atresia; TEF, tracheoesophageal fistula.

[a]Type III fistula enters above tracheal bifurcation; type IV fistula enters at carina.

*Source:* Reproduced with permission from Goldstein AM, Doody DP, Donahoe PK. Esophageal atresia and tracheoesophageal fistula. In: Pearson FG, Cooper JD, Deslauriers J, et al. *Esophageal Surgery*, New York: Churchill Livingstone, 2002. Copyright Elsevier.

esophageal pouch can be delineated on plain radiographs. Furthermore, dilute barium through the tube or air in the stomach may confirm TEF. The presence of a "gasless" abdomen suggests EA without TEF. Some centers favor endoscopy in an effort to identify a TEF and place a stent prior to surgical repair.

Diagnostic investigations for associated anomalies for patients diagnosed antenatally may include fetal echocardiogram and karyotyping. In the absence of dysmorphism and urinary difficulties, a chest plain film to evaluate vertebral anomalies and echocardiogram may be sufficient. Some centers include a renal ultrasound routinely.

If undiagnosed, infants suffer from aspiration and subsequent respiratory distress and cyanosis during feedings. In severe cases of aspiration, infants may become apneic and bradycardic with subsequent cardiopulmonary arrest. Infants with a distal TEF may develop more severe pulmonary infections and pneumonitis with subsequent severe respiratory distress since gastric secretions reflux into the tracheobronchial tree.

Delayed diagnosis of EA–TEF with survival beyond 25 days of life is rare but has been reported.[17] Because the esophagus remains in continuity, delay in diagnosis is more common for N-type TEF. These infants will present with recurrent cough on feeding, recurrent pneumonias, cyanosis, increased flatulence, and intermittent abdominal distention.

## Preoperative Management

Preoperative management of infants with EA–TEF includes suctioning with an esophageal tube, nil per os, and head of bed elevation to reduce regurgitation and aspiration risk. Intravenous access should be obtained, and maintenance intravenous fluids initiated. In the event of intubation, gastric distention can be reduced by positioning the tip of the endotracheal tube distal to any TEF. Although rare, gastric distention with subsequent perforation is a catastrophic complication, requiring emergency ligation of the distal TEF.

## Surgical Management

Primary repair of EA–TEF is readily achieved through an extrapleural approach via a right posterolateral, muscle-sparing thoracotomy in the fourth intercostal space (Fig. 13-1). The TEF is identified and divided, and the tracheal cuff oversewn. The upper pouch and distal esophagus is identified and mobilized, and then repaired in a primary fashion using interrupted absorbable sutures. Advancement in minimally invasive techniques and technology has made thoracoscopic surgery a viable alternative to standard open repair for EA–TEF. Some series have shown equivalent results to open surgery, although long-term data are elusive.[18,19]

The presence of 13 ribs or a short upper pouch suggests a "long gap." Many strategies have been adopted to tackle the long gap and subsequent anastomotic tension. These approaches have had varying results and include circular or spiral myotomies, mobilization of the distal esophagus, and tubularization of an upper pouch flap.[20–23] Optimal repair for this group of patients is controversial, although a number of centers are now advocating retention of the native esophagus and the benefits of delayed primary repair.[24]

## Postoperative Complications

Anastomotic leak, which occurs in 15 to 20 percent cases, and subsequent sepsis remains a common and serious complication of EA–TEF repair in the early postoperative setting.[25] These infants may present with tension pneumothorax requiring thoracostomy tube placement and/or reoperation to oversew the leak. Smaller leaks are more common, and can be managed conservatively, but may lead to stricture or recurrent fistula in the long term.

Mid-to-long-term postoperative complications include feeding difficulty, fistula recurrence, strictures, reflux, and aspiration. Feeding difficulties are common after repair of EA–TEF and are thought to be secondary to esophageal dysmotility, leading to reflux and potentially aspiration. Some children require enteral nutrition through nasogastric or postpyloric feeding. The incidence of fistula recurrence is likely improved from 5 to 15 percent, historically quoted due to improved techniques, imaging, and instruments. Risk factors predisposing to recurrence include a primary EA–TEF repair under tension and an anastomotic leak.[26] TEF recurrence is suspected when a child develops multiple lower respiratory tract infections with mediastinal air outlining the esophagus on chest radiograph. Surgery is required to correct the recurrent TEF. Up to half of all anastomotic leaks may be complicated by esophageal stricture, and anywhere from 6 to 40 percent of patients develop stricture following EA–TEF repair. An anastomosis under tension, devascularization of the distal esophagus on mobilization, and gastroesophageal reflux are all thought to play a role in the development of esophageal stricture following EA–TEF repair. Most of these patients will require serial esophageal dilations. Up to 40 percent of patients following EA–TEF repair will develop gastroesophageal reflux, half of which are successfully managed with medical therapy, and the remaining may require fundoplication.[27]

# ESOPHAGEAL DUPLICATION CYSTS

## Epidemiology

Esophageal duplication cysts are benign cystic masses that are usually spherical or tubular structures adhering to the esophagus and represent 10 to 15 percent of foregut duplication cysts and 5 to 10 percent of mediastinal cysts. The true incidence of esophageal duplication cysts is unknown.

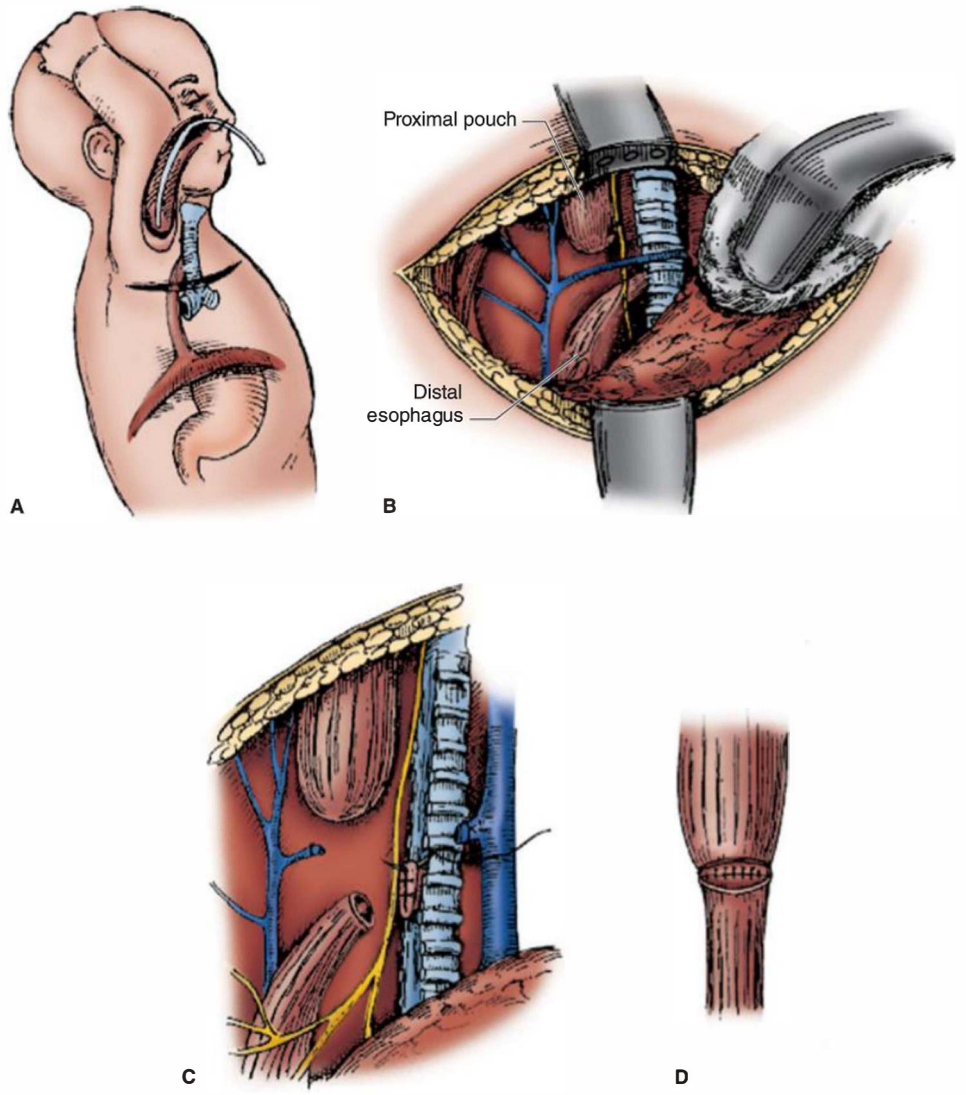


**FIGURE 13-1** Surgical repair of type I esophageal atresia. **A.** A right posterolateral thoracotomy through the fourth intercostal space is a standard approach. **B.** The proximal esophageal pouch and distal esophagus are exposed with anterior traction of the lung and mediastinal pleura. **C.** Division and closure of the tracheoesophageal fistula. **D.** Single-layer primary anastomosis between the proximal and distal esophageal segments using interrupted absorbable sutures. (Reproduced with permission from O'Neill JA. *Operative Surgery, Principles and Techniques,* 3rd ed. Philadelphia: Saunders, 1990:1072. Copyright Elsevier.)

## Embryology

Esophageal duplication cysts arise from errors in foregut budding during the third through sixth week of gestation. During development, the laryngotracheal groove divides into dorsal (esophagus) and ventral (respiratory tract) parts. Esophageal duplication cysts arise when epithelial cell secretory vacuoles, during esophageal development, fail to coalesce.[28] When the budding error occurs determines the location of the cyst.

## Classification, Clinical Presentation, and Diagnosis

Esophageal duplication cysts are cystic remnants of the foregut lined with gastrointestinal epithelium and covered by two layers of smooth muscle. Histologically, the gastrointestinal epithelial lining of esophageal duplication cysts can be composed of squamous, columnar, cuboidal, pseudostratified, or ciliated cells. They can occur in the cervical, thoracic, or abdominal segments. Luminal communication is uncommon.

Many patients with esophageal duplication cysts are asymptomatic and never diagnosed. Approximately, 25 percent are children. When symptoms develop, they result from tracheal and esophageal compression and include chest fullness, dysphagia, and/or hematemesis. When the cyst involves the upper esophagus, obstructive symptoms are more prevalent. Anorexia, weight loss, regurgitation, gastrointestinal bleeding, vomiting, cough, recurrent pneumonitis, and chest pain may also occur. In certain cases, patients with esophageal duplication cysts are at risk for bleeding, ulceration, and cyst rupture. If the esophageal cyst ruptures, patients may develop mediastinitis. Associated anomalies include neural or gastrointestinal anomalies. Adults are usually asymptomatic, but if left untreated, usually develop symptoms.

It is important to differentiate esophageal duplication cysts from other mediastinal masses, including bronchogenic cysts and malignancies. Most esophageal duplication cysts are found in the right posterior–inferior mediastinum and are often detected incidentally on plain chest radiographs as a large, unilateral, sharply defined, spherical, or tubular mass. The mass may displace the trachea and/or esophagus. To confirm the diagnosis, barium contrast esophagography can be performed demonstrating a filling defect with distortion of the lumen. Unfortunately, esophagography is poor at distinguishing cystic from solid tumors. On CT, esophageal duplication cysts are located in the posterior mediastinum, are round, homogenous, have smooth margins, do not invade adjacent structures, and do not enhance with contrast. Once CT has been performed, esophagoscopy should be performed to rule out abnormal appearing mucosa overlying the cyst. Endoscopic ultrasound can also be used to define the cyst as intra- or extramural, and to help delineate cystic versus solid tumor. These cysts should not be aspirated given the risk of infection. Cysts with gastric epithelial lining that present with ulceration or bleeding can be revealed with technetium scanning.

### Surgical Management

All patients with symptomatic esophageal duplication cysts require resection and pathologic workup to rule out malignancy. In a high-risk patient with a definitive diagnosis of esophageal duplication cyst, conservative management is a reasonable option. On the other hand, in the good surgical candidate, surgical resection is advised to avoid cyst enlargement and subsequent compression, ulceration, bleeding, infection, rupture, or malignancy.

The approach to surgical resection may involve a limited posterolateral thoracotomy or video-assisted thoracoscopy. A minimally invasive approach may be more appropriate, given the lesions are benign and often easily dissected. Intramural cysts are enucleated by dividing overlying esophageal musculature while maintaining esophageal wall integrity. In the event the cyst is in continuity with the esophageal lumen, the continuity should be closed and the esophageal wall reapproximated carefully to avoid stricture.

## ESOPHAGEAL STENOSIS AND WEBS

### Epidemiology

Congenital esophageal stenosis occurs in 1 in 25,000 to 50,000 live births.[29]

### Embryology

The embryologic origin of esophageal stenosis and webs is unknown. The most common etiology is fibromuscular thickening. Other common causes include tracheobronchial remnants due to incomplete separation of the primitive foregut and respiratory tract, as well as congenital webs from failure of complete vacuolization of the primitive esophageal lumen.

### Classification, Clinical Presentation, and Diagnosis

Congenital esophageal stenosis can be classified on an anatomic basis into fibromuscular thickening, tracheobronchial remnants, and membranous web. Those that result from fibromuscular thickening have diffuse fibrosis of the esophageal wall with hypertrophy of the muscularis and submucosal layers. These stenoses are located commonly in the distal esophagus, and therefore are commonly associated with EA. Stenoses due to tracheobronchial remnants are also located in the distal esophagus and contain cartilage, respiratory mucous glands, or ciliated epithelium. These remnants form a rigid and focal stenosis. Membranous webs, the rarest of congenital esophageal stenoses, consist of a thin membrane lined with epithelium and have an eccentrically located opening. Membranous webs are found in all segments of the esophagus.

Congenital esophageal stenosis will present in infants as progressive dysphagia and postprandial emesis. Severity of disease depends on the location and degree of stenosis: A proximal stenosis leads to an inability to swallow solid food, a distal stenosis results in regurgitation, and a complete stenosis/obstruction resembles infants who present with EA. Diagnosis is based on barium esophagography and endoscopy, which can define the location and severity of stenosis.

### Management

Treatment of congenital esophageal stenosis revolves around treating symptoms. Initially, esophageal dilatation using Maloney or Avaray bougies can be used to treat children with thin esophageal webs or mild fibromuscular thickening. Dilatation is not without complications, which include esophageal leak and recurrent stenosis

requiring repetitive dilatations to maintain patency. If conservative management fails, resection with primary end-to-end anastomosis is performed. The approach is usually through a right thoracotomy for middle-third stenoses, or a left thoracotomy for distal stenoses. If the stenosis is near the gastroesophageal junction, a concomitant antireflux procedure should be performed.

## CONGENITAL ESOPHAGEAL ANOMALIES BOARD REVIEW QUESTIONS (CHAPTER 13)

1. Which of the following is correct regarding esophageal atresia?
   A. The incidence is 1 in 200.
   B. There is a slight preponderance in females.
   C. Chromosomal abnormalities have been reported in nearly 50 percent of cases.
   D. About 10 percent will be associated with other anomalies.
   E. The CHARGE association includes cardiac defects.

2. Which anatomic configuration is most common?
   A. Esophageal atresia with distal tracheoesophageal fistula
   B. N-type tracheoesophageal fistula
   C. Esophageal atresia with proximal tracheoesophageal fistula
   D. Esophageal atresia with both proximal and distal tracheoesophageal fistula
   E. Isolated esophageal atresia

3. Which is true regarding complications after surgery for esophageal atresia?
   A. Anastomotic leak occurs in 5 to 10 percent.
   B. Feeding difficulties are uncommon.
   C. The incidence of fistula recurrence has not improved overtime.
   D. Up to 25 percent of all anastomotic leaks are complicated by stricture.
   E. Gastroesophageal reflux occurs in nearly 40 percent of patients.

4. Which is correct regarding esophageal duplication cysts?
   A. These cysts are considered premalignant.
   B. They represent 5 to 10 percent of all mediastinal cysts.
   C. They result from abnormal foregut budding during the sixth and ninth weeks of gestation.
   D. The cyst is lined with gastrointestinal epithelium and does not have a smooth muscle covering.
   E. Luminal communication is common.

5. Which is correct regarding diagnosis of esophageal duplication cysts?
   A. Most patients are asymptomatic.
   B. Over 75 percent present in children.
   C. Obstructive symptoms are more common when the cyst involves the lower esophagus.
   D. Most are located in the left posterior–inferior mediastinum.
   E. These cysts should be aspirated for cell analysis.

## ANSWERS

1. **Answer: D.** The CHARGE associated defects include coloboma, heart, atresia choanae, retarded development, genital hypoplasia, and ear abnormalities. The incidence of esophageal atresia is about 1 in 3400 and there is a slight preponderance in males. Chromosomal abnormalities occur in 6 to 10 percent cases and up to 60 percent will have other associated anomalies.
2. **Answer: A.** Esophageal atresia with distal tracheoesophageal fistula is the most common configuration, occurring in over 85 percent cases.
3. **Answer: E.** Gastroesophageal reflux is common, occurring in up to 40 percent of patients after operative repair. Anastomotic leak occurs in 15 to 20 percent, and half of these will be complicated by stricture. Feeding difficulties are common after surgical repair. The incidence of fistula recurrence likely has improved with modern techniques and instrumentation.
4. **Answer: B.** Esophageal duplication cysts represent 5 to 10 percent of all mediastinal cysts. These are benign cysts that result from abnormal foregut budding during the third and sixth weeks of gestation. The cyst is lined with gastrointestinal epithelium and is covered with two layers of smooth muscles. Luminal communication is uncommon.
5. **Answer: A.** Most patients are asymptomatic and are diagnosed incidentally. Only 25 percent present in children. Obstructive symptoms are more common when the cyst involves the upper esophagus. Most are located in the right posterior–inferior mediastinum. These cysts should not be aspirated to avoid infection.

# Gastroesophageal Reflux Disease and Esophageal Motility Disorders

*Shelly Bansal*
*Brian Goodman*
*Edmund S. Kassis*

## KEY CONCEPTS

- Epidemiology
  - Gastroesophageal reflux disease (GERD) is one of the most frequently encountered problems seen in clinical practice today. It is estimated that 60 million adults report suffering from reflux symptoms at least once a month. Almost 24 percent of the population report heartburn daily and 43 percent have weekly episodes.
  - Achalasia is a disease affecting 1/10,000 people, making it the second most common esophageal motility disorder. It affects men and women equally from the ages of 20 to 40 years.
- Pathophysiology
  - GERD develops when the normal protective barrier of the esophagus is overcome and exposed to chronic insult. The pathogenesis of GERD is multifactorial, including anatomic factors, motor abnormalities, impaired esophageal clearance, and altered mucosal resistance.
  - Achalasia is a result of neuronal degeneration of the myenteric plexus. The consequence is an unopposed sympathetic response and increased pressure at the level of the lower esophageal sphincter (LES), leading to a functional obstruction of the esophagus.
- Clinical features
  - GERD is variable in its presentation. Heartburn, regurgitation, and chest pain are the most common complaints. Extraesophageal symptoms include pneumonia, airway inflammation, chronic cough, laryngitis, and hoarseness.
  - Achalasia presents as progressive dysphagia, initially presenting with dysphagia to solids and then to liquids.
- Diagnostics
  - Diagnostic studies for GERD include 24-hour pH monitoring, BRAVO probe, endoscopy, and manometry.
  - The pathognomonic finding in achalasia is of a "bird's beak" on esophagogram. Manometry is the gold standard for achalasia. Classic findings are a hypertensive LES (resting pressure >45 mm Hg), incomplete relaxation of the LES with swallowing, residual pressure >8 mm Hg, and esophageal aperistalsis.
- Treatment
  - Initial management of GERD includes lifestyle medication and proton pump inhibitors (PPIs). Failure of medical therapy or inability to tolerate PPIs is an indication for surgery. Laparoscopic Nissen fundoplication is the surgery of choice. Alternate options include partial fundoplication or Collis gastroplasty for patients with esophageal motility disorders or a short esophagus.
  - Multiple options for the treatment of achalasia include smooth muscle relaxants, dilation, botulinum toxin, and Heller myotomy.
- Outcomes
  - Laparoscopic Nissen fundoplication has shown equal efficacy to an open approach in controlling GERD and is associated with decreased length of stay (LOS), less pain, and lower costs. The overall complication rate is between 5 and 10 percent. Laparoscopic antireflux surgery (LARS) is associated with an improvement in symptoms compared with those treated medically but is associated with a 6-percent rate of severe dysphagia.
  - Laparoscopic Heller myotomy has been shown to be superior to botulinum toxin injection and pneumatic dilation. Recent series show excellent long-term relief of symptoms at 2 years.

## INTRODUCTION

Gastroesophageal (GE) reflux is a normal physiologic process whereby gastric and pancreaticobiliary secretions reflux into the esophagus. This process becomes pathologic when the normal response to reflux fails and symptoms ensue. Gastroesophageal reflux disease (GERD) is one of the most frequently encountered problems seen in clinical practice today. The American College of Gastroenterology estimates that roughly 60 million adults report suffering from reflux symptoms at least once a month.[1] Almost 24 percent of the population report heartburn daily and 43 percent have weekly episodes.[2] The reported incidence of GERD has nearly doubled in the last 3 decades,[3] with current annual expenditure on proton pump inhibitors (PPIs) in excess of US$ 14 billion.[4]

## PATHOPHYSIOLOGY

### Lower Esophageal Sphincter

GERD develops when the normal protective barriers employed by the esophagus are overcome, exposing it to repeated and chronic insult. A crucial role in the pathogenesis of GERD is mediated by contact of the esophageal mucosa with refluxate that can be composed of acid, bile, and pancreaticobiliary secretions. The mechanisms involved in the pathogenesis of GERD are multiple and include anatomic factors, motor abnormalities, impaired esophageal clearance, and altered mucosal resistance.

### Anatomic Barrier

The lower esophageal sphincter (LES) is a 3- to 4-cm segment of distal esophagus.[5] This high-pressure zone remains under tonic contraction, with resting pressures maintained at 10 to 30 mm Hg. Although large fluctuations are seen during a 24-hour period, resting pressure does not directly correlate with the severity of reflux.[6]

The LES mechanism has three distinct characteristics: sphincter length, pressure, and location.[7] The overall intra-abdominal length of the LES is of crucial importance to the esophageal surgeon. A decrease in overall length or intra-abdominal LES correlates directly with the degree of LES incompetence (Fig. 14-1).[8] In addition, the location of the LES is also important in maintaining competence. The LES is subject to elevated pressures, but due to its intra-abdominal position, the sphincter collapses and prevents reflux.[6]

### Acid Clearance and Bile Exposure

Normal acid clearance is dependent on esophageal motility. Esophageal dysmotility is found in 40 to 50 percent of the GERD population.[9] In these patients, decreased clearance leads to increased acid and bile exposure, resulting in esophagitis, stricture, and initiation of malignant degeneration.[9]

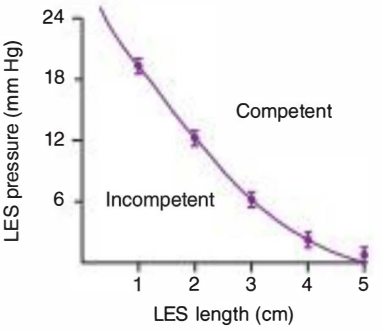

**FIGURE 14-1** The relationship between the pressure and length of the LES. Note that the shorter the overall length of the high-pressure zone, the higher the pressure must be to maintain sufficient resistance to be competent. (From DeMeester TR. Evolving concepts of reflux: The ups and downs of the LES. *Can J Gastroenterol* 2002;16(5):327–331. With permission.)

### Hiatal Hernias

Hiatal hernias are frequently found in patients with GERD and are present in 70 to 90 percent of patients with severe reflux. In the presence of a sliding hiatal hernia, the compression of the crus and the angle of His are disrupted. Hiatal hernias change the acute angle produced by the angle of His and disrupt the flap valve mechanism that prevents reflux.[6] In addition, a hiatal hernia results in dilation of the diaphragmatic crus and loss of the extrinsic compression provided by the diaphragm on the GE junction.[10] Migration of the stomach into the chest results in the disassociation of the LES from the crural diaphragm, resulting in failure of the antireflux barrier. The disruption of the GE junction lowers the threshold for LES relaxation, worsens positional reflux, diminishes esophageal clearance, and acts as a reservoir for gastric and duodenal secretions.[11]

### Causes of GERD and Progression

In a normal individual, lower esophageal relaxation occurs after a swallow. The swallow decreases LES tone to allow entry of food or fluids into the stomach. In GERD, transient LES relaxation or TLESRs are found to be the underlying cause of pathologic reflux.[12] TLESRs are defined as brief episodes of LES relaxation that are unrelated to swallowing or peristalsis. Neurophysiology studies indicate that TLESRs are visceral reflexes with vagal afferent and efferent pathways that transmit information to and from the dorsal nucleus of the vagus.[10] Gastric distension, by stimulation of proximal gastric tension and stretch receptors, has been recognized as a major factor inducing TLESRs.[5] TLESRs are found in both normal individuals without symptomatic reflux and those with GERD.

With increasing frequency of these episodes, mucosal inflammation follows. Inflammation and injury lead to shortening of the esophagus. This critical point is termed as the permanently defective LES.[7] Characteristics include an

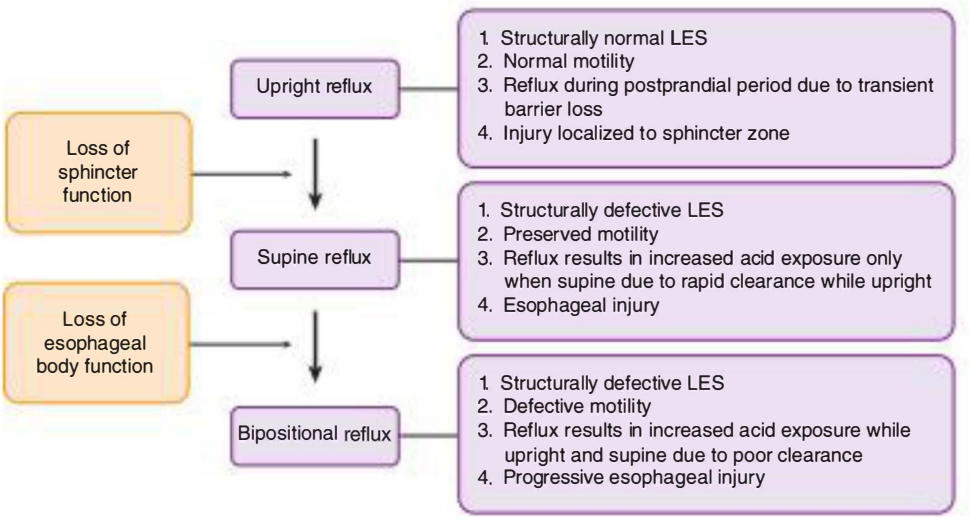

**FIGURE 14-2** Schema for progression of GERD. Initially, esophageal acid exposure occurs only in the upright awake position after meals due to gastric distension causing TLESRs. With inflammatory changes of the LES, the barrier becomes permanently defective, and an increase in esophageal acid exposure occurs in the supine position, while the esophageal body effectively clears the refluxed acid during the day. Inflammatory injury to the esophageal body results in loss of the esophageal body clearance function or bipositional reflux. (From DeMeester TR. Evolving concepts of reflux: The ups and downs of the LES. *Can J Gastroenterol* 2002;16(5):327–331. With permission.)

average pressure less than 6 mm Hg, length less than 2 cm, and an intra-abdominal length less than 1 cm.[7] As the cycle continues, advanced GERD becomes a more difficult disease process to manage medically; while symptoms may be controlled by acid suppression, reflux is still present (Fig. 14-2). This continued exposure can lead to the Barrett's metaplasia, stricture, and cancer.

## SYMPTOMS

The presentation of GERD is highly variable and symptoms are divided into two broad categories: esophageal and extraesophageal symptoms. Heartburn and regurgitation are the most common complaints. The classic presentation is retrosternal pain occurring 30 to 60 minutes after a meal, particularly in the recumbent position. The combination of both heartburn and regurgitation is 90 percent accurate in the diagnosis of GERD. Odynophagia and dysphagia are other common esophageal symptoms. Alarm symptoms include unintended weight loss, hematemesis, black or bloody stool, and recurrent vomiting. They are present in about 10 percent of patients presenting to primary care and require urgent endoscopy.[13]

Extraesophageal symptoms are increasingly being linked to reflux disease.[14] In most cases, the symptoms are not recognized. Pulmonary complications due to aspiration of gastric contents into the pulmonary system lead to pneumonia, airway inflammation, and chronic cough. Reflux that reaches the oral cavity can result in water brash, sour taste in the mouth, and dental erosions. Finally, reflux to the vocal cords can result in laryngitis and hoarseness.[14]

## DIAGNOSIS

A patient with typical symptoms, such as heartburn and regurgitation, can be diagnosed with GERD, and a trial of acid-reducing medications is indicated.[15] Although not a truly diagnostic technique, response to empiric therapy with PPIs is strongly suggestive of GERD and is also a predictor of patients who benefit from antireflux surgery. A recent American Gastroenterological Association position statement supports the use of diagnostic testing for esophageal reflux to (1) avoid misdiagnosis, (2) identify complications of reflux disease, and (3) evaluate empirical treatment failures.[11] Patients with atypical symptoms or who have failed medical therapy require additional testing.

Flexible endoscopy is essential in the evaluation of GERD. Endoscopic findings of a "mucosal break" or areas of slough or erythema demarcated from adjacent normal-appearing mucosa are confirmatory findings of esophagitis. Furthermore, it is mandatory to obtain mucosal biopsies to exclude malignancy. Endoscopy can also be used to grade the degree of disruption of the flap valve mechanism.[16] This is done on a retroflexed view of the GE junction. The flap valve is graded according to the Hill classification (Hill grade 1–4; 1 = normal closed valve, 4 = open valve, associated hiatus hernia).[16]

Twenty-four-hour pH monitoring is the gold standard test to evaluate reflux esophagitis. A pH probe is placed 5 cm above the manometrically determined LES. The probe records the total number of acid exposures with a pH less than 4, total acid-exposure time, upright and supine episodes, number of reflux episodes, number of episodes lasting greater than 5 minutes, and the duration of the longest episode. An overall composite score is calculated and can be

used to quantify the severity of GERD. Simpler methods to determine abnormal reflux can be used and can be calculated by finding the percent time the pH is less than 4; in normal individuals, this should be less than 4 percent.[17]

Finally, manometric testing is required particularly in patients who are being considered for surgical intervention. Esophageal manometry is performed by inserting a water-perfused catheter into the esophagus and then withdrawing the catheter as the patient swallows. Manometry gives information regarding the location, pressure, and length of the LES. Manometry also helps to assess the esophageal body and the effectiveness of peristalsis. Normally, a patient should have 80 percent successful swallows but when that number drops to 60 percent, the diagnosis of ineffective esophageal dysmotility is given.[18]

Newer techniques for esophageal functional testing such as wireless pH capsule monitoring, duodenogastroesophageal reflux (formerly referred to as alkaline or bile reflux) detection, and esophageal impedance testing have been introduced over the past decade. These techniques have been shown to have superior sensitivity and recording accuracy and provide more information to predict patients most at risk for future complications.[19]

## MEDICAL MANAGEMENT

Medical management of GERD is severity based. Most patients with mild symptoms can be treated with lifestyle modification including smoking cessation or weight loss, while others may be treated with over-the-counter antacids or $H_2$-blockers for the prevention of occasional symptoms of reflux.[15] Patients with moderate-to-severe symptoms require scheduled pharmacotherapy. Antisecretory drugs are strongly recommended for both symptomatic relief and healing of erosive esophagitis. PPIs have been shown to be superior to $H_2$-receptor antagonists and are normally 90 percent effective in treating erosive esophagitis. There is good evidence that twice-daily PPI therapy may be an effective treatment in patients who fail daily therapy. Most patients are treated for 8 to 10 weeks, and although they will heal, many will relapse in 6 to 9 months if taken off therapy (Fig. 14-3). Debate still

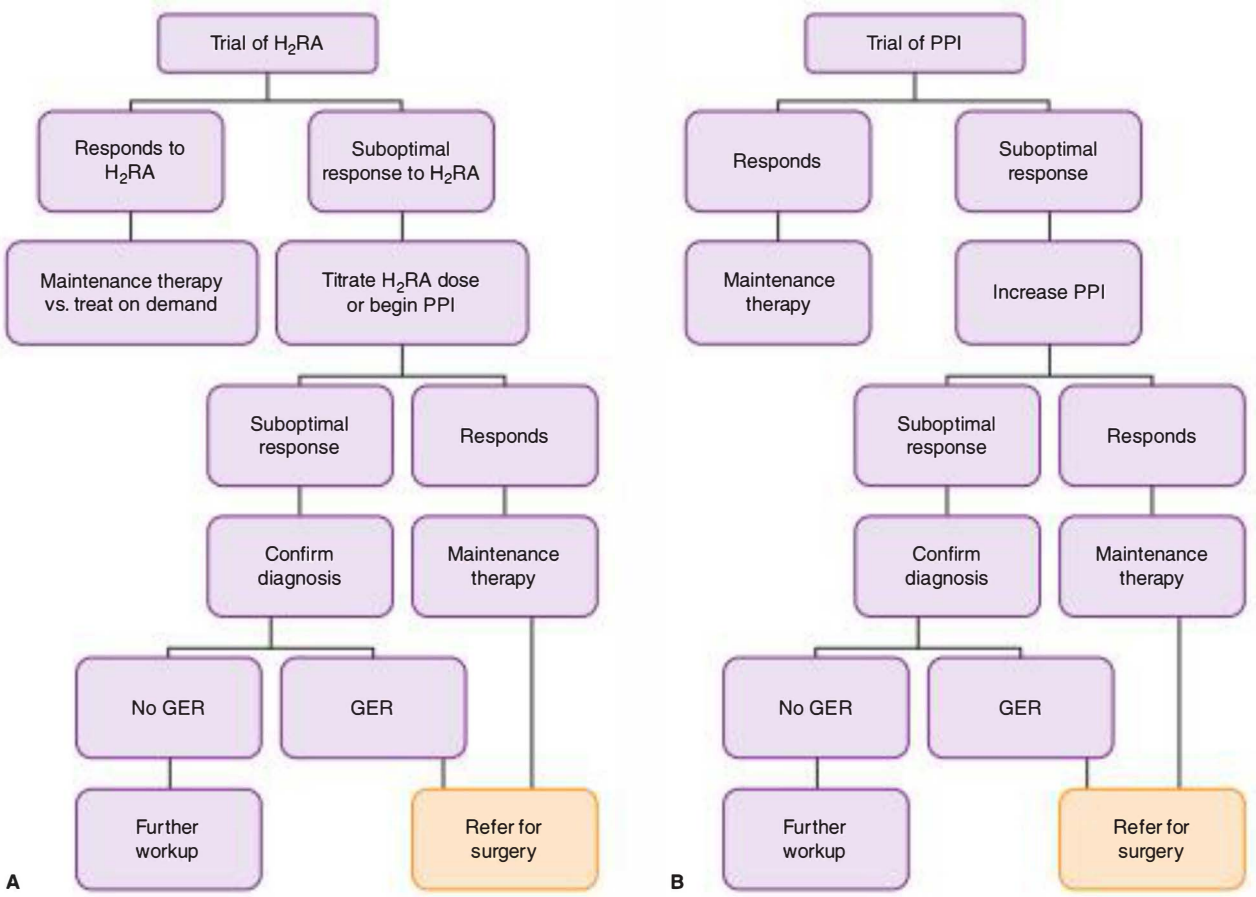

**FIGURE 14-3** Management algorithm for treatment of uncomplicated (**A**) and complicated (**B**) gastroesophageal reflux (based on endoscopic findings). $H_2$RA, $H_2$ receptor antagonist. (From Smith CD. *Surg Gastrointest Endosc Clin N Am* 2009;19(1):35–48. With permission.)

surrounds the optimal management of the patient who suffers from GERD, but it is now well accepted that surgical intervention is an alternative and possibly a superior option for many patients with reflux disease.[20]

## SURGICAL INDICATIONS

An indication for antireflux surgery is often a failure to respond to or inability to tolerate PPI therapy. The best evidence for efficacy of surgery exists for patients with severe esophagitis and/or excessive distal esophageal acid exposure when PPI therapy is held.[11] Patients who are symptomatic after 3 months of medical therapy with stricture, aspiration, or bleeding, or those who have a large hiatal hernia are candidates for an antireflux procedure. It is important to document the correct diagnosis and demonstrate the presence or absence of esophageal dysmotility. All surgical candidates should undergo manometry and pH testing.

## PRINCIPLES OF SURGERY

The goals of antireflux surgery are to reestablish the LES pressure, relocate the LES within the abdomen, and finally close any hiatal defect. The laparoscopic Nissen fundoplication has emerged as the procedure of choice in antireflux surgery. When done either open or laparoscopically, the key elements of the Nissen fundoplication include the following:

1. Complete dissection of the esophageal hiatus and both crura
2. Mobilization of the gastric fundus by division of the short gastric vessels
3. Closure of the hiatal defect by nonabsorbable sutures
4. Creation of a tensionless 360-degree gastric wrap at the distal esophagus around a 50-to-60-F bougie
5. Creation of a 1.5- to 2-cm wrap with the distal suture incorporating the anterior position of the stomach.[21]

With multiple modern trials that have now been published, there are data that show laparoscopic antireflux surgery (LARS) is more cost-effective and results in better overall symptom control than medical management.[20,22,23] Long-term data continue to accrue and suggest that laparoscopic Nissen fundoplication has become the standard for surgical treatment of GERD, with improved morbidity, length of stay, and return to work.[24] Every attempt should be made preoperatively to determine the degree of abdominal esophageal length to allow for a tension-free fundoplication. If sufficient intra-abdominal length is not available, an esophageal-lengthening procedure should be performed. Concern about esophageal motility could also influence operative strategy. Studies have shown that preoperative evidence of motility problems may or may not be associated with higher rates of dysphagia.[21] This has prompted some surgeons to choose a 270-degree fundoplication (Toupet) that other studies have validated as having a decreased incidence of reoperation for failure (usually due to dysphagia).[24]

## TECHNIQUE

### Laparoscopic Nissen Fundoplication

After intubation and decompression of the stomach with a nasal or orogastric tube, the patient is laid in a supine position. Pneumoperitoneum of 15 mm Hg is established and five trocars are placed. Exposure of the hiatus starts with deploying a fan retractor to retract the left lobe of the liver. The gastrohepatic ligament is incised, and the right crus of the diaphragm is identified. The esophagus is dissected away from the right crus of the diaphragm. The phrenoesophageal ligament is incised with care to protect the anterior vagus nerve. The dissection is carried to the left crus. We then carry the dissection into the mediastinum. Once complete, the crural and mediastinal dissection should allow for 2 to 3 cm of tension-free intra-abdominal esophagus. If the length of intra-abdominal esophagus is inadequate, an esophageal-lengthening procedure should be performed.[21] Attention is then turned to the division of the short gastric vessels and mobilization of the fundus of the stomach. The lesser sac is entered and the short gastrics are divided by a harmonic scalpel. A window is then created posterior to the esophagus while avoiding injury to the posterior vagus nerve. The fat pad is dissected off the GE junction. A 50- to 56-F bougie is then passed to allow for appropriate sizing of the fundoplication. A grasper is then passed through the posterior window, and the fundus is pulled through the window. Care should be taken to ensure that the mobilized fundus is under no tension. Both edges of the wrap can be grasped and gently "shoeshined" back and forth to check adequate length and tension. The fundus is then approximated anterior to the esophagus using full-thickness bites of nonabsorbable suture. The fundoplication length should be 1.5 to 2 cm.[25] Each stitch should incorporate partial thickness of the distal esophagus. The bougie is then removed and the crural defect is closed with heavy nonabsorbable sutures (Fig. 14-4).

### Laparoscopic Partial Fundoplication

This is generally performed for patients with concomitant GERD and esophageal motility disorders. The approach to the partial 270-degree fundoplication is essentially the same as the laparoscopic Nissen except for the extent of the posterior wrap. The wrap is secured to the left and right crura.

Transient dysphagia, due to edema, is the most common complication; it occurs in almost half of the population and resolves within 3 weeks of the operation. Wrap failure is another early complication and is attributed to a malpositioned wrap at the time of initial operation. In addition, postoperative retching and nausea has been implicated in wrap migration and should be aggressively managed during the postoperative period.[21] Additional early complications include pneumothorax and esophageal perforation. Reported rates of perforation range from 0 to 4 percent in most series.

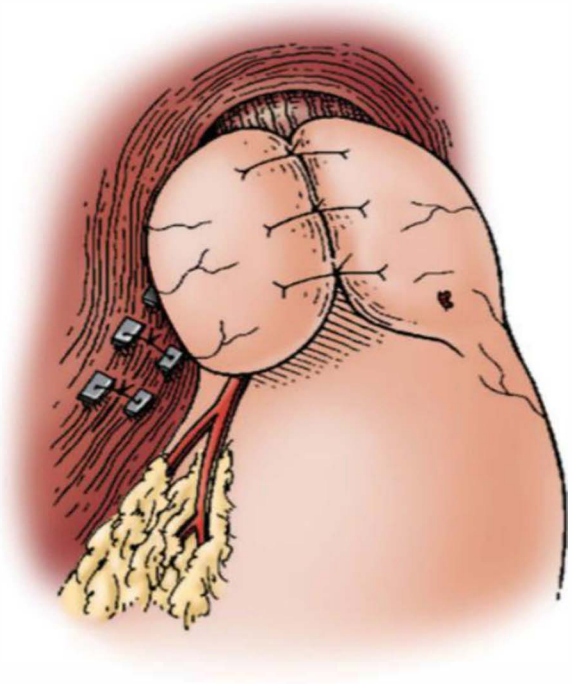

**FIGURE 14-4** Completed Nissen fundoplication. (From Smith CD. *Surg Gastrointest Endosc Clin N Am* 2009;19(1):35–48. With permission.)

## OUTCOMES

Laparoscopic Nissen fundoplication has largely supplanted open fundoplication for surgical management of GERD. The laparoscopic approach has shown equal efficacy with the open approach with respect to long-term management of GERD and is associated with shorter hospitalization, less postoperative pain, faster recovery and return to work, and lower total costs. The overall complication rate is between 5 and 10 percent and includes ileus, pneumothorax, dysphagia, gas bloat, and splenic injury. Multiple studies have reported superiority of LARS over medical management with regard to control of GERD symptoms.[20,22,23] Lundell and colleagues reported a significant rate of sustained remission in surgically treated patients compared with those treated medically. There were significantly more reflux symptoms with medical treatment; however, dysphagia was much more common after surgery.[20] Multiple studies consistently report about a 6-percent rate of severe dysphagia, and other complications include early satiety, abdominal bloating, inability to vomit, and diarrhea. Rates of reoperation reported in US studies were 2.3 to 7 percent.[26] Ultimately, between 10 and 11 percent of patients with either therapy will have recurrent esophagitis,[20] and 30 to 60 percent of patients who have undergone ARS will continue to use antisecretory medication.[27] Most importantly, all available trials to date show relative equivalence between the two therapies with regard to development of Barrett's esophagus or esophageal adenocarcinoma.[26]

## ENDOSCOPIC APPROACHES

Endoscopic treatment currently seems best suited for patients with GERD who are PPI dependent with small (<3 cm) or absent hiatal hernias and have no evidence of severe esophagitis or Barrett's esophagus. Several endoscopic antireflux procedures have been evaluated for the treatment of GERD. Injection of material to augment the LES as well as application of radiofrequency energy has been attempted but failed in the long term and is no longer available. The most promising techniques currently focus on endoluminal suturing/plication.

EndoCinch is a transoral gastroplication system performed under direct visualization. The EndoCinch is inserted through a 9-mm endoscope and a fold of tissue at the GEJ is grasped. A suture is placed through the device, and the device is then rotated, grasping more tissue and plicating the mucosa. The circumference is completed, and four separate plications are completed below the level of the GE junction. The EndoCinch (BARD, Billerica, MA) initially demonstrated efficacy but had problems with suture loss over time, and despite using more sutures, it seems as if the durability of the repair has not been greater than 12 months.[28]

The Plicator (NDO Surgical, Mansfield, MA) was designed to create a transmural full-thickness plication at the angle of His. The plication is formed with a pretied, suture-based implant. This plicating device remodels the antireflux barrier at the angle of His by fashioning a pleat of full-thickness tissue and permitting serosa-to-serosa contact. Data suggest that placement of two to three implants are needed to optimally restructure the GE junction. NDO was subsequently acquired by another company, and the Plicator is no longer available for commercial use.[28]

EsophyX (EndoGastric Solutions, Redmond, Washington) is a large overtube device with an insertion channel for a videogastroscope. The system is designed to create a 270-degree circumferential endoscopic plication at the angle of His by attaching the fundus to the anterior and left lateral wall of the distal esophagus slightly below the esophagogastric junction.[29] The method involves the placement of approximately 6 to 14 sutures to create a near circumferential gastroplication of 180 to 270 degrees.[28] The technique is known as transoral incisionless fundoplication (TIF), and it is being used more often in the United States. There are published studies with 24 months of follow-up in Europe with assessment of all outcomes in each patient showing that 79 percent of patients experienced complete cure (29 percent) or remission (50 percent) of GERD at 2 years.[29]

## ACHALASIA

Achalasia is a result of neuronal degeneration of the myenteric plexus. The consequence is an unopposed sympathetic response and increased pressure at the level of the LES, leading

to a functional obstruction of the esophagus.[30] If left untreated, the esophagus progressively dilates and becomes aperistaltic.

## Pathology

The etiology of primary achalasia is unknown, but pathologic findings show diminished myenteric ganglion, collagen deposition, and lymphocytic infiltration. Given these findings, some consider a virus to be the cause of achalasia.[30] Another theory implicates decreased levels of nitric oxide synthase, suggesting that achalasia is an autoimmune disorder rather than a viral one.[31] A common cause of secondary achalasia is Chagas disease, passed by the protozoan *Trypanosoma cruzi*. It infects the intramural neurons, resulting in autonomic dysfunction and elevated LES pressures. Finally, psuedoachalasia is another entity in which the LES is infiltrated by cancer, resulting in inadequate LES relaxation.

Achalasia is a premalignant condition. Longstanding mucosal irritation due to stagnant undigested food leads to metaplasia and finally frank carcinoma. Squamous carcinoma occurs in 2 to 8 percent of patients with longstanding achalasia.[32]

## Clinical Features

Achalasia is a disease affecting 1/10,000 people,[32] making it the second most common esophageal motility disorder. It affects men and women equally from the ages of 20 to 40 years.[33] It is a slowly progressive disease that results in a delay in presentation. The time from onset of symptoms to presentation is approximately 6 years.[34]

The most common symptom is dysphagia; initially, patients have problems with solids foods and then with liquids. In addition, 70 to 80 percent of patients complain of regurgitation of food, which can result in aspiration and chronic pulmonary symptoms. Other common symptoms include chest pain and heartburn. Heartburn can complicate the picture of achalasia and may be present in up to 48 percent of patients.[30] Invariably, these patients are misdiagnosed and treated with PPIs that are usually unsuccessful.[31]

## Diagnosis

A barium esophagogram is often the first study performed for patients with dysphagia. It is diagnostic, showing a dilated esophagus with an air-fluid level and the pathognomonic finding of a "bird's beak" with advanced achalasia (Fig. 14-5A–C). At endoscopy, a dilated esophagus with a tight LES that "pops" open with gentle pressure is seen. Other endoscopic findings include retained food and saliva, but most importantly, endoscopy rules out strictures and obstruction unrelated to achalasia. However, normal endoscopy may be present in 40 percent of patients.[31]

Esophageal manometry is the gold standard diagnostic modality. Classic manometric abnormalities can be identified including hypertensive LES (resting pressure >45 mm Hg),

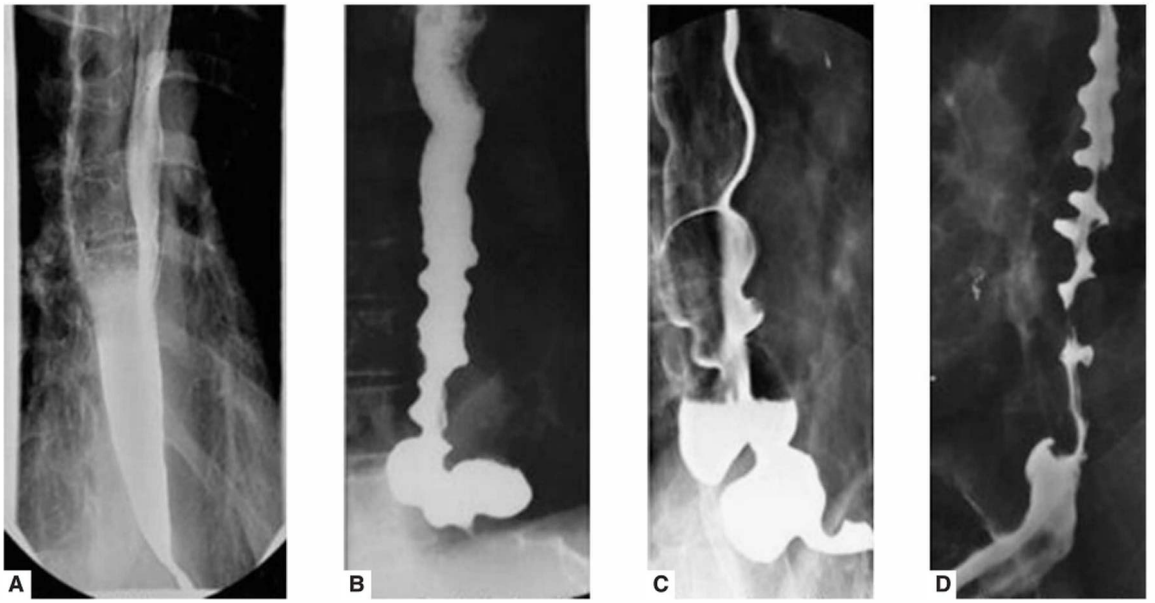

**FIGURE 14-5** Barium esophagograms of achalasia patients demonstrating the classic "bird's beak" (**A**), diffuse narrowing of the esophagus with a spastic appearance often seen in "vigorous" achalasia (**B**), a dilated and tortuous esophagus with early "sigmoidization" of the esophagus observed in long-standing achalasia accompanied by multiple pulsion diverticula (**C**), and the typical "corkscrew" appearance of the esophagus in a patient with diffuse esophageal spasm (**D**). (**A–C**: From Francis DL. Achalasia: Update on the disease and its treatment. *Am Gastroenterol Assoc* 2010;139(2):369. With permission from Elsevier. **D**: From Woltman T. Surgical management of esophageal motility disorders *J Surg Res* 2004;117(1):34–43. With permission.)

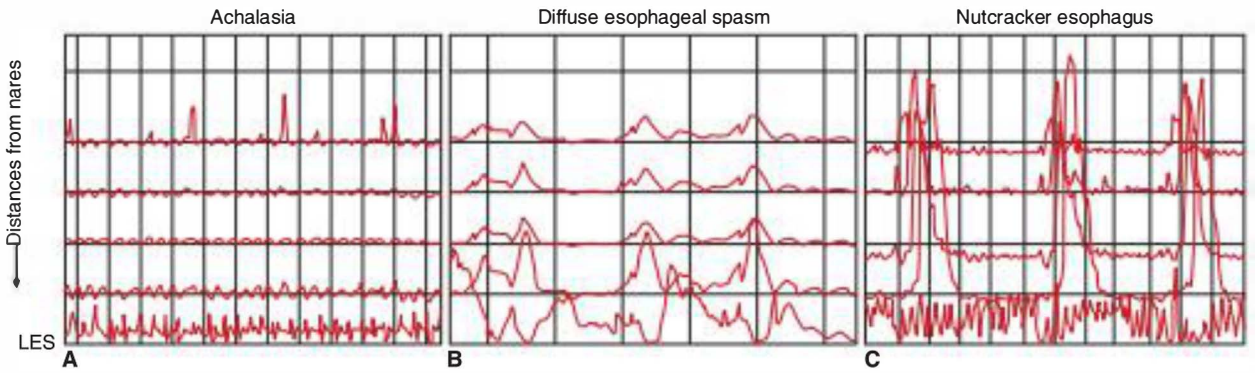

**FIGURE 14-6** Manometry tracing from a patient with achalasia. Notice the lack of peristalsis in the esophageal body and the failure of relaxation of the lower esophageal sphincter (LES) (**A**). A patient with diffuse esophageal spasm (DES), demonstrating simultaneous contractions throughout the esophagus (**B**). Tracing from a patient with nutcracker esophagus (NE) demonstrating high-altitude contractions. Contraction amplitudes measured in mm Hg at different distances from nares (cm) (**C**). (From Woltman T. Surgical management of esophageal motility disorders *J Surg Res* 2004;117(1):34–43. With permission.)

incomplete relaxation of the LES with swallowing, residual pressure > 8 mm Hg, and esophageal aperistalsis (Fig. 14-6A).[30] A variant of achalasia, vigorous achalasia, has similar findings of an aperistaltic esophagus, but with associated high-amplitude contractions (60 mm Hg). High-resolution manometry is an alternate and newer diagnostic modality that will aid in the diagnosis of achalasia (see Chapter 12). Still in its infancy, it may yield superior and reproducible results in the future.[35]

## Medical Therapy

Since the cause of achalasia is unknown, treatment is directed toward symptom relief. Medical treatment options include oral nitrates and calcium channel blockers in an attempt to facilitate LES relaxation. Therapy is usually ineffective since most patients are unable to tolerate the side effects that include headaches, hypotension, and tachyphylaxis. Therefore, medical therapy is generally reserved for patients who are not candidates for surgical intervention.[32]

Endoscopic botulinum toxin and pneumatic dilatation are alternate options. Endoscopically injected botulinum toxin blocks the release of acetylcholine, resulting in lower resting and basal LES pressures.[33] Although botulinum toxin is effective in approximately half of the patients at 6 months, the rest require multiple injections.[34,36] Repeated injections of botulinum toxin results in an inflammatory response at the LES, making later surgical intervention difficult. Most surgeons agree that botulinum toxin should be reserved for patients who are not surgical candidates.[31,33] Pneumatic dilation is another option. Dilation is aimed at fracturing the muscularis propria.[31] Pneumatic dilation carries a 2-to-7-percent risk of complication and a mortality rate of less than 1 percent.[37]

A recent Cochrane review compared pneumatic dilation with botulinum toxin and found pneumatic dilation to be a much better option. Symptom reoccurrence was reviewed at 1, 6, and 12 months. Seventy percent of patients who underwent botulinum toxin had symptom recurrence and treatment failure at 12 months versus 30 percent who underwent dilation.[38] Therefore, current data only support the use of botulinum in patients who are unfit for surgery or as a bridge to definitive therapy.

## Surgical Myotomy

Surgical myotomy is the procedure of choice in patients diagnosed with achalasia who do not have multiple medical comorbidities. The Heller myotomy was first introduced in 1913 by Ernest Heller. The original Heller myotomy was performed using both an anterior and a posterior longitudinal myotomy, disrupting the LES. More recently, the procedure has been modified and is limited to an anterior longitudinal myotomy.

After port placement, the laparoscopic Heller myotomy is performed by exposing the hiatus by placing gentle inferior and lateral retraction on the stomach. The phrenoesophageal fat pad is excised and the hiatus is exposed. The myotomy is then performed by splitting the muscular fibers of the LES, and exposing the bulging mucosa. Care is taken not to perforate the mucosa. Once the myotomy is created, it is carried proximally 5 to 6 cm and distally on to the stomach by 2 cm. Mucosal integrity is then checked by endoscopic insufflation. A Dor fundoplication (270-degree wrap) is added to control for postoperative reflux.[32]

Nearly 50 percent of patients develop GERD after a Heller myotomy.[32] Currently, most esophageal surgeons perform a partial wrap (Fig. 14-7) to control the symptoms of reflux. There is some debate regarding the type of wrap but a recent study showed that the Dor fundoplication is associated with good control of reflux symptoms and less dysphagia than a Nissen.[33,39]

## Outcomes

Several studies have demonstrated superiority of laparoscopic Heller myotomy when compared with botulinum toxin injection and pneumatic dilation. Myotomy provides long-term relief of dysphagia, chest pain, and regurgitation.

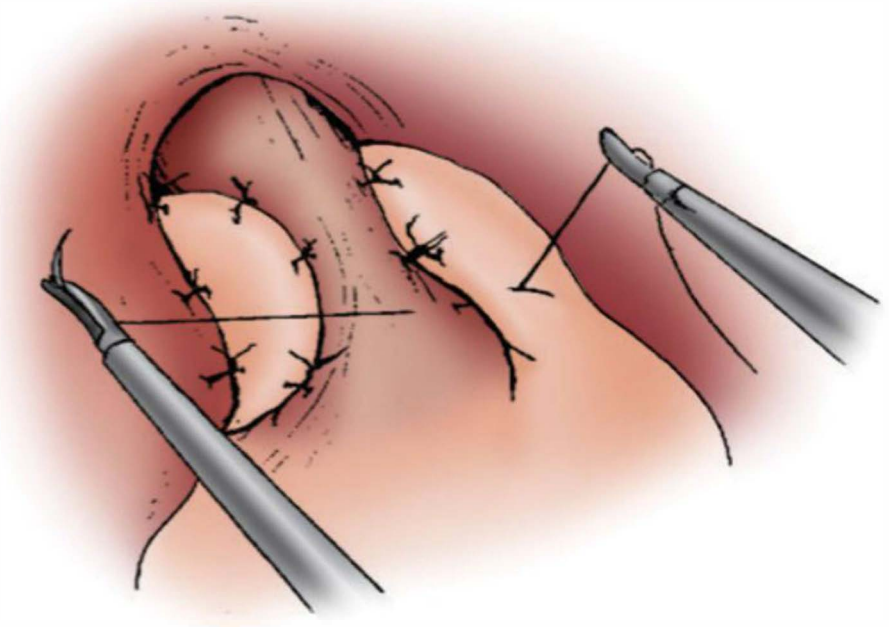

**FIGURE 14-7** Completed Toupet partial fundoplication. (From Smith CD. *Surg Gastrointest Endosc Clin N Am* 2009;19(1):35–48. With permission.)

Several authors believe that surgical myotomy should be the primary therapy for all patients who have achalasia.[30,31] Most recent series show excellent long-term relief of symptoms at 2 years. A study by Portale et al. reported on 113 patients who underwent Heller myotomy. They showed relief of symptoms at 2 years and greater than 90 percent probability of patients remaining asymptomatic at 5 years.[40,41]

## DIFFUSE ESOPHAGEAL SPASM

Diffuse esophageal spasm (DES) is a motility disorder of unknown etiology. It occurs in 3 to 5 percent of patients with esophageal motility disorders.[42] DES is characterized by simultaneous high-amplitude contractions associated with severe chest pain or dysphagia. There is no optimal treatment option for these patients, and the goal of therapy is to relieve symptoms and improve quality of life.

### Clinical Features and Workup

DES usually presents with severe chest pain. After cardiac causes have been ruled out, history reveals dysphagia or chronic pulmonary symptoms due to aspiration. Discerning the diagnosis may be difficult in this patient population, because up to 50 percent can have GERD. Similar to achalasia, DES patients should undergo endoscopy, esophagogram, and manometry. Esophagogram shows the classic appearance of the "corkscrew" esophagus (Fig. 14-5D). Manometry is the gold standard. DES is defined as simultaneous contractions in greater than 20 percent of wet swallows.[18] Manometry may also show long-duration contractions, high-amplitude waves, and spontaneous contractions not associated with swallows (Fig. 14-6B).

### Treatment

Since DES is rare, there is no clear treatment. Both medical and surgical options are available but without any evidence of their efficacy. Medical therapy includes smooth muscle relaxants including nitrates and calcium channel blockers. But many times these medical therapies are ineffective. There is some evidence for the use of antipsychotic and benzodiazepines, but there are no data supporting their use.[18]

Surgical options for DES include the creation of a long esophageal myotomy. A long esophageal myotomy is performed through a left thoracotomy or thoracoscopically.[43,44] Once access is gained, the esophagus is mobilized from the level of the aortic arch to the hiatus. A longitudinal incision is made, dividing the hypertrophied muscle from the arch to the hiatus. If the patient has evidence of a hypertensive LES, the myotomy is extended along the gastric wall, and a fundoplication is added to control reflux.[45]

Surgical outcomes for the long esophageal myotomy are good. A review of the surgical management of DES showed a decrease in symptoms from 50 to 86 percent, with no mortality and a low reintervention rate.[44] A more recent study looking at long esophageal myotomy in 20 patients found excellent outcomes; 90 percent had no dysphagia, and

100 percent were chest-pain free.[46] Overall, the outcomes are good, but the data are limited. Currently, there are no guidelines, but when patients have had failure of medical management, surgical options should be considered.

## NUTCRACKER ESOPHAGUS

Nutcracker esophagus was first described in 1978. As with DES, patients experience crushing chest pain and dysphagia. Esophagogram and endoscopy are usually normal in these patients. Manometry demonstrates high-amplitude contractions, greater than 180 mm Hg that may last up to 6 seconds.[18] Other manometric findings may include elevated LES pressures with normal relaxation and normal peristalsis (Fig. 14-6C). Treatment options for nutcracker esophagus are similar to DES, including pharmacotherapy and surgical intervention for patients who are refractory to medical management.

## ESOPHAGEAL DIVERTICULA

Esophageal diverticula are mucosal outpouchings of the esophagus. Diverticula are described on the basis of location and wall thickness. The majority of esophageal diverticula are acquired and develop secondary to esophageal motility disorders.[47] There are three types of diverticula based on location: Zenker's diverticulum located at the level of the cricopharyngeus, peribronchial diverticulum, and epiphrenic diverticulum. Of the three, Zenker's and epiphrenic diverticulum are pulsion diverticula that arise in areas of elevated intraesophageal pressures. The peribronchial diverticulum is a traction diverticulum, rarely seen today. Goals of treatment include restoration of normal motility and improvement of symptoms.

### Zenker's Diverticulum

#### PATHOPHYSIOLOGY

Zenker's diverticulum is located proximal to the UES on the posterior wall. The UES is composed of the inferior pharyngeal constrictors and the cricopharyngeus, the sling-like muscle completing the circumference of the cricoid cartilage.[48] There is an inherent area of weakness between these two muscles, allowing mucosa to protrude in response to elevated UES pressures and uncoordinated contraction of the pharynx and upper cervical esophagus.[49]

The physiologic function of the UES is based on the cricopharyngeus. It is composed of striated muscle and remains under tonic contraction due to vagal innervation. Inability of the cricopharyngeus to relax in response to a bolus of food results in elevated pressures. It is not clear why the cricopharyngeus fails, but pathologic examination of the cricopharyngeus has shown muscle fiber degeneration, necrosis, and fibroadipose tissue deposition.[50] These changes may lead to decreased elasticity of the muscle and restricted opening.

#### CLINICAL FEATURES

Zenker's occurs most commonly in the seventh and eighth decades of life. Prevalence is less than 1 percent in the general population.[49] Symptoms of a cricopharyngeal diverticulum include dysphagia and halitosis due to undigested food in the diverticulum. Other symptoms may include chronic cough, aspiration, and weight loss secondary to worsening dysphagia. The most striking clinical feature in patients with an enlarged diverticulum may be cervical borborygmi[49] or a gurgling noise when swallowing. If left untreated, there is a small risk of malignant degeneration of these pouches.[51]

#### DIAGNOSIS

As in all esophageal motility disorders, CXR, esophagogram, and endoscopy are required not only for diagnosis but to rule out additional pathology. The CXR for large diverticulum can be impressive. Air–fluid levels are seen on the lateral views within the pouch. Esophagogram is diagnostic, showing a large outpouching in the cervical esophagus.

#### TREATMENT

Treatment is indicated in all patients who have symptoms. Since most of these patients are elderly, comorbidities are the limiting factor in repair. Options for treatment include open myotomy, with or without resection of the diverticulum, diverticulopexy, and endoscopic treatment.

The traditional Zenker's repair is performed through the left neck. The proximal esophagus is identified medial and posterior to the anterior border of the sternocleidomastoid. The diverticulum is dissected to the base. The myotomy is performed in both directions, beginning at the base of the diverticulum. For smaller diverticula, it may be possible to leave the diverticulum in place, but for larger diverticula, diverticulectomy is preferred.[45] Other options include a diverticulopexy, in which the mouth of the diverticulum is tacked in a dependent fashion so that it drains and does not accumulate secretions.

Endoscopic treatment of a Zenker's diverticula is an alternative to the open approach. Under general anesthesia, a rigid endoscope is inserted. The septum and cricopharyngeal mask between the esophageal lumen and the Zenker's is identified. A cutting stapler is fired, transecting the septum and cricopharyngeal mask, creating a common channel between the two.[45] Current data suggest that endoscopic therapy of Zenker's results in improvement of symptoms with low complication rates.[49]

### Midesophageal Diverticula

Midesophageal diverticula are rare. Known as a traction diverticulum, periesophageal inflammation such as granulomatous disease results in full-thickness outpouching of the midesophagus. Patients occasionally present with symptoms of dysphagia and retrosternal chest pain. Barium esophagogram confirms the diagnosis of a small wide-mouthed

diverticulum. Excision of a traction diverticulum is rarely indicated since they are not symptomatic, and surgery is reserved for larger diverticulum.[52]

## Epiphrenic Diverticulum

Epiphrenic diverticula are mucosal outpouchings that occur within 10 cm of the distal esophagus.[53] These are pulsion diverticula that develop secondary to increased intraesophageal pressure usually associated with motility disorders.[54] Dysphagia, regurgitation, and heartburn are all common symptoms. Esophagography, endoscopy, and manometry identify the diverticulum as well as the underlying motility disorder. Seventy to one hundred percent of patients have an underlying motility disorder despite normal manometry.[47,54] In spite of normal manometry, a myotomy is still indicated.[53]

Treatment goals for epiphrenic diverticula are threefold: resection of the diverticulum, a long esophagomyotomy for treatment of the underlying motility disorder, and an antireflux procedure for the incompetent LES. Approaches include right or left thoracotomy and minimally invasive procedures. When comparing the approaches, open techniques have lower leak rates and similar morbidity to minimally invasive approaches. Most centers currently advocate an open approach and minimally invasive surgery in centers with experience.[54]

## Benign Esophageal Strictures

Benign esophageal strictures are a common cause of dysphagia in patients. The most common cause is peptic stricture and accounts for 60 to 70 percent of cases.[55] Other etiologies include Schatzki rings, caustic ingestion, radiation therapy, or anastomotic strictures. Strictures can be classified according to their complexity. Most simple strictures are short, focal, and straight and allow a normal endoscope to pass easily; others are more complex. Long (>2 cm), angulated, or severely narrowed strictures are termed complex strictures.[55] Although simple strictures are amenable to one to three dilations, complex strictures are more difficult to treat.[56]

## Treatment

Treatment is directed toward relief of dysphagia. Options include dilation, medical therapy, stenting, and in refractory cases, surgery (Fig. 14-8). Dilators vary; mechanical dilators such as the

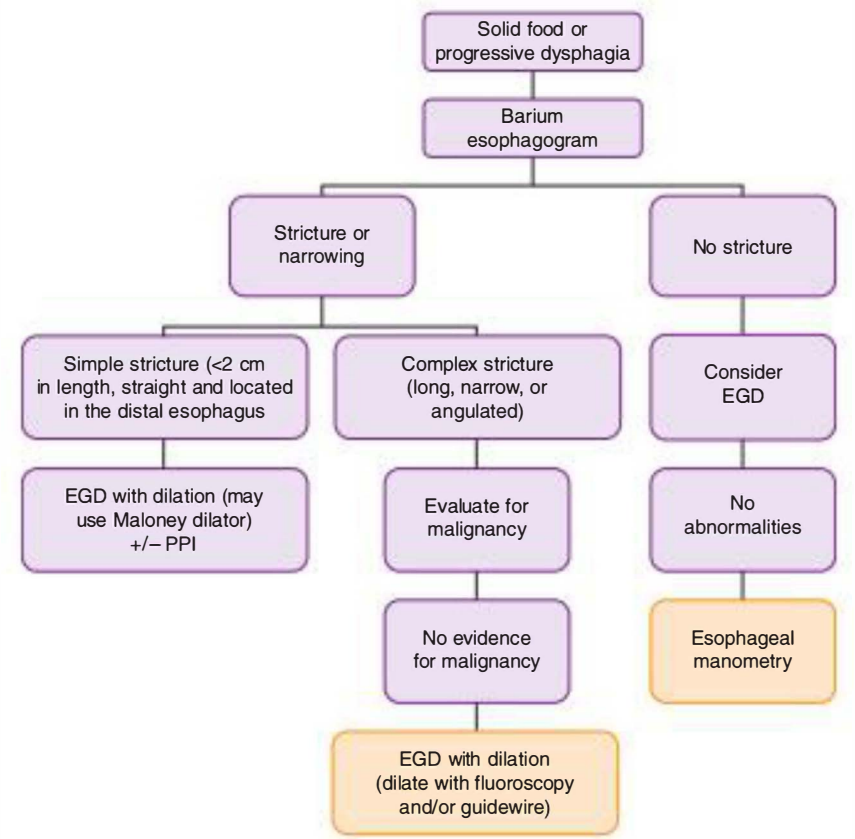

**FIGURE 14-8** Management algorithm for benign esophageal stricture. (From Ferguson DD. Evaluation and management of benign esophageal strictures. *Dis Esophagus* 2005;18(6):359–364. With permission.)

Maloney or Savary dilator can be passed without the use of a guidewire. In comparison, balloon dilators are passed over a wire and are insufflated under direct vision. Complications include perforation, hemorrhage, and bacteremia.[56] To minimize the risk of complications, the "rule of three"[57] should be applied. Dilators should be passed no more than three times through the stricture, and the diameter of the esophagus should not be increased by any more than 2 to 3 mm.[57] Overall, dilation of benign esophageal strictures is safe with minimal morbidity, but outcomes are variable and may require further treatment.

## GASTROESOPHAGEAL REFLUX DISEASE AND ESOPHAGEAL MOTILITY DISORDERS BOARD REVIEW QUESTIONS (CHAPTER 14)

1. Which is correct regarding manometry for the diagnosis of achalasia?
   A. Normal peristalsis, with contraction amplitude >2 standard deviations above normal and greater than 180 mm Hg in distal esophagus with contractions greater than 6 seconds.
   B. Hypertensive LES with resting pressure >45 mm Hg, incomplete relaxation of the LES with swallowing, residual pressure of >8 mm Hg, and esophageal aperistalsis.
   C. Simultaneous contractions in greater than 20 percent of wet swallows and occasionally long-duration contractions, high-amplitude waves, and spontaneous contractions not associated with swallows.
   D. Hypertensive LES with resting pressure >45 mm Hg, incomplete relaxation of the LES with swallowing, residual pressure of >8 mm Hg, and esophageal peristalsis.
   E. Hypotensive LES, absence of LES relaxation with swallowing, and residual pressure >15 mm Hg.

2. A 60-year-old woman presents to your office with long-standing dysphagia. She has complaints of difficulty swallowing solids and occasionally liquids. A barium esophagogram is performed and is consistent with her diagnosis. What would be the expected findings on endoscopy?
   A. Normal esophageal mucosa
   B. Tongues of red mucosa, projecting proximally along the mucosal surface
   C. Retained food and saliva with esophagitis secondary to stasis
   D. Edematous, friable walls which are easily perforated
   E. Stricture at the upper esophageal sphincter

3. All of the below are implicated in LES dysfunction except:
   A. Recumbent position
   B. Intra-abdominal length of the LES
   C. Dilation of the diaphragmatic crus secondary to a hiatal hernia
   D. Esophageal motility
   E. Gastric distension

4. Which of the following is not an indication for surgery in GERD?
   A. Failure to respond to or inability to tolerate PPI therapy
   B. Patients who are symptomatic after 3 months of medical therapy
   C. A large hiatal hernia
   D. Barrett's with high-grade dysplasia
   E. Severe esophagitis

5. Laparoscopic Nissen fundoplication is associated with the following except:
   A. Shorter hospital stay
   B. Improved control of reflux symptoms and dysphagia
   C. More rapid return to work
   D. Less postoperative pain
   E. Lower total cost

## ANSWERS

1. **Answer: B.** Characteristic findings of achalasia on manometry are a hypertensive LES with resting pressure >45 mm Hg, incomplete relaxation of the LES with swallowing, residual pressure of >8 mm Hg, and esophageal aperistalsis.
2. **Answer: C.** This patient has poor esophageal function and the anticipated endoscopic findings would be stasis with subsequent retained food and saliva, and underlying esophagitis.
3. **Answer: A.** The recumbent position is not associated with LES dysfunction. A shortened intra-abdominal length of the LES, dilation of the diaphragmatic crus, decreased esophageal motility, and gastric distension are all associated with LES dysfunction.
4. **Answer: D.** The presence of Barrett's disease alone is not an indication for surgical intervention. Failure to respond to PPI therapy, continued symptoms on adequate medical therapy, a large hiatal hernia, and severe esophagitis are indications for surgery.
5. **Answer: B.** Laparoscopic Nissen fundoplication has equivalent control of reflux symptoms and dysphagia compared to open Nissen fundoplication. The laparoscopic approach is associated with shorter hospitalization, lower cost, more rapid return to work, and less postoperative pain.

**KEY CONCEPTS**

- Epidemiology
  - Iatrogenic instrumentation (e.g., endoscopy, dilatation, tube passage, etc.) has replaced spontaneous rupture as the leading cause of esophageal perforation and accounts for 60 to 75 percent of esophageal injuries.
- Pathophysiology
  - Esophageal perforation results in leakage of esophageal and gastric contents into the mediastinum, producing a chemical burn and superinfection. Left untreated, this leads to a severe inflammatory response and sepsis.
  - Esophageal perforations are broadly divided into intraluminal and extraluminal types. Intraluminal injuries are caused by instrumentation, foreign bodies, caustic ingestion, esophagitis, carcinoma, infection, or barotrauma. Extraluminal causes include stab or gunshot wounds, blunt trauma, and operative injuries.
- Clinical features
  - Patients sustaining a cervical esophageal perforation typically present with cervical pain, odynophagia, subcutaneous emphysema, and neck tenderness and crepitus. Dysphagia, pain, tachycardia, and fever usually occur shortly after iatrogenic perforation. Intra-abdominal esophageal perforation usually presents with peritonitis. Late manifestations of untreated perforations often include hypoxia, sepsis, and shock.
- Diagnostics
  - An antecedent history of instrumentation or vomiting often points to the etiology and possibility of esophageal perforation. Plain chest radiography may show pneumomediastinum, subcutaneous emphysema, or subdiaphragmatic air. Diagnosis is usually confirmed with esophagography, which demonstrates a leak in 50 to 60 percent of cervical and 80 to 90 percent of thoracic esophageal perforations. Esophagoscopy and computed tomography are other diagnostic modalities used in selected circumstances.
- Treatment
  - The initial management of patients presenting with esophageal perforations includes cessation of oral intake, fluid resuscitation, and broad-spectrum antibiotics. Definitive treatment of perforations is divided into nonoperative and operative management. Nonoperative management may be undertaken in selected patients with limited perforations that drain back into the esophagus and are not associated with distal obstruction, communication with the abdominal cavity, or systemic sepsis. Operative treatment is predicated on adequate debridement, reinforced primary repair, wide drainage, and distal feeding tube placement. In the absence of underlying esophageal disease, there is a trend toward primary reinforced repair, regardless of the perforation's duration. Underlying esophageal disease is best addressed before or at the time of perforation repair.
- Outcomes
  - Esophageal perforation has an associated mortality rate of 20 percent.

## INTRODUCTION

Esophageal perforation was first described in 1724 by the Dutch physician Hermann Boerhaave, who published the presentation, clinical course, and autopsy findings of spontaneous rupture of the esophagus in his patient Lord van Wassenaer, High Admiral of the Dutch Navy. In this seminal work, he described the clinicopathologic correlation between esophageal perforation and a fatal outcome, one that remained inevitable for over 200 years. Despite modern surgical techniques, perforation of the esophagus still represents a true surgical emergency. In the mid-20th century, successful primary repair of esophageal perforation was first reported by Barrett in 1946 and later by Olsen and Claggett in 1947, and esophagectomy for esophageal perforation was described by Satinski and Kron in 1952, all of which led the

way to the modern treatment of these injuries.[1-4] Although spontaneous esophageal rupture is uncommon today, the dramatic increase in the use of invasive procedures for the diagnosis and treatment of gastrointestinal diseases has resulted in a significant increase in the incidence of esophageal perforation.

## PATHOPHYSIOLOGY

The esophagus is prone to rupture by various mechanisms due to the lack of an enveloping serosal layer. As a consequence of its location, perforation of the esophagus can rapidly develop into a fatal disease process unless a prompt diagnosis is made and proper treatment is initiated immediately. Following perforation, the negative intrathoracic pressure pulls esophageal and gastric contents into the mediastinum. Oral bacteria present in saliva as well as digestive enzymes, acidic gastric secretions, and bile produce a chemical burn that can lead to a necrotizing superinfection of adjacent mediastinal and upper abdominal organs. This combination of insults leads to a severe local inflammatory response and if left untreated, eventually develops into systemic sepsis.

## CLINICAL FEATURES

### Epidemiology

The incidence of esophageal perforation in the United States is estimated to be 3 per 100,000 people.[5] The most common location for perforation is in the intrathoracic esophagus (54 percent), followed by the cervical esophagus (27 percent) and intra-abdominal esophagus (19 percent).[5] A recently published analysis of modern series of over 500 patients with esophageal perforations identified iatrogenic injuries as the most common cause of esophageal perforation (59 percent), followed by spontaneous perforation (15 percent), ingestion of foreign bodies (12 percent), trauma (9 percent), operative injuries (2 percent), malignancy (1 percent), and other causes (2 percent).[6] A relationship between cause and location exists (Fig. 15-1).

### Etiology

Perforation of the esophagus can be divided into intraluminal or extraluminal causes.

#### INTRALUMINAL CAUSES

***Instrumental Injuries.*** Iatrogenic perforations account for the majority of esophageal perforations and can occur during routine diagnostic endoscopy, therapeutic dilatation, stent placement, enteral tube passage, or endoscopic ultrasound or echocardiography. The actual risk of perforation during routine endoscopy alone is quite low and is estimated to be 0.11 percent with traditional rigid esophagoscopes and even lower (0.03 percent) with modern flexible endoscopes.[6] Nevertheless, the risk of perforation increases considerably with therapeutic intervention and ranges from 0.3 percent after balloon dilatation to 25 percent after palliative stent placement for malignancy.[7,8] In the absence of a diseased esophagus, iatrogenic injuries occur most commonly in Killian's triangle, which is formed by the inferior pharyngeal constrictor and the cricopharyngeus muscles, but perforation of the esophagus also occurs at areas of normal anatomic narrowing, such as the distal esophagus just proximal to the gastroesophageal junction and the impingement of the aortic arch and left mainstem bronchus.[9]

***Foreign Bodies.*** Nearly all objects (80–90 percent), especially those less than 2 cm in size, will typically be able to

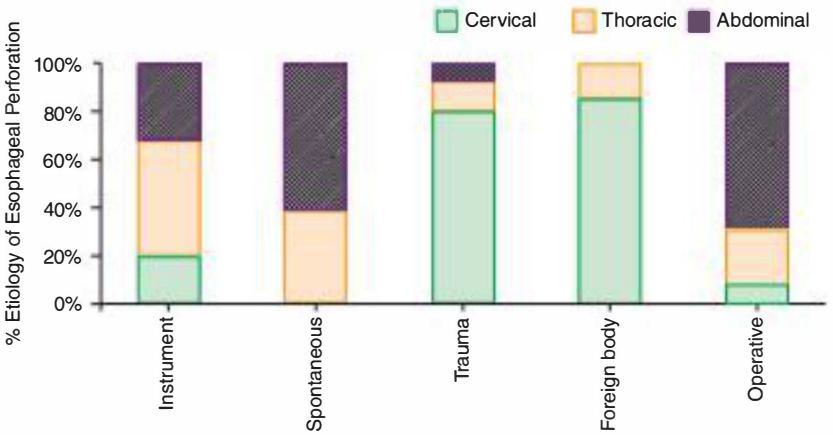

**FIGURE 15-1** Relationship of cause with anatomic location of esophageal perforation. (Adapted with permission from Brinster et al. Evolving options in the management of esophageal perforation. *Ann Thorac Surg* 2004;77:1475–1483. Copyright Elsevier.)

pass through a nonpathologic esophagus and the remainder of the gastrointestinal tract without difficulties.[10,11] Objects with sharper edges (e.g., chicken or fish bones, nails, razor blades, safety pins, etc.), or those of larger size (e.g., coins) can, however, cause acute perforation in areas of anatomic esophageal narrowing. This occurrence is more common in children and those with concomitant psychiatric illness, and is often associated with a delay in diagnosis that can lead to the development of mediastinal abscess or empyema.

***Chemically Induced Perforation.*** Prior to the widespread availability of proton pump inhibitors, reflux esophagitis with esophageal ulcer was a relatively common cause of esophageal perforation. Currently, reflux disease alone rarely leads to perforation of the esophagus. Today, ingestion of caustic alkaline or acidic materials is the most common form of chemical injury and often occurs intentionally by suicidal adults or accidentally by young children. Severity of injury is dependent on both the type and the concentration of the caustic agent as well as the length of time in contact with the esophageal mucosa.[12] Severe chemical insults resulting in perforation typically occur several days after ingestion, following necrosis and as the injured esophagus attempts repair of the damage from the offending agent.[13] Chemical damage with subsequent perforation following the retention of pills in the esophagus and delayed entry into the stomach has been reported for various pharmaceutical agents such as aspirin/NSAIDs, bisphosphonates, and antibiotics/antivirals.[14]

***Esophageal Carcinoma.*** Perforation in patients with esophageal cancer is typically secondary to instrumentation, but can also occur spontaneously with locally advanced tumors. The prognosis of these patients is grim and mortality from this condition approaches 50 percent.[15]

***Infection.*** Severe esophageal infections with human immunodeficiency virus (HIV), herpes simplex virus (HSV), cytomegalovirus (CMV) *Candida* species, and tuberculosis, typically in immunocompromised patients, all have been reported to cause esophageal perforation.[16]

***Spontaneous Perforation (Boerhaave Syndrome and Barotraumas).*** Perforation of the esophagus may be related to a rapid increase in intraluminal pressure (e.g., emesis, coughing, weight lifting, seizures). If the upper esophageal sphincter fails to relax, the increase in intra-abdominal pressure may lead to a tremendous pressure rise within the esophagus, resulting in perforation. When the perforation due to a rise in intra-abdominal pressure is postemetic in nature, the condition is known as Boerhaave syndrome and typically occurs in the distal third of the esophagus on the left.[17]

### EXTRALUMINAL CAUSES

***Traumatic Injuries.*** Esophageal perforation from penetrating thoracic trauma typically involves the cervical esophagus and is rarely fatal by itself.[18] Esophageal perforation secondary to blunt trauma is rare, but can occur secondary to compression of the esophagus between the sternum and spine in motor vehicle accident.[19]

***Operative Injuries.*** Perforation of the esophagus has been reported with pulmonary resections, atrial operations, thoracic aortic aneurysm repair, mediastinoscopy, operations on the anterior cervical spine, laparoscopic fundoplication or myotomy procedures, and even thyroid surgery.[6]

## CLINICAL PRESENTATION

The diagnosis of esophageal perforation may be suspected from the patient's clinical history as often an antecedent episode of vomiting, or recent instrumentation can be elicited from patients with esophageal perforation. The clinical presentation of esophageal perforation depends on three factors: location, degree of containment, and time elapsed since injury. The differential diagnosis includes myocardial infarction, peptic ulcer disease, pancreatitis, aortic dissection, spontaneous pneumothorax, and pneumonia.

Physical examination findings may include fever, tachycardia, hypotension, tachypnea, and other end-organ manifestations of sepsis. Local tenderness is associated with an upper esophageal perforation and peritonitis with an abdominal esophageal perforation. There may be crepitus present. Among patients with esophageal injuries, pain is the most frequently reported symptom (71 percent), followed by fever (51 percent), dyspnea (24 percent), and crepitus (22 percent).[20] The classical association of vomiting, lower chest pain, and subcutaneous emphysema (Mackler triad) is only found in half of the patients with esophageal perforation.[21]

Cervical perforation typically presents with cervical pain, odynophagia, and subcutaneous emphysema with neck tenderness and crepitus on palpation. Iatrogenic perforation usually presents shortly after the procedure, with dysphagia, pain, tachycardia, and fever. If left untreated, this progresses to hypoxia, sepsis, and shock. Spontaneous esophageal rupture or Boerhaave syndrome occurs more commonly outside the hospital setting. The typical patient is an elderly male with a history of recent emesis. These patients tend to present late and have a worse prognosis. Intra-abdominal perforations usually present with abdominal tenderness or frank peritonitis and rapidly deteriorate into septic shock.

## DIAGNOSTIC MODALITIES

Evidence of esophageal perforation is present on 90 percent of plain-film radiographs, and findings include pneumomediastinum, subcutaneous emphysema, hydrothorax, pneumothorax, or hydropneumothorax, and subdiaphragmatic air.[22] These findings may not be present early after injury.

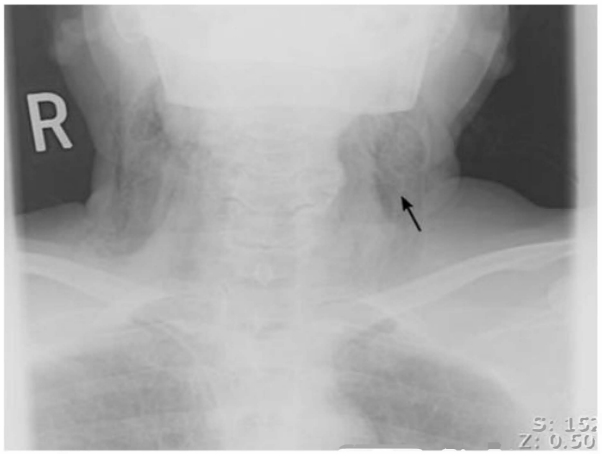

FIGURE 15-2 Anteroposterior view of neck radiograph. The arrow points to subcutaneous air.

The diagnosis is usually confirmed with an esophagogram with water-soluble (e.g., Gastrografin) contrast, which will demonstrate the leak in 50 percent of cervical and 75 to 80 percent of thoracic perforations (Figs. 15-2 to 15-4).[23] If there is no demonstration of extravasation of water-soluble contrast and the suspicion of esophageal perforation remains high, an esophagram with thin barium contrast should be performed as nearly one-quarter of patients with a negative Gastrografin esophagram are found to have a positive barium swallow study.[5] Barium has been shown to be able to detect up to 60 percent of cervical and up to 90 percent of intrathoracic esophageal perforations.[6] Such studies should be performed with the patient in the right lateral decubitus position so as to avoid rapid transit of contrast into the stomach, in which case a small leak may be missed. Esophagrams may have to be repeated in the face of negative Gastrografin and barium studies if the diagnosis of esophageal perforation remains likely.

FIGURE 15-3 Lateral view of Gastrografin contrast study. The arrow points to contrast extravasation in the midesophagus.

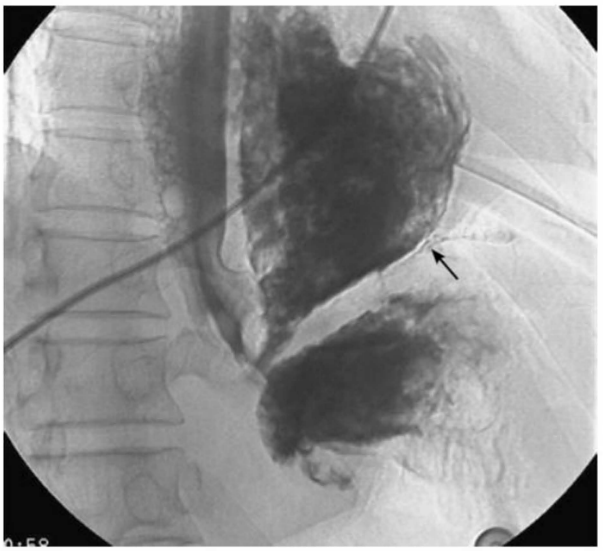

FIGURE 15-4 Lateral view of Gastrografin contrast study. The arrow points to contrast extravasation in the distal esophagus at the gastroesophageal junction.

Esophagoscopy without insufflation is the diagnostic option in unstable or mechanically ventilated patients and has a sensitivity of 100 percent and specificity of 83 percent for detecting perforation.[24] Any discoloration or submucosal hematoma on upper endoscopy should be considered highly suspicious for perforation.

Computed tomography (CT) of the chest and abdomen is useful in selected patients when esophagography is unavailable or the findings from such studies are nondiagnostic. CT is particularly useful after the perforation has sealed and may help direct percutaneous, catheter-based drainage of any fluid collections. Abnormalities on chest CT may include mediastinal free air, esophageal thickening, or an air–fluid level adjacent to the esophagus, representing a mediastinal abscess cavity.[25,26]

## THERAPY

The overriding consideration in the treatment of esophageal perforation is the status of the native (preperforation) esophagus and, in particular, the presence of cancer, achalasia, or

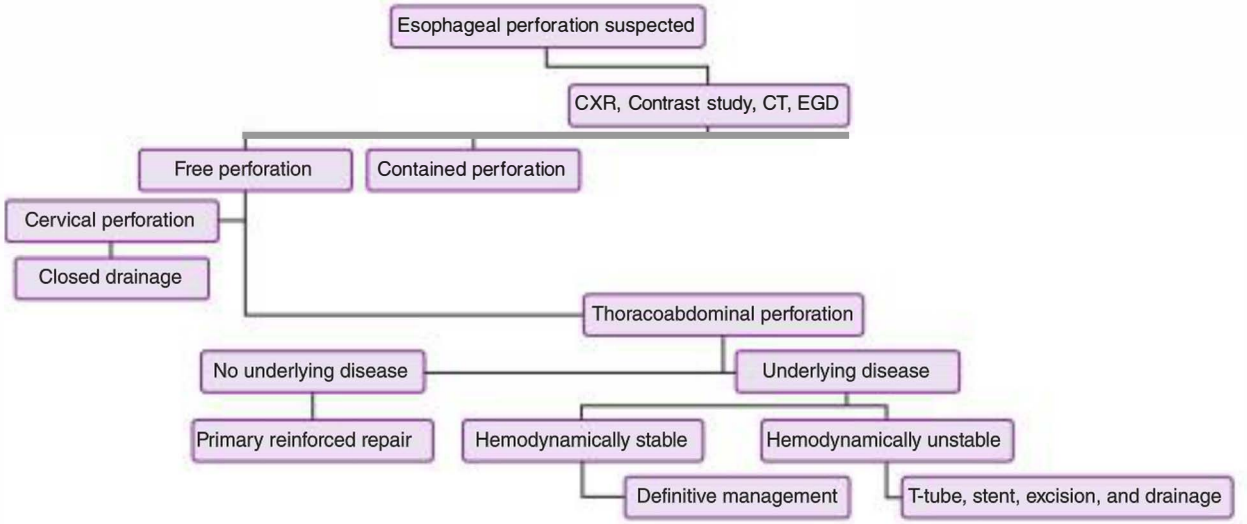

**FIGURE 15-5** Decision-making flowchart. An algorithm outlining the current management of esophageal perforation.

stricture.[27] Other considerations include contained versus free leak, the patient's clinical status, time since perforation, and location of the perforation. The treatment principles are based on (1) debridement of necrotic tissues to control infection and prevent continued soilage, (2) elimination of any distal esophageal obstruction, (3) secure closure of the perforation with appropriate drainage, and (4) establishment of enteral access. Treatment options are operative and nonoperative, and an algorithm outlining the current management of esophageal perforation is shown in the decision-making flowchart (Fig. 15-5).

## Nonoperative Management

In 1979, Cameron published the criteria for nonoperative management of esophageal perforation with a delay in diagnosis, which were updated by Altorjay in 1997.[28,29] These criteria include (1) intraluminal dissection, (2) transmural perforation that drains back into the esophagus, (3) no associated obstruction in the distal esophagus, (4) no perforation within the abdominal cavity, and (5) no evidence of systemic sepsis. More recently, Abbas et al. created an esophageal perforation severity score based on clinical data at the time of presentation (Fig. 15-6).[30] Up to 18 points are given as follows: 1 point each for age >75 years, tachycardia >100 beats per minute, leukocytosis >10,000 WBC/mL, or pleural effusion, 2 points each for fever >38.5°C, noncontained leak, or respiratory compromise (tachypnea >30 beats per minute or mechanical ventilation), time to diagnosis >24 hours, and 3 points each for cancer or hypotension, for a total of 18 points. A retrospective analysis of 119 patients using this scoring system revealed a correlation between morbidity and mortality and esophageal perforation severity scores. Those patients with lower severity scores had shorter hospital stays, fewer complications, and lower mortality, and those patients successfully treated with nonoperative management had lower clinical score than those who underwent operative intervention.[30]

**Esophageal perforation severity score**

| Variable | Score (range 1–3) |
|---|---|
| Age >75 years | 1 |
| Tachycardia >100 beats/min | 1 |
| Leukocytosis >10,000 WBC/ml | 1 |
| Pleural effusion (on CXR or CT) | 1 |
| Fever >38.5°C | 2 |
| Noncontained leak (on CT or barium swallow) | 2 |
| Respiratory compromise (respiratory rate >30, mechanical ventialtion) | 2 |
| Time to diagnosis >24 h | 2 |
| Cancer | 3 |
| Hypotension | 3 |
| **Total potential score** | **18** |

CT, computed tomography; CXR, chest x-ray, white blood cell.

**Outcomes of patients with esphageal perforation based on a perforation score (0–18)**

| | Clinical score | | |
|---|---|---|---|
| | ≤2 ($n$ = 44) | 3–5 ($n$ = 49) | >5 ($n$ = 26) |
| Complication rate (%) | 53 | 65 | 81 |
| Mortality (%) | 2 | 6 | 27 |
| Length of stay (days) | 10 | 16 | 28 |

**FIGURE 15-6** Esophageal perforation severity score and association with clinical outcome. (Adapted with permission from Abbas G, Schuchert MJ, Pettiford BL, et al. Contemporaneous management of esophageal perforation. *Surgery* 2009;146:749–755. Copyright Elsevier.)

Common to all types of perforation, once esophageal perforation is suspected, oral intake is stopped, fluid resuscitation is instituted, and broad-spectrum antibiotics are initiated. Acid secretion is reduced with proton pump inhibitors, and patients are sustained on total parenteral nutrition. Mediastinal and pleural collections should be drained via tube thoracostomy or by percutaneous catheters placed under CT guidance. The importance of continued monitoring for any clinical deterioration cannot be overemphasized as operative intervention should be performed immediately on any such clinical changes.

## Operative Management

### PERFORATION OF THE CERVICAL ESOPHAGUS

Perforation of the cervical esophagus is usually treated nonoperatively with complete cessation of oral intake, institution of broad-spectrum antibiotics, and frequent oral suctioning.[20]

Subsequent development of an abscess above the aortic arch, however, can be managed with drainage alone through a cervical approach. An incision is made along the anterior border of the left sternocleidomastoid muscle. The omohyoid and strap muscles are divided. The carotid sheath is identified and mobilized laterally, and the inferior thyroid artery is ligated. The recurrent laryngeal nerve can be found as it courses into the tracheoesophageal groove, just anterior to the inferior thyroid artery. The esophagus is identified and a search is made for the site of perforation. Closure of the perforation is not mandatory, especially when severe inflammation is present and there is no distal obstruction; however, closure of an accessible early perforation may be carried out provided that minimal dissection is performed. In such repairs, the esophageal mucosa is approximated with interrupted fine absorbable sutures and the muscle layer closed separately. An associated mediastinal abscess can often be drained by blunt dissection through the thoracic inlet down into the abscess. Placement of a closed suction drain in the abscess cavity and closing the wound complete the procedure. Regardless of whether simple drainage or surgical closure is used for cervical perforations, most patients recover promptly and have a low mortality rate. A repeat swallow study is necessary prior to resuming oral intake.

### INTRATHORACIC AND ABDOMINAL ESOPHAGEAL PERFORATION

The mortality rates of intrathoracic esophageal perforation are almost three times those of cervical esophageal injuries.[31] The most favorable outcomes are obtained after primary repair of such perforations within 24 hours. However, accumulating experience suggests that, regardless of the duration of the injury, primary repair should be attempted in patients without an underlying abnormality of the esophagus and with stable hemodynamics.[32] Perforations of the middle third of the esophagus are best approached through a right thoracotomy, whereas a left thoracotomy is best for perforations of the lower esophagus. Perforations should be approached on the side of pleural contamination. Abdominal esophageal perforation without significant intrapleural contamination may be approached through an upper midline incision.

After surgical exposure has been gained, contaminated fluid is drained and mediastinal and esophageal devitalized tissues are debrided. Next, the location of the perforation is sought. When this has been identified, exposure is facilitated by incising the muscle layers proximally and distally. Once well exposed, the mucosal defect is trimmed and closed using interrupted fine monofilament absorbable suture. Subsequently, the muscle layer is approximated over the mucosal closure. It is important to buttress the repair with adjacent tissues to reduce the rate of leak. The choice of buttressing tissue depends on the approach used for the repair. During a thoracic approach, a pleural intercostal muscle or an elevated diaphragmatic pedicle flap can be used to bolster the primary repair.[33,34] Wide mediastinal drainage is mandatory in addition to the repair. Drainage is achieved by opening the mediastinal pleura above and below the level of the tear from the thoracic inlet to the diaphragm and then irrigating and draining the mediastinum with well-positioned chest tubes and drains. If a laparotomy is performed for perforation of the lower esophagus, the repair can be reinforced with omentum or a fundoplication.[35]

### LATE ESOPHAGEAL PERFORATION

Esophageal perforation with a delayed presentation or diagnosis results in increased mediastinal contamination, inflammation, tissue destruction, and hemodynamic instability. In the absence of underlying esophageal disease, many believe that a primary reinforced repair is the procedure of choice regardless of the perforation's duration. Drainage alone is acceptable in selected cases of cervical perforations. Unstable patients represent a unique challenge and are best served with either resection, control of the esophageal fistula with a T tube and wide pleural drainage, or endoscopic placement of a removable self-expandable Silastic stent and drainage. Esophageal exclusion and diversion is rarely necessary or appropriate with the number of options currently available.

### ESOPHAGEAL PERFORATION ASSOCIATED WITH ESOPHAGEAL DISEASES

Primary repair is ill advised in the presence of preexisting esophageal disease such as cancer or stricture, since the underlying process remains and is associated with a high likelihood of repair breakdown and subsequent mortality.[36,37] In most circumstances, the best option for distal malignant obstruction is resection with delayed reconstruction.[38] In selected patients with an early diagnosis of esophageal

perforation and minimal pleural and mediastinal contamination, gastrointestinal continuity may be reestablished at the time of the primary resection.[38,39]

Patients with achalasia who develop a perforation during balloon dilatation should undergo mucosal closure of the perforation with closure of the overlying muscle, followed by a complete myotomy on the opposite side of the esophagus.[40] The repair is buttressed with a partial fundoplication.

When perforation occurs in the presence of severe gastroesophageal reflux, an antireflux procedure is indicated both to buttress the repair and to treat the reflux. In the setting of severe caustic injuries, primary repair is rarely undertaken. The injured esophagus and/or stomach are resected through a transhiatal approach. The esophageal hiatus is closed to avoid herniation of intra-abdominal organs into the chest. The contaminated chest is drained, and a gastrostomy or feeding jejunostomy tube is placed. Patients are returned to the operating room at a later date for definitive reconstruction.

## OUTCOMES

Meta-analyses of patients with esophageal perforations from 1980–1990 to 1990–2003 have demonstrated an overall mortality of 18 to 22 percent in the modern era.[6,41] Several factors have been found to influence outcomes following esophageal perforation, including etiology, anatomic location, and time to repair. According to etiology, spontaneous perforation has the highest average mortality of 36 percent (range 0–72 percent), followed by iatrogenic perforation 19 percent (7–33 percent), and traumatic perforation 7 percent (0–33 percent).[6] By anatomic location, thoracic esophageal perforation has the highest average mortality of 27 percent (0–44 percent), followed by abdominal esophageal perforation 21 percent (0–43 percent), and cervical 6 percent (0–16 percent).[6] Time to repair is also important; mortality rates for those repaired within 24 hours of injury have the lowest mortality of 25 percent, which rises to 65 percent for those repaired from 24 to 48 hours after injury, and 75 to 89 percent after 48 hours following perforation.[6]

## SUMMARY

Esophageal perforation continues to pose a diagnostic and therapeutic challenge and has an associated mortality rate of approximately 20 percent. Instrumentation has replaced spontaneous rupture as the leading cause of esophageal perforation. Nonoperative management is appropriate in selected patients, but patients with evidence of systemic illness require prompt intervention. In the absence of cancer or an undilatable stricture, reinforced primary repair is the preferred treatment for patients who require an operation. Selection of treatment must be individualized and take into account many variables, including cause, duration, underlying esophageal disease, and the patient's condition.

## ESOPHAGEAL PERFORATION BOARD REVIEW QUESTIONS (CHAPTER 15)

1. Which of the following is correct regarding esophageal injury?
   A. Trauma is the most common cause for esophageal rupture.
   B. With modern techniques, instrumentation injuries have been eliminated.
   C. The thoracic esophagus is the most common location for esophageal rupture.
   D. Cervical perforations are a common complication of difficult esophageal intubation.
   E. Insufflation should be avoided during evaluation of an obstructive lesion.

2. Which is correct regarding instrumental injury of the esophagus?
   A. Instrumentation causes over 50 percent of all esophageal perforations.
   B. In the absence of esophageal pathology, the most common site for iatrogenic injuries is the GE junction.
   C. Perforation rarely occurs at Killian's triangle.
   D. Rigid endoscopy has minimized iatrogenic perforation.
   E. Stent placement for malignancy is associated with a perforation rate of 5 percent.

3. Which of the following is true concerning the diagnosis of esophageal perforation?
   A. Thin barium contrast should be used for initial swallow studies.
   B. CT scanning is the modality of choice in an unstable or mechanically ventilated patient.
   C. Pleural effusion is a late finding on chest imaging.
   D. Water-soluble contrast will demonstrate intrathoracic leak in over 90 percent of patients.
   E. Esophagoscopy has a low sensitivity and specificity for perforation.

4. Which is true regarding the surgical approach for esophageal perforation?
   A. Perforations of the middle third of the esophagus are best approached through a left thoracotomy.
   B. Perforations should be approached on the side of pleural contamination.
   C. Perforations above the aortic arch are best approached through a right-neck incision.
   D. Conservative therapy is acceptable if there is extraluminal dissection.
   E. Closure of the perforation is mandatory.

5. Which is correct regarding treatment of an esophageal perforation in the presence of concomitant esophageal disease?
   A. Patients with achalasia should undergo mucosal closure of the perforation, closure of the overlying muscle, complete myotomy on the opposite side, and partial fundoplication.
   B. An antireflux procedure is not indicated in the setting of severe GERD.
   C. Primary repair is preferred in the presence of stricture.
   D. Formal esophageal resection should be performed for associated squamous cell carcinoma.
   E. Primary repair is indicated in a severe caustic injury to preserve esophageal length.

## ANSWERS

1. **Answer: C.** The thoracic esophagus is the most common location for esophageal rupture. Esophageal rupture after trauma is rare. Instrumentation injuries have increased due to more aggressive use of balloon dilation and esophageal stenting. Cervical perforation is rare during difficult esophageal intubation. Insufflation is necessary for thorough evaluation of an obstructive lesion.
2. **Answer: A.** Instrumentation is the cause of about 59 percent of all esophageal perforations. The most common site of iatrogenic injury is Killian's triangle in the cervical esophagus. Rigid endoscopy has a higher rate of iatrogenic injury compared with flexible endoscopy, and stent placement for malignancy is associated with a 25 percent perforation rate.
3. **Answer: C.** Pleural effusion is a late finding on chest imaging. Water-soluble contrast should be used for initial swallow studies, but will only demonstrate in the leak in 50 to 80 percent of patients. CT scanning is best reserved for patients after the perforation is sealed.

Esophagoscopy has a high sensitivity and specificity for detection of perforation.

4. **Answer: B.** Perforations should be approached on the side of pleural contamination. Perforations of the middle third are best approached through a right thoracotomy. Perforations above the aortic arch are managed with a left-neck incision. Conservative therapy is not indicated if there is extraluminal dissection. Closure of the perforation is not mandatory if there is adequate drainage.
5. **Answer: A.** Patients with achalasia should undergo mucosal closure of the perforation, closure of the overlying muscle, complete myotomy on the opposite side, and partial fundoplication. An antireflux procedure is indicated in the setting of severe GERD. Primary repair is not indicated for stricture or caustic injury, as the repair has a high likelihood of breakdown and mortality. Delayed reconstruction is preferred for patients with malignancy.

**KEY CONCEPTS**

- Epidemiology
  - Esophageal adenocarcinoma is the fastest growing solid malignancy in the United States.
- Pathophysiology
  - Barrett metaplasia is the precursor lesion to esophageal adenocarcinoma.
- Clinical feature
  - Most patients presenting with symptoms already have systemic disease.
- Diagnostic
  - In selecting the optimal treatment, endoscopic ultrasound is an important tool in determining the depth of invasion and regional nodal involvement.
- Treatment
  - Neoadjuvant chemoradiation may improve survival particularly in patients with a complete pathologic response.
- Prognosis
  - The stage at diagnosis is the most important prognostic factor.

## INTRODUCTION

The incidence of esophageal cancer in the United States is approximately 13,000 cases per year. Adenocarcinoma of the esophagus (EAC) is the fastest growing solid malignancy, and it is now more frequent than esophageal squamous cell carcinoma (ESCC) in the United States. Although resection offers the best chance for cure, most patients who present with symptoms already have systemic disease and are incurable. The most important prognostic factor for esophageal cancer remains the stage of disease at the time of diagnosis. Currently, the best strategy for improving survival is early diagnosis followed by resection. Neoadjuvant chemoradiation is being used increasingly in the treatment of locally advanced disease. However, despite improvements in operative technique and postoperative care, the overall 5-year survival remains less than 15 percent, highlighting the need for novel diagnostic and treatment modalities.

## Pathophysiology

### ESOPHAGEAL SQUAMOUS CELL CARCINOMA

Nutritional deficiencies, including low levels of vitamins A, C, and riboflavin as well as minerals such as selenium, molybdenum, and zinc contribute to the pathogenesis of ESCC. High levels of nitrates and nitrites, found in pickled and preserved foods, are converted to N-nitrosamines and have been associated with ESCC. Several studies have linked alcohol and tobacco use with the development of esophageal cancer, and one study found ethanol to be associated with nearly 80 percent of esophageal cancers.[1] Other predisposing conditions include long-standing achalasia, caustic injury, tylosis, and Plummer–Vinson syndrome.

### ESOPHAGEAL ADENOCARCINOMA

Barrett metaplasia, and specifically intestinal-type columnar mucosa, is the precursor lesion to EAC. Microscopically, columnar epithelium is seen with mucosal glands that contain intestinal goblet cells (Fig. 16-1A). On endoscopy, Barrett mucosa appears as red, velvety areas between smooth, pale esophageal squamous mucosa (Fig. 16-2A). After the squamous epithelium is injured chronically by reflux, there is a metaplastic change to a columnar epithelium. With further injury and multiple genetic changes, progression occurs in a metaplasia–dysplasia–adenocarcinoma sequence.

In patients with Barrett metaplasia, the risk of EAC is increased 30 to 125 times that of the age-matched

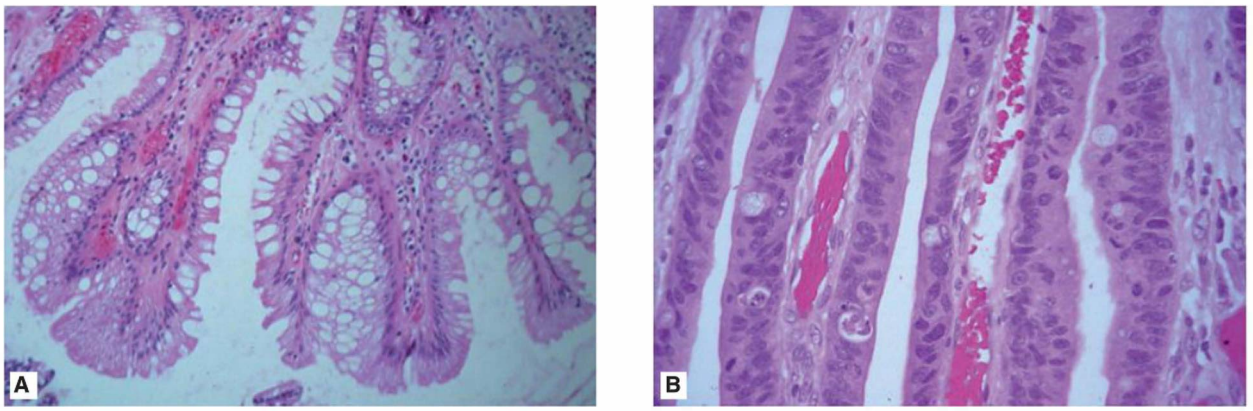

**FIGURE 16-1** Photomicrograph. **A.** Barrett mucosa showing columnar epithelium with mucosal glands containing intestinal goblet cells. **B.** High-grade dysplasia with nuclear atypia.

population. Barrett esophagus results from chronic inflammation due to gastroesophageal reflux. At endoscopy, Barrett mucosa is found in 12 to 18 percent of patients with reflux.[2] Although the esophageal mucosa is relatively resistant to acid, mixed reflux with bile acids, pepsin, and gastric acid appears to be more harmful, and up to 67 percent of patients with Barrett metaplasia have bile-stained duodenogastric reflux.

EAC is believed to have a 4- to 5-year preclinical phase, suggesting that surveillance may be effective. Cancers detected during surveillance tend to be less advanced, and the American College of Gastroenterology has suggested that patients with chronic reflux undergo upper endoscopy. Abnormal mucosa is biopsied to diagnose Barrett metaplasia and to detect the presence of dysplasia (Fig. 16-1B). Surveillance intervals are increased to every 3 years after two consecutive biopsies are negative for dysplasia.

Other risk factors for EAC include ectopic gastric mucosa, obesity, smoking, diets high in saturated fat and red meat, and medications that reduce lower esophageal sphincter pressure. Concerns have also been raised that the treatment of *Helicobacter pylori*, specifically the acid-suppressing effects of the Cag A+ strain, may actually increase the incidence of EAC.

Although the majority of ESCCs are located in the middle third of the esophagus, EACs (approximately 79 percent) arise in the distal esophagus. High-grade dysplasia (HGD) remains the best predictor of progression to adenocarcinoma. An extensive lymphatic network and the long interval during which esophageal tumors remain asymptomatic contribute to the high incidence of nodal disease with 30 to 58 percent of patients having lymph node metastases when the submucosa is involved.[3] The extent of invasion and the presence or absence of lymph node metastases are important in determining patient prognosis. The most common sites of distant metastases include the liver, lungs, bone, brain, and adrenal glands (Table 16-1).

## Clinical Features

### EPIDEMIOLOGY

In the United States, the annual incidence of ESCC is 2.6 per 100,000. The incidence is four to five times higher in African Americans than in Caucasians. Regions with a high incidence are generally located in poorer areas of the world including parts of China, Central Asia, and Latin America. The overall 5-year survival rate is approximately 15 percent.

The incidence of EAC has increased progressively from the 1970s, and esophageal adenocarcinoma is the most rapidly increasing solid malignancy in the United States. Adenocarcinoma has surpassed ESCC as the most common cancer of the esophagus in America, and esophageal carcinoma is the seventh leading cause of cancer-related deaths. The median age at diagnosis is 68. Men are affected six to eight times more frequently than are women, and Caucasians are affected three to four times as often as African Americans. The incidence is higher in developed countries.

### CLINICAL PRESENTATION

Dysphagia is the most common initial symptom but generally only occurs when the tumor involves more than 50 percent of the circumference of the esophagus. Odynophagia is the next most common symptom and may be caused by an ulcerated lesion. Constant pain in the mid-back or midchest suggests mediastinal invasion. Hoarseness may develop with proximal tumors and indicates involvement of the recurrent laryngeal nerve. Regurgitation may occur as the growing tumor narrows the esophageal lumen, and weight loss is frequently present at presentation. Although patients often have a history of reflux symptoms, clinical features do not distinguish patients with or without Barrett, which is frequently asymptomatic. The evaluation of a suspected esophageal adenocarcinoma is outlined in Figure 16-3.

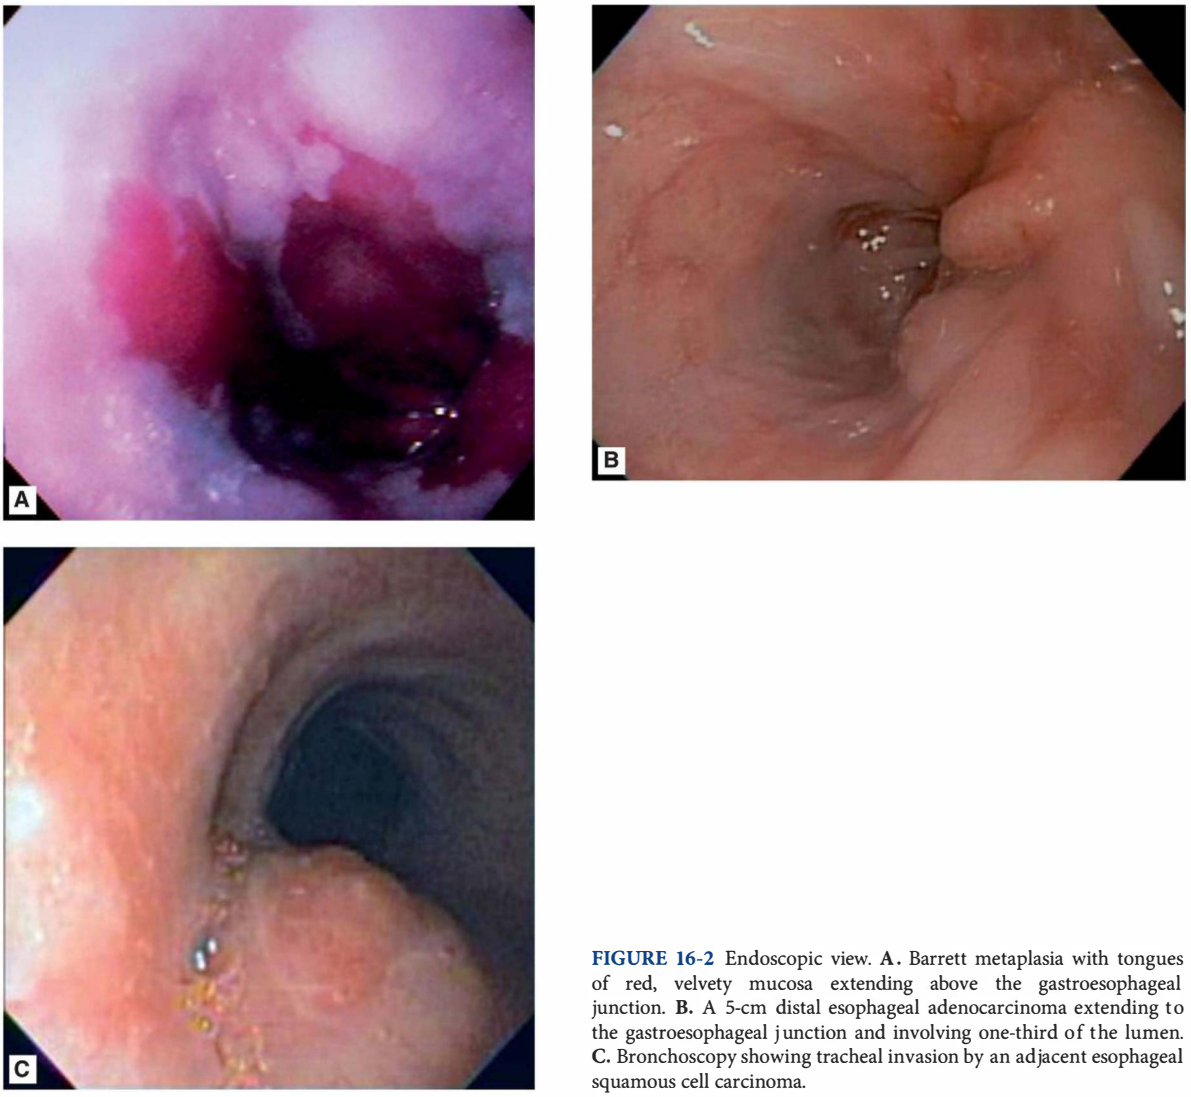

**FIGURE 16-2** Endoscopic view. **A.** Barrett metaplasia with tongues of red, velvety mucosa extending above the gastroesophageal junction. **B.** A 5-cm distal esophageal adenocarcinoma extending to the gastroesophageal junction and involving one-third of the lumen. **C.** Bronchoscopy showing tracheal invasion by an adjacent esophageal squamous cell carcinoma.

## Diagnostic Modalities

### ENDOSCOPY

The management and prognosis of esophageal carcinoma depend on accurate clinical staging. Endoscopic evaluation is essential in all patients suspected of having esophageal carcinoma (Fig. 16-2B). The location of the lesion, degree of obstruction, and the length of the lesion should be determined in all patients. Any abnormal lesions should be biopsied. Other findings to be noted include the presence of Barrett mucosa or a hiatal hernia, and the fundus should be closely examined on retroflexion for any tumor involvement. Although advanced carcinoma is easily identified, early mucosal changes may be difficult to recognize. Chromoendoscopy with indigo carmine or acetic acid and

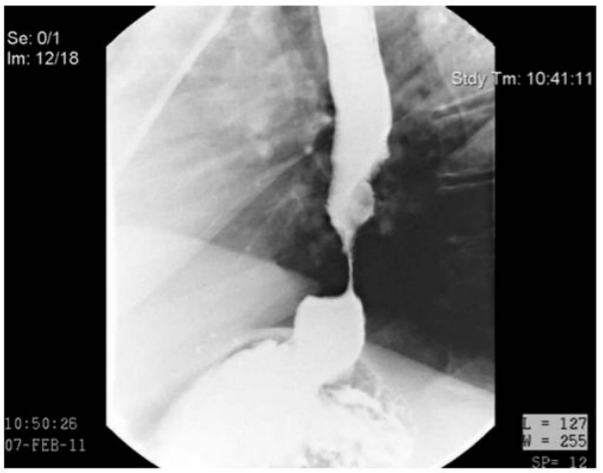

**FIGURE 16-3** Barium esophagram demonstrating a circumferential distal esophageal mass proximal to a hiatal hernia consistent with a Barrett adenocarcinoma associated with gastroesophageal reflux.

narrow band imaging can highlight mucosal details a nd the microvasculature by using blue and green light with shorter wavelengths resulting in better penetration of superficial tissues. Lugol's solution can be used to identify dysplastic squamous lesions. Normal epithelium, which contains glycogen, is stained by the iodine. New techniques are being developed to improve visualization including confocal endomicroscopy and fluorescent-labeled peptides designed to bind to dysplastic or cancerous lesions.[4] Mapping biopsies with four-quadrant biopsies obtained every 1 to 2 cm can also help to delineate abnormal lesions.

Bronchoscopy is important to evaluate possible tracheal invasion by tumors in the upper or middle thirds of the esophagus (Fig. 16-2C). Patients with infracarinal bulky tumors or subcarinal lymphadenopathy on computed tomography (CT) should also undergo bronchoscopy. Findings may range from bulging of the bronchial wall and subtle mucosal changes to frank tumor invasion or the presence of a tracheoesophageal fistula. The carina may appear widened due to subcarinal lymphadenopathy. Bronchial biopsies are obtained to confirm that airway invasion is present.

## RADIOGRAPHIC STUDIES

***Contrast Studies.*** The barium swallow is an essential diagnostic study in the evaluation of dysphagia and allows visualization of the esophageal mucosa, distensibility, and motility (Fig. 16-3). Involvement of the fundus can also be seen on the esophagram. Subtle mucosal irregularities, ulcerations, or small polypoid lesions are best seen on a double-contrast esophagram.

***Computed Tomography.*** Staging CT scans of the chest and upper abdomen are useful in the initial evaluation of esophageal carcinoma as well as assessing the response to neoadjuvant therapy. CT is used to determine the local extent of the tumor, the relationship to adjacent structures, lymphadenopathy, and the presence of distant metastases. CT cannot distinguish the layers of the esophageal wall and is not as useful in determining the T stage. However, loss of fat planes can be useful in determining invasion of adjacent structures. The sensitivity for detecting lymphadenopathy (>1 cm) is 30 to 60 percent in the mediastinum and 50 to 75 percent in the abdomen, whereas CT has a 70 to 80 percent sensitivity for identifying metastatic disease greater than 2 cm.[5]

***Endoscopic Ultrasound.*** Endoscopic ultrasound (EUS) provides the most accurate assessment of the depth of tumor invasion, or T stage, and is able to identify five distinct layers in the esophageal wall (Fig. 16-4). EUS is most useful in the staging of early carcinoma. EUS is also more sensitive in detecting regional lymphadenopathy and can evaluate the

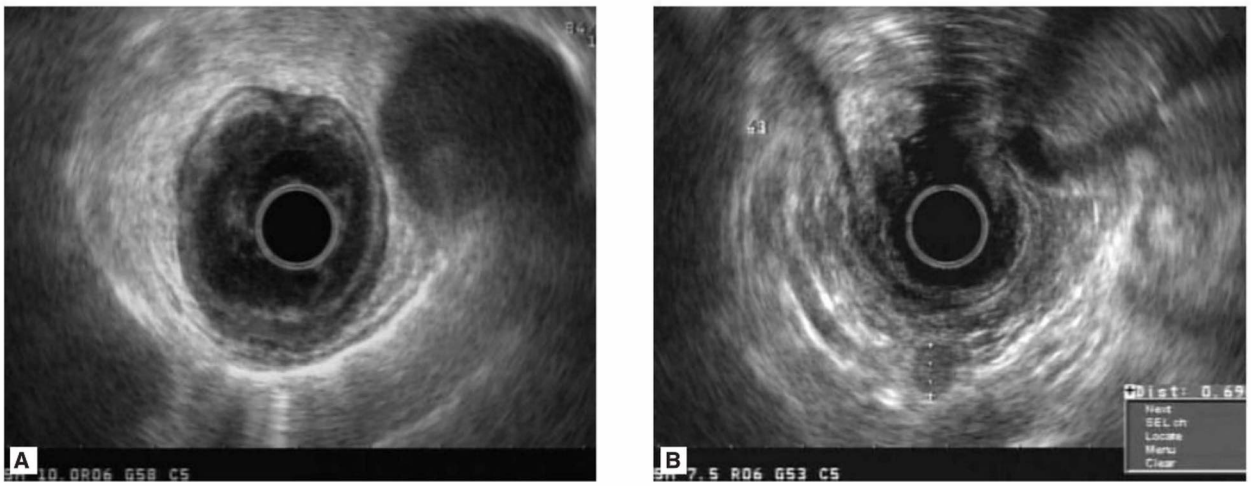

**FIGURE 16-4** **A.** Endoscopic ultrasound shows a hypoechoic 6-cm distal esophageal mass with sonographic evidence of invasion into the adventitia. **B.** Sonographic view of an abnormal hypoechoic lymph node with well-defined margins visualized in the gastrohepatic ligament.

extent of periesophageal invasion. Curvilinear arrays assist in the performance of fine-needle aspiration (FNA), which is up to 98 percent sensitive and 100 percent specific. EUS has also been evaluated for assessing the response to neoadjuvant therapy but may be prone to overstaging.

***Positron Emission Tomography.*** Positron emission tomography (PET) improves staging by identifying distant disease not seen on CT alone. PET has a higher sensitivity than CT in detecting nodal and distant metastases, although PET cannot distinguish the primary tumor from peritumoral lymph nodes. Sensitivity ranges from 78 to 95 percent, and specificity from 95 to 100 percent. The role of PET in restaging after neoadjuvant treatment needs to be further evaluated. Although studies suggest that decreased activity seen on PET corresponds with response to chemoradiation, PET is not sensitive enough to identify complete responders.

### THORACOSCOPY AND LAPAROSCOPY

Thoracoscopic and laparoscopic staging offer direct visualization and the ability to obtain biopsies to determine nodal status, the extent of local invasion, and the presence of metastatic disease and can be useful in specific circumstances. Laparoscopy should be considered in patients with suspected intraperitoneal metastases to assess for tumor implants whereas thoracoscopy is useful to evaluate for small pulmonary nodules or mediastinal lymph nodes not accessible by endobronchial ultrasound (EBUS) or CT-guided biopsy. Laparoscopic ultrasound is also being investigated as a staging modality and may provide improved accuracy in T and N staging. Laparoscopic ultrasound may be more accurate in staging celiac nodes than EUS, providing closer access for the ultrasound probe as well as direct inspection.

### STAGING

Accurate staging is essential for treatment selection, and the stage at diagnosis is the most important prognostic factor. The evaluation of patients with suspected esophageal cancer should include appropriate diagnostic studies as described above as well as biopsies of any suspected metastatic lesions (Fig. 16-5). Although patients with stage I tumors have a 65 percent 5-year survival, those with biopsy-proven distant metastatic disease have a mean survival of only 6 months and are considered unresectable. Both esophageal squamous cell and adenocarcinoma are staged according to the American Joint Committee for Cancer TNM system. Significant changes in the 7th edition take into account the histology, grade, and number of regional lymph nodes involved.

## Medical Therapy

### RADIATION THERAPY

Results of a large review published by Earlam and Cunha-Melo with more than 8000 inoperable patients due to prohibitive surgical risk or unresectable esophageal carcinoma showed 1-, 2-, and 5-year survival rates of 18, 8, and 6 percent after definitive radiotherapy.[6] Postoperative radiotherapy has been shown to decrease local recurrence but has not improved survival rates. Several trials of neoadjuvant radiotherapy have also failed to show increased resection rates or improved survival compared with surgery alone.

### CHEMOTHERAPY

Law et al. showed that neoadjuvant chemotherapy resulted in significant downstaging of disease in nearly 50 percent of patients, but a pathologic complete response was seen in less than 10 percent.[7] A marginal survival benefit was noted in this subgroup of patients. Kelsen et al. reported a large multicenter study of neoadjuvant chemotherapy versus surgery alone, which included 440 patients. At 2-year follow-up, no significant survival benefit was seen.[8]

### CHEMORADIOTHERAPY

The Radiation Therapy Oncology Group (RTOG) randomized trial reported by Al-Sarraf et al. provided convincing evidence of the superiority of chemoradiation over radiation alone.[9] The 2- and 5-year survival rates were 36 and 27 percent in the chemoradiation group compared with 10 and 0 percent in the group treated with radiation alone. There was also a reduction in both local recurrence and distant disease. However, the toxicity of the treatments was significant. Many surgeons advocate neoadjuvant therapy for patients with esophageal carcinoma, except in patients with early disease, due to the poor survival rates following resection alone. Neoadjuvant chemoradiotherapy is routine at the University of Michigan in patients with tumors staged as T2 or greater or patients with positive nodal disease (Fig. 16-5). Neoadjuvant therapy is limited to patients younger than 75 years due to the significant toxicity and the decrease in patients able to complete trimodality therapy with increasing age.

The combination of chemoradiation with surgery has resulted in significant downstaging of disease, but a survival advantage has not been consistently demonstrated in randomized trials. Most regimens are cisplatin-based and commonly combined with 5-fluorouracil. Chemoradiation is followed by resection 5 to 6 weeks after completion of therapy. Walsh et al. reported a randomized trial of 113 patients receiving neoadjuvant therapy or surgery alone and showed significantly improved survival after neoadjuvant treatment of 17 months versus 12 months.[10] However, the survival in the surgery arm was lower than most published series. Urba et al. performed a randomized trial of 100 patients who underwent either transhiatal esophagectomy following neoadjuvant chemoradiation therapy or surgery alone.[11] Seventy-five percent of patients had adenocarcinoma. Twenty-eight percent had a complete pathologic response. Survival at 3 years was 30 percent after neoadjuvant therapy versus 16 percent after surgery alone although this was not statistically significant.

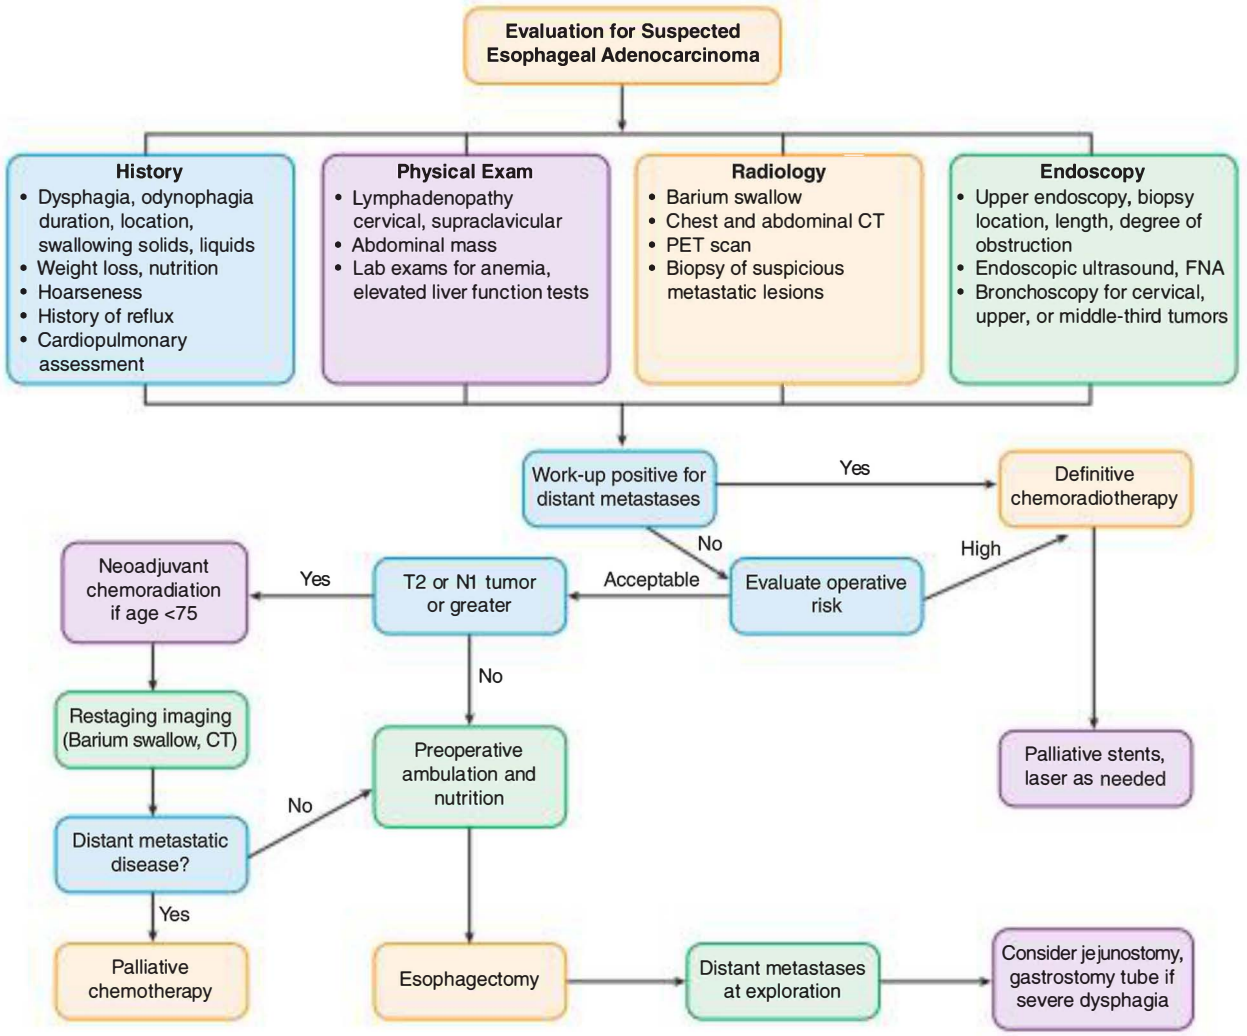

**FIGURE 16-5** Diagnostic algorithm in the evaluation of a patient with suspected esophageal adenocarcinoma. FNA, fine-needle aspiration.

A meta-analysis of randomized trials comparing trimodality therapy with surgery alone showed a slight increase in overall survival with a complete pathologic response associated with the best survival.[12] Gebski et al. performed a meta-analysis including 1200 patients undergoing neoadjuvant chemoradiation and found a hazard ratio (HR) of 0.81 (95 percent CI 0.70–0.93; $p = 0.002$).[13]

Cancer and Leukemia Group B (CALGB) 9781 was a prospective, randomized phase III trial comparing trimodality therapy with cisplatin and 5-FU to surgery alone.[14] Although the study was closed early due to low accrual after 56 patients, the authors reported a 5-year survival of 39 percent compared with 16 percent in patients undergoing surgery alone supporting the use of trimodality therapy. Newer agents including taxanes and irinotecan are being evaluated in chemoradiotherapy trials and may have promising antitumor activity as well as improved tolerance.

## TARGETED THERAPIES

In addition, new targeted therapies against growth factor receptors such as EGFR and HER-2/Neu and angiogenesis factors including VEGF are being investigated in the treatment of esophageal carcinoma. Inhibitors include small-molecule tyrosine kinase inhibitors and monoclonal antibodies. Several phase II trials evaluating EGFR inhibitors have been completed in patients with advanced esophageal carcinoma with modest response rates seen in 10 percent of patients.[15] Larger phase III trials will be needed to determine which patients may benefit from therapy. The ToGA trial was a randomized, prospective phase III trial evaluating 594 patients with advanced HER-2-positive gastric and gastroesophageal junction (17–20 percent of patients) tumors with cisplatin and 5-FU with or without trastuzumab, an anti-HER-2 monoclonal antibody.[16] There was a significant increase in survival of 13.5 versus

11.1 months (HR 0.74; 95 percent CI 0.60–0.91; $p = 0.046$) and progression-free survival of 6.7 versus 5.5 months. Complete response was seen in 5 percent versus 2 percent and a partial response in 42 percent versus 32 percent. Patients with high HER-2 expression had a median overall survival of 16 months (HR 0.65; 95 percent CI 0.51–0.83). For the subgroup of patients with gastroesophageal junction tumors, The HR was 0.67 (95 percent CI 0.42–1.08). Trastuzumab was recently added to the National Comprehensive Cancer Network Guidelines for combination treatment of advanced esophageal and gastric adenocarcinomas. RTOG 1010 is currently accruing patients in a phase III trial evaluating the addition of trastuzumab to trimodality therapy in HER-2 overexpressing esophageal adenocarcinomas.

At this time, surgery remains the standard treatment for resectable esophageal carcinoma. For patients with advanced disease or those unfit for surgery, chemoradiation therapy appears to be a reasonable alternative.

## ENDOSCOPIC THERAPIES

***Mucosal Ablation.*** Some investigators have had success with mucosal ablation of Barrett mucosa with squamous re-epithelialization. Effective antireflux therapy is critical. Techniques include laser, photodynamic therapy, cryotherapy, and radiofrequency ablation. Salo et al. reported successful Nd-YAG laser ablation after antireflux surgery in 11 patients who had complete squamous regeneration after a mean of 26 months.[17] However, Wang and Sampliner have found persistent areas of intestinal metaplasia underlying the squamous epithelium.[18]

Photodynamic therapy (PDT) involves the systemic injection of a photosensitizer, porfimer sodium, targeting dysplastic cells. After 24 to 48 hours, light is used to produce oxygen radicals. All devitalized tissue is irrigated away 48 hours later. Using this technique, Overholt et al. reported 90 percent of lesions cleared or downstaged to low-grade dysplasia although 83 percent required repeat laser treatment 3 to 6 months later for residual Barrett mucosa.[19] Esophageal mucosal re-epithelialization occurred over 2 to 3 months and was complicated by strictures in 34 percent. Patients also need to avoid sun exposure due to photosensitivity for up to 3 months.

In the prospective, multicenter AIM-II trial endoscopic radiofrequency ablation was evaluated in patients with nondysplastic Barrett mucosa. Complete eradication was achieved in 98.4 percent of patients at 2.5 years and 92 percent at 5 years (46/50 patients). The four patients with focal Barrett were re-treated with RFA. The authors reported no buried glands, dysplasia, or strictures. Although this technique may be useful for Barrett mucosa, as an ablative procedure, pathology specimens are not obtained, and ablation should not be used for HGD or esophageal carcinoma where pathologic examination to determine the histology, depth of invasion, lymphovascular involvement, and margins is critical.

***Endoscopic Mucosal Resection.*** Endoscopic mucosal resection (EMR) was first reported in Japan and involves injecting saline and epinephrine into the submucosal space to elevate the target area, which is then lifted with a suction cap or banded and removed with a polypectomy snare. Failure of the lesion to lift after saline injection suggests submucosal invasion. High-frequency EUS is useful in defining the depth of invasion prior to resection. Risks include bleeding, perforation, and stricture. The overall complication rate is 13 to 17 percent.[20] Strictures are reported in 6 to 23 percent of cases and are more likely after circumferential EMR or in combination with ablation such as PDT. The risk of bleeding is 0.6 to 11 percent. Bleeding requiring transfusions occurs in 3.8 percent, and perforation occurs in 0 to 2.5 percent.

Recurrence of dysplasia or carcinoma has been reported in 12 to 21 percent of patients with a mean follow-up of 43 to 63 months although these lesions were often treated with repeat EMR.[20] The risk of recurrence is increased with long-segment Barrett (relative risk 1.9; 95 percent CI 1.06–3.3), larger lesions requiring piecemeal resection (RR 2.44; 95 percent CI 1.13–4.89), and multifocal carcinoma (RR 2.1; 95 percent CI 1.16–3.99). Residual metaplastic mucosa can also persist beneath the regenerating squamous mucosa. Close endoscopic follow-up is mandatory and persistent lesions, involvement of the submucosa, or positive margins warrants an esophagectomy.

HGD is being treated increasingly with EMR although esophagectomy remains the gold standard. Another alternative is intensive surveillance with four-quadrant biopsies taken every centimeter and repeated every 3 months. However, there are inherent false negatives as biopsies may miss dysplasia and carcinomas separated by large areas of Barrett epithelium. Several retrospective studies have shown difficulty in differentiating HGD from adenocarcinoma using endoscopic surveillance. In addition, the majority of patients with HGD will have invasive adenocarcinoma develop within 10 years with 25 percent at 1.5 years, 50 percent at 3 years, and 80 percent at 8 years on surveillance biopsies. Zhu et al. evaluated 127 esophagectomy specimens performed for high-grade dysplasia.[21] Patients with biopsies showing only HGD were found to have adenocarcinoma in 5 percent of esophagectomy specimens while more than 80 percent of patients with HGD suspicious for carcinoma were found at resection to have adenocarcinoma suggesting that these patients may be more appropriately treated as patients with carcinoma.

Early intramucosal carcinomas (T1a) have also been treated with endoscopic resection especially in debilitated patients who are not surgical candidates. EACs confined to the mucosa have 1 to 5 percent risk of lymph node metastases while invasion of the submucosa increases the risk to 30 to 58 percent.[3,20] Long-term results are not yet available and surgery remains the gold standard with curative intent in these patients.

***Surgical Therapy.*** Surgical therapy currently offers the best chance for cure with a complete R0 resection and provides

effective palliation with relief of dysphagia. Although mortality rates have decreased significantly over the past few decades, relatively high postoperative morbidity remains. Appropriate pulmonary and cardiac evaluation as well as aggressive preoperative preparation including preoperative ambulation, nutrition, incentive spirometry, patient education, and smoking cessation are critical. Although the goal is to proceed with resection 5 to 6 weeks after completion of neoadjuvant therapy, it is important to wait until patients have returned to their baseline function prior to proceeding with esophagectomy.

Controversy continues to surround the optimal surgical approach to esophagectomy as well as the extent and necessity of regional lymph node dissection. Proponents of the combined thoracotomy and laparotomy approach described by Ivor Lewis emphasize the direct visualization during mediastinal dissection, an en bloc resection, and a wider lymphadenectomy resulting in improved staging. Two meta-analyses comparing the two approaches showed higher perioperative morbidity and mortality after the transthoracic approach with no difference in long-term survival.[22,23] The choice of approach depends on the location of the tumor, planned extent of lymphadenectomy, and the preference of the surgeon. The role of palliative resection is limited with the availability of esophageal stents, laser ablation, and radiation therapy.

***Transhiatal Esophagectomy.*** The transhiatal approach avoids the morbidity of a thoracotomy in debilitated patients as well as the potential occurrence of a disastrous intrathoracic anastomotic disruption. Although accessible subcarinal, paraesophageal, and celiac lymph nodes are sampled, no attempt is made to perform an en bloc resection. Although critics have questioned the oncologic principles arguing for the need to perform an aggressive mediastinal lymph node resection, survival has been reported in several series to be equivalent to that seen after a transthoracic resection. Transhiatal esophagectomy is technically possible in the majority of patients even with a history of prior operations, esophageal perforation, or radiation treatment and provides a maximal esophageal margin. In addition, the stapled side-to-side cervical anastomosis has decreased the anastomotic leak rate to less than nine percent at the University of Michigan, and most cervical leaks are treated conservatively by opening the wound at the bedside and dressing changes.[24,25] Less frequent complications include intrathoracic hemorrhage, recurrent nerve paralysis, and tracheal laceration.

## OPERATIVE TECHNIQUE

***Abdominal Phase.*** The abdomen is entered through a midline supraumbilical incision, and the liver and peritoneal cavity are examined for metastatic disease. The triangular ligament is divided, and the stomach is carefully examined for tumor involvement. The right gastroepiploic artery is identified and protected. This may be difficult if there is a history of previous abdominal surgery. The left gastroepiploic and short gastric vessels are ligated, and the esophagogastric junction is mobilized. After examining the gastrohepatic ligament for a replaced left hepatic artery, the left gastric artery is ligated near its origin taking the left gastric lymph nodes with the specimen. The right gastric artery is preserved as the dissection is continued along the lesser curvature. A Kocher maneuver is then performed to allow mobilization of the pylorus to the level of the hiatus. A pyloromyotomy is performed to decrease the incidence of postvagotomy delayed gastric emptying. Clips are placed at the level of the pyloromyotomy for future radiographic studies. A jejunostomy tube is placed and is used as needed to supplement postoperative nutrition.

The distal 5 to 10 cm of esophagus is mobilized through the hiatus. The mobility of the esophageal tumor is then assessed to ensure that there is no invasion of the prevertebral fascia, aorta, or surrounding mediastinal structures. Deaver retractors inserted into the hiatus allow ligation of the periesophageal tissues to the level of the carina under direct vision using long right-angle clamps.

***Cervical Phase.*** An oblique incision is made along the anterior border of the sternocleidomastoid muscle. Care is taken to avoid retraction on the left recurrent laryngeal nerve in the tracheoesophageal groove. The middle thyroid vein and inferior thyroid artery are ligated as needed. After dissecting down to the prevertebral fascia, blunt finger dissection is continued into the superior mediastinum. Sharp dissection is used along the anterolateral surface of the esophagus staying posterior to the recurrent laryngeal nerve. The upper thoracic esophagus is mobilized almost to the level of the carina using blunt dissection keeping the fingers directly on the esophagus.

***Mediastinal Dissection.*** One hand is inserted through the diaphragmatic hiatus posterior to the esophagus while a sponge stick is placed through the cervical incision dissecting the esophagus off the prevertebral fascia (Fig. 16-6A). The blood pressure is carefully monitored to prevent hypotension, and a sump catheter is inserted through the cervical incision to evacuate blood from the posterior mediastinum. The anterior mobilization is performed from both the abdominal and the cervical incisions with the fingers directly against the anterior esophagus to avoid injury to the membranous trachea. The esophagus is held in the superior mediastinum between the index and middle fingers of the hand inserted through the hiatus, and the remaining attachments are lysed with a downward motion (Fig. 16-6B). A partial upper sternotomy can be performed for improved exposure in patients with a short, broad neck or poor neck extension. The upper esophagus is then divided obliquely, and the thoracic esophagus is delivered through the diaphragmatic hiatus. Using Deaver retractors, the posterior mediastinum is inspected for hemostasis through the hiatus. If the pleural cavities have been entered, which occurs in three-quarters of cases, chest tubes are placed. The posterior mediastinum is temporarily packed with gauze pads to tamponade minor bleeding.

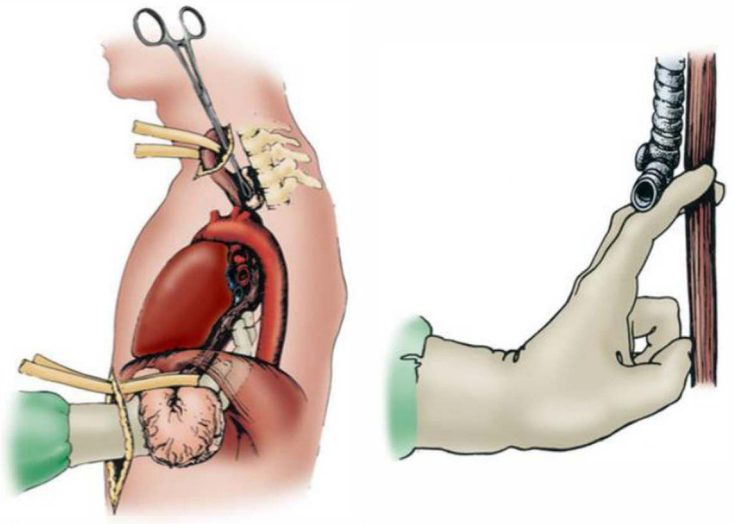

**FIGURE 16-6** **A.** Esophageal mobilization from the prevertebral fascia is performed using a half-sponge stick from the cervical wound and a hand inserted through the diaphragmatic hiatus. (From Orringer MB, Sloan H. Esophagectomy without thoracotomy. *J Thorac Cardiovasc Surg* 1978;76(5):643–654. Copyright Elsevier.) **B.** A downward raking motion with the esophagus held between the index and the middle fingers is used to take down the lateral periesophageal attachments. (From Orringer MB. Transhiatal blunt esophagectomy without thoracotomy. In: Cohn LH (ed.). *Modern Techniques in Surgery*, Vol. 62. Cardiovascular Surgery. New York: Futura Publishing, 1983:1.)

A partial proximal gastrectomy 4 to 6 cm distal to the esophagogastric junction is performed using a GIA stapler (Fig. 16-7A). For tumors of the middle esophagus or benign disease, the amount of stomach resected is minimized to preserve collateral circulation to the fundus. The staple line is oversewn. The mobilized stomach is passed through the hiatus and delivered 4 to 5 cm above the clavicles by pushing the stomach up through the mediastinum and guiding it with a Babcock clamp from the cervical incision (Fig. 16-7B). Traction sutures and suction devices to pull the stomach

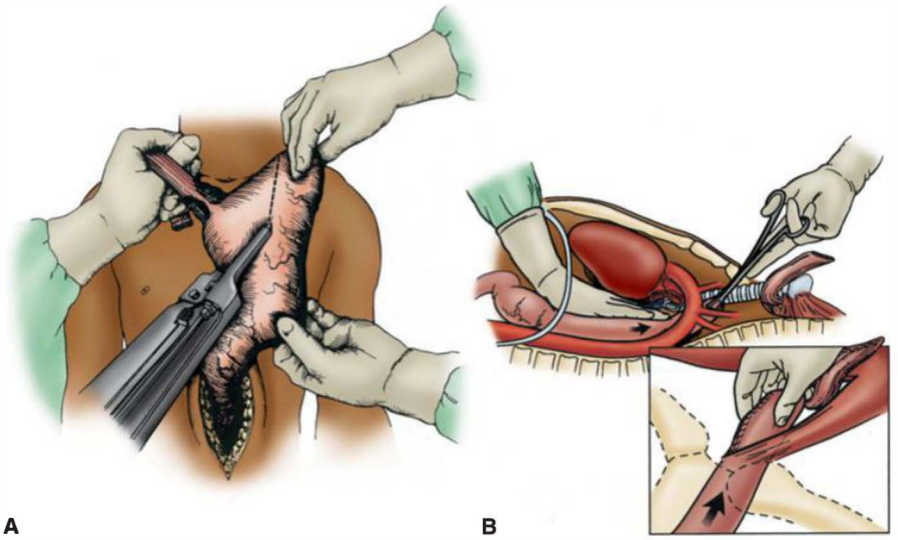

**FIGURE 16-7** **A.** Partial proximal gastrectomy is performed by sequentially applying the GIA stapler. (Reproduced with permission from Orringer MB, Sloan H. Esophageal replacement after transhiatal esophagectomy without thoracotomy. In Nyhus LM, Baker RJ (eds). *Mastery of Surgery*, 2nd ed. Boston: Little, Brown, 1992:569.) **B.** The mobilized stomach is gently passed into the posterior mediastinum. A Babcock clamp is used to carefully grasp the stomach in the superior mediastinum, but the stomach is delivered primarily by pushing from below. (Reproduced with permission from Orringer MB, Marshall B, Iannettoni MD. Eliminating the cervical esophagogastric anastomotic leak with a side-to-side stapled anastomosis. *J Thorac Cardiovasc Surg* 2000;119(2):277–288. Copyright Elsevier.)

through the mediastinum are avoided to minimize trauma to the gastric conduit. Care is taken to ensure that there is no torsion of the conduit.

The abdominal phase is then completed to avoid contamination with bacteria from the cervical esophagus. The diaphragm is reapproximated using silk sutures so that the hiatus allows three fingers to pass alongside the stomach. The anterior gastric wall is approximated to the edge of the hiatus, and the triangular ligament is re-attached to the diaphragm to help prevent a hiatal hernia. The pyloromyotomy is covered with omentum.

***Cervical Esophagogastric Anastomosis.*** A traction suture is placed in the anterior gastric wall to elevate the stomach into the wound. A 1.5-cm vertical gastrotomy is made in the anterior gastric wall low enough down to allow the Endo GIA to be fully inserted into the stomach (Fig. 16-8A). The cervical esophageal staple line is then amputated obliquely with enough redundancy for a tension-free anastomosis and sent to pathology as the proximal esophageal margin. After placing stay sutures to align the stomach and esophagus, the Endo GIA is inserted and closed (Fig. 16-8B). Before opening the stapler, two suspension sutures between the esophagus and adjacent stomach are placed on either side of the anastomosis. After removing the stapler, a nasogastric tube is guided across the anastomosis, and the anterior wall of the anastomosis is reapproximated in two layers (Fig. 16-8C). Clips are placed beside the anastomosis as radiographic markers, and the wound is closed after placing a penrose drain.

***Minimally Invasive Approaches.*** Luketich et al. reported a series of 222 patients undergoing a minimally invasive laparoscopic and thoracoscopic approach with a cervical anastomosis.[26] A pyloroplasty is performed and the cervical anastomosis is completed using an EEA stapler. Neoadjuvant chemotherapy was used in 35.1 percent and radiation in 16.2 percent. Conversion to an open esophagectomy was performed in 7.2 percent. The average hospital stay was 7 days, and operative mortality was 1.4 percent. The anastomotic leak rate was 11.7 percent. The leak rate was affected by the width of the gastric conduit with a leak rate of 6.1 percent with a conduit greater than 6 cm in width versus 25.9 percent with a narrower conduit. Recurrent laryngeal nerve injury occurred in 3.6 percent and pneumonia in 7.7 percent.

More recently, this group has described performing a minimally invasive Ivor Lewis esophagectomy in 50 patients.[27] Fifteen of the patients were approached by thoracoscopy while the remainder had a planned mini thoracotomy for the anastomosis that was performed with an EEA stapler. The operative mortality was 6 percent and the leak rate 6 percent. Although there were no recurrent laryngeal nerve injuries with avoidance of the cervical dissection, a return to an intrathoracic anastomosis could increase the morbidity of an intrathoracic leak compared with the relatively benign consequences of a cervical anastomotic leak.

Minimally invasive esophagectomy is technically demanding and should be performed in centers with extensive laparoscopic and thoracoscopic experience. Care must be taken to balance the benefits of smaller incisions and less pain

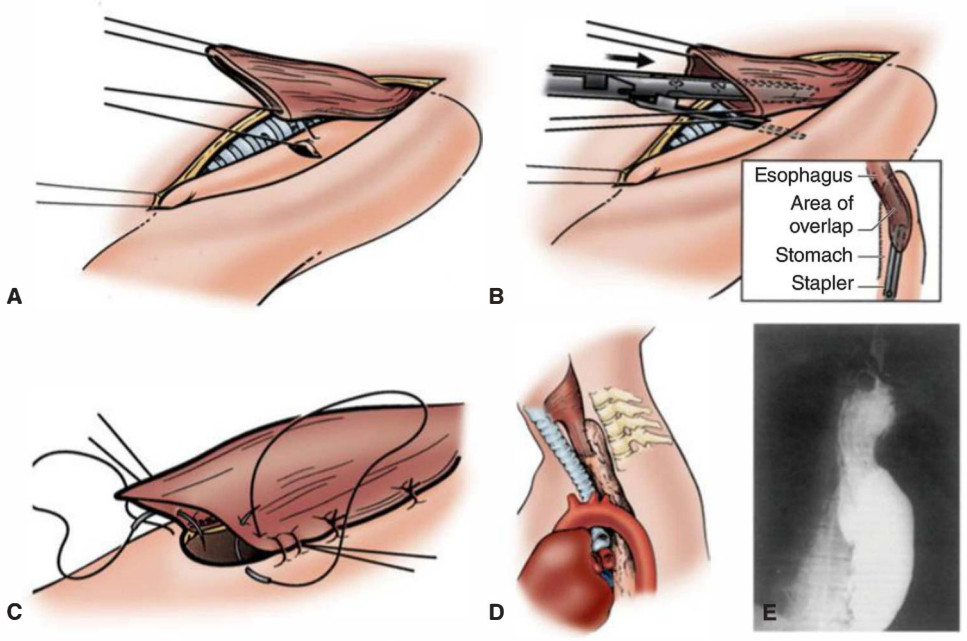

**FIGURE 16-8** Cervical stapled side-to-side anastomosis after transhiatal esophagectomy. **A.** The esophagogastrostomy is aligned using stay sutures. **B.** An Endo-GIA stapler is inserted. **C.** The semimechanical anastomosis is completed. **D.** The completed cervical side-to-side anastomosis. **E.** Postoperative barium swallow. (Reproduced with permission from Orringer MB, Marshall B, Iannettoni MD. from retraction with not compromising key components of the esophagectomy including avoiding trauma to the gastric conduit, adequately unrolling the stomach so that it reaches to the neck without tension, making an adequate mediastinal tunnel to avoid venous congestion of the conduit, and performing an adequate gastric drainage procedure. Further prospective studies are needed to determine if there are significant differences in costs, complication rates, and postoperative pain and recovery.

***Outcomes/Prognosis.*** Five-year survival for patients with esophageal carcinoma remains poor at less than 15 percent. Tumor stage and lymph node status are the strongest predictor of survival. Other factors associated with a poor prognosis include increased age, African American race, lower esophageal tumors, and increasing length and depth of the tumor. Five-year survival greater than 80 percent can be seen after esophagectomy for early lesions limited to the mucosa, and early diagnosis continues to be the best strategy for improving survival. Overall, esophagectomy is potentially curative in 20 percent of patients.

Orringer et al. reported the largest experience with transhiatal esophagectomy in 2007 patients.[24] When comparing group I (1976–1998) and group II (1998–2006), there was a significant decreases in in-hospital mortality (4 vs. 1 percent). A gastric conduit was used in 97 percent of patients and only 4 percent of patients in group II required intensive care postoperatively. Complications included recurrent nerve palsy (<1 percent), atrial fibrillation (6.6 percent), and pneumonia (2 percent). The incidence of anastomotic leak decreased from 14 to 9 percent in group II ($p$ <0.001) and correlated with the introduction of the side-to-side cervical esophagogastric anastomosis in 1997.[25] Ninety-four percent of those with leaks were treated with wound packing alone. Chylothorax occurred in less than 1 percent and should be treated aggressively with thoracic duct ligation. Fifty percent of patients in group II were discharged at 1 week with a median length of stay of 8 days. In cancer patients, functional results were good in 80 and 75 percent reporting no regurgitation or dumping. Fifty-two percent of patients in group II underwent neoadjuvant chemoradiation. A complete pathologic response was found in 21 percent of patients with a significant improvement in 5-year survival of 58 percent in complete responders compared with 22 percent for those with residual disease.

***Hospital Volume.*** Several studies have evaluated the relationship of hospital volume to outcomes after a variety of complex procedures including coronary artery bypass grafting, aortic aneurysm repair, heart transplantation, and pancreatic resections. Esophagectomy is technically demanding, and outcomes have been shown to be related to hospital volume. Dimick et al. reviewed 1136 patients in a Maryland statewide database and found that high-volume centers, defined as hospitals performing greater than 15 esophagectomies per year, had a fivefold reduction in hospital mortality.[28] Kuo et al. found similar results in 1193 patients in Massachusetts with a 2-day decrease in length of stay and a 3.7-fold decrease in hospital mortality in centers performing greater than six esophagectomies per year.[29] Outcomes have also been associated with the experience of the individual surgeon. Miller et al. found a significant decrease in hospital mortality rates in patients treated by surgeons who perform greater than six esophagectomies per year.[30]

## CONCLUSIONS

The evaluation and management of esophageal cancer continues to present a significant challenge for the thoracic surgeon. The incidence of EAC has increased rapidly and is the fastest growing solid malignancy in the United States. Although advances have been made in surgical techniques and postoperative care resulting in significantly improved perioperative mortality rates, the overall prognosis for patients with esophageal carcinoma remains poor and highlights the need for novel diagnostic, staging, and treatment modalities.

## ESOPHAGEAL CANCER BOARD REVIEW QUESTIONS (CHAPTER 16)

1. Which of the following risk factors is LEAST associated with the development of esophageal squamous cell carcinoma?

   A. Molybdenum deficiency
   B. Diet high in N-nitrosamines
   C. Achalasia
   D. Alcohol use
   E. Obesity

2. The best diagnostic study for evaluating the extent of tumor invasion (T stage) is?

   A. PET scan
   B. CT scan
   C. Endoscopic ultrasound
   D. Barium swallow
   E. Bronchoscopy

3. Which of the following is true regarding the use of neoadjuvant chemoradiation?

   A. The majority of randomized studies have not found a significant difference in survival.
   B. Neoadjuvant treatment is used to downstage tumors in patients with invasion of surrounding structures such as the aorta.
   C. Patients with T1 tumors are most likely to achieve a complete response.
   D. Complete response is a good prognostic factor and is seen in 64 percent of patients.
   E. Surgery should be performed within 2 weeks of neoadjuvant therapy to minimize postradiation adhesions.

4. Which of the following is true regarding Barrett mucosa?

   A. Barrett mucosa is a precursor to esophageal adenocarcinoma and is congenital in origin.
   B. Esophageal adenocarcinoma can develop within short segment Barrett mucosa.
   C. Barrett mucosa is a risk factor for esophageal squamous cell carcinoma.
   D. Patients with Barrett mucosa require close follow-up every 3 months.
   E. Barrett mucosa develops in 40 percent of patients with long-standing reflux.

5. Which of the following is true regarding a transhiatal esophagectomy?

   A. A narrow gastric conduit is preferable.
   B. Esophagectomy is potentially curative in 20 percent of patients.
   C. The gastric conduit is based on the left gastroepiploic artery.
   D. Esophagectomy is contraindicated in patients with carcinoma that has metastasized to one periesophageal lymph node.
   E. Neoadjuvant radiation alone is indicated in patients with T3 tumors or greater.

## ANSWERS

1. **Answer: E.** Nutritional deficiencies, including low levels of vitamins A, C, and riboflavin as well as mineral elements such as selenium, zinc, and molybdenum, have been found to contribute to the pathogenesis of esophageal squamous cell carcinoma (ESCC). High levels of N-nitrosamines in pickled vegetables and preserved meats have also been associated with ESCC, and several studies have linked alcohol and tobacco use with the development of ESCC. Other predisposing conditions include long-standing achalasia, caustic injury, tylosis, and Plummer–Vinson syndrome. Obesity has been associated with the development of esophageal adenocarcinoma.

2. **Answer: C.** CT can determine the local extent of disease when there is bulging or thickening of the airway or involvement of the aorta. However, CT, PET, and barium swallow cannot distinguish the layers of the esophageal wall. EUS provides the most accurate assessment of the depth of tumor invasion, or T stage, and is able to identify five distinct layers in the esophageal wall. Bronchoscopy is useful in evaluation for airway involvement by tumors in the upper or middle thirds of the esophagus.
3. **Answer: A.** Tumors directly invading the aorta are not resectable, and neoadjuvant therapy is not indicated in patients with T1 tumors who can proceed directly to resection. A complete response is a good prognostic sign and occurs in approximately 20 percent of patients with a significant improvement in survival. Surgery should be performed approximately 5 to 6 weeks after chemoradiation, although it is important to wait until the patients have returned to their baseline function prior to proceeding to esophagectomy. This provides sufficient time for edema to resolve, for restaging imaging to be performed, and prior to the onset of radiation fibrosis. Although most randomized trials have not shown a significant improvement in survival, two meta-analyses have shown a slight increase in overall survival with a hazard ratio (HR) of 0.81.
4. **Answer: B.** Barrett mucosa is a premalignant lesion that increases one's risk of developing esophageal adenocarcinoma (EAC) by 30- to 125-fold. Approximately 12 to 18 percent of patients with gastroesophageal reflux will have Barrett mucosa on endoscopy. Barrett can be continuous or discontinuous, and cancer can develop in short-segment Barrett. Endoscopic follow-up is important for the early detection of carcinoma and can be performed every 3 years as long as no dysplasia is found on two consecutive endoscopies.
5. **Answer: B.** Patients with distant metastatic disease are not candidates for esophagectomy. However, patients with regional nodal disease should undergo resection after neoadjuvant treatment with the removal of any clinically positive lymph nodes. Overall, esophagectomy is potentially curative in 20 percent of patients. Patients with early-stage disease or complete response after neoadjuvant therapy have the best prognosis. The gastric conduit is based on the right gastroepiploic artery and should be greater than 6 cm in width to preserve collateral circulation.

*Lee Plantmason*
*Natalie Lui*
*Pierre Theodore*

## KEY CONCEPTS

- Epidemiology
  - Thymic tumors are the most common primary neoplasm of the anterior mediastinum, accounting for about 20 percent of anterior mediastinal masses. Their peak incidence is in middle-aged adults between the ages of 30 and 50 years. Although lymphomas are the most common neoplasm of the mediastinum, primary mediastinal lymphomas are rare and account for less than 10 percent of lymphomas. Mediastinal germ cell tumors, including both seminomas and nonseminomas, account for about 20 percent of anterior mediastinal masses and, with the exception of teratomas, occur almost exclusively in males. All of these tumors have a peak incidence in young adults in their third decade of life. In general, extragonadal germ cell tumors are rarely primary tumors, with the mediastinum frequently being a site of metastasis.
- Pathophysiology
  - Pathophysiologic processes range from the antibody-mediated effects of myasthenia gravis (MG) seen with thymoma to the mass effects of tumors as noted in superior vena cava (SVC) syndrome. The primary mediastinal lymphomas include Hodgkin, non-Hodgkin, and lymphoblastic lymphomas. Seminomas, which occur exclusively in men, are generally malignant but highly responsive to treatment, whereas nonseminomas can range from benign teratomas that have a very low percentage of malignant transformation (<1 percent) to primary mediastinal nonseminomatous germ cell tumors that have a very poor prognosis.
- Clinical features
  - The majority of patients with thymoma are asymptomatic at presentation with an incidentally discovered mass on imaging. Those who do present symptomatically have symptoms associated with local compression or invasion, such as chest pain, cough, or dyspnea. About one-half of patients with thymoma have MG and present with muscle weakness, diplopia, ptosis, or blurry vision. Lymphomas commonly present with "B-type" symptoms of fever, night sweats, weight loss, and malaise, in addition to mediastinal compression symptoms. Most patients with seminomas and nonteratomal nonseminomas present with systemic endocrine changes such as gynecomastia. In contrast, most patients with teratomas will have compression of nearby structures causing cough and dyspnea, or direct connection with the bronchial tree causing expectoration of teratoma contents.
- Diagnostics
  - The primary diagnostic modalities include plain radiography, computed tomography (CT), magnetic resonance imaging (MRI), radionuclide scans, serum markers, and biopsy.
- Treatment (medical/surgical)
  - Treatment of thymoma includes complete surgical resection. Patients with larger malignant tumors (>8 cm) often receive neoadjuvant chemotherapy, and patients with Masaoka Stage III or IV often receive comprehensive treatment with chemotherapy, radiotherapy, and surgery. Treatment of MG includes immunosuppression with prednisolone, cyclosporine, and azathioprine; rituximab and cyclophosphamide for severely drug-resistant patients; cholinesterase inhibitors such as pyridostigmine; plasma exchange; and thymectomy. Treatment of lymphomas includes chemotherapy, radiotherapy, and immune modulators such as rituximab. Treatment of teratomas is surgical resection. Treatment of seminomas is cisplatin-based chemotherapy. For patients suffering from relapse, high-dose chemotherapy with autologous stem cell transplantation is suggested. In general, surgical resection is not performed for relapse due

to the excessive morbidity from the desmoplastic reaction induced by chemotherapy. Treatment of nonseminomas includes chemotherapy and surgical excision for residual disease, given the poor results noted with salvage chemotherapy.

- Outcomes/Prognosis
  - Most patients with thymoma can expect a favorable outcome, while patients with concomitant MG can expect a normal life expectancy with more than 70 percent noting remission or marked improvement in symptoms with oral corticosteroids alone. Patients with early-stage Hodgkin disease can expect five-year survival rates of greater than 90 percent and remission rates of 70 percent. Patients with non-Hodgkin lymphoma have less favorable outcomes; those with low, low-intermediate, high-intermediate, and high risk disease have five-year overall survival rates of 73, 51, 43, and 26 percent, respectively. The five-year survival rate for seminomas is 88 percent, while the survival rate for nonseminomas varies depending on the primary location of the tumor. Five-year survival rates of 45 percent have been noted; for patients with recurrence, the salvage rate is less than 10 percent.

## INTRODUCTION

The mediastinum is a complicated space associated with a variety of malignant and nonmalignant processes. Due in part to the confinement by the taut mediastinal pleurae, disease of this space may progress rapidly, compress vital structures, or be associated with fulminant inflammatory processes in need of surgical intervention. In this regard, "benign" processes such as infection or traumatic injuries of the mediastinum can be significant threats to the patient.

The mediastinum is the space between the thoracic inlet superiorly, vertebral column posteriorly, sternum anteriorly, and diaphragm inferiorly. The lateral borders of the mediastinum are the mediastinal pleurae. With the exception of the lungs, which lie in the pleural space, all contents of the thorax lie within the mediastinum.

It is useful to consider the mediastinum in terms of three compartments that also serve to organize disease processes, which tend to be localized to one compartment or another (Table 17-1).

**TABLE 17-1: Differential Diagnosis by Mediastinal Subcompartment**

| | |
|---|---|
| Anterior mediastinum | Thymic tumors (thymomas, thymic carcinomas, thymic carcinoid, lipomas), cysts (pericardial cysts), germ cell tumors, lymphomas, intrathoracic thyroid tumors, parathyroid tumors, soft tissue tumors (lipomas, liposarcomas, rhabdomyosarcoma, and hemangiomas) |
| Middle mediastinum | Proximal airway tumors, paraganglioma (chemodectoma), bronchogenic cysts, lymphomas, lymphadenopathy (inflammatory or malignant) |
| Posterior mediastinum | Neurogenic tumors, esophageal tumors, esophageal duplication cysts, esophageal diverticula, hiatus hernia, diaphragmatic hernia, neurenteric cysts |

The *anterior–superior mediastinum* contains blood vessels (the transverse aortic arch, innominate artery, origin of the left common carotid artery, innominate veins, and the upper portion of the superior vena cava), peripheral nerves (the vagus, phrenic, and left recurrent laryngeal nerves), as well as the trachea, esophagus, thoracic duct, thymus, and some lymph nodes.

The *middle mediastinum* contains the pericardium and heart, the ascending aorta, junction of the superior vena cava with the right atrium, junction of the superior vena cava and the azygos vein, tracheal bifurcation, mainstem bronchi, proximal pulmonary artery and bifurcation, confluences of the left and right pulmonary veins, phrenic nerves adjacent to the pericardium, and the peritracheal and subcarinal lymph nodes. The middle mediastinum is bordered posteriorly by the pericardium.

The *posterior mediastinum* runs parallel to the vertebral column behind and is bounded anteriorly by the pericardium, inferiorly by the diaphragm, and laterally by the mediastinal pleurae. It contains the descending aorta, azygos and hemiazygos veins, esophagus, thoracic duct, splanchnic nerves, and lymph nodes.

Surgical approaches to the mediastinum differ based on compartment, and the differential diagnosis for clinical phenomena in this irregularly shaped space is often organized based on location (Fig. 17-1).

The risk of malignancy is about two-thirds for anterior mediastinal masses, compared to 15 to 20 percent for posterior mediastinal lesions.[1]

Embryologically, the space arises from the combination of the ventral and dorsal mesenteries of the esophagus. During embryonic life, the dorsal mesoesophagus supports the esophagus, dorsal primitive aortas, and the cardinal veins in addition to lymphatics and both sympathetic trunks. The ventral mesoesophagus contains the lungs, pericardium, and the heart. The penetrating vessels to the esophagus that arise with the mesoesophagus and the direct lymphatic drainage to the thoracic duct (perhaps contributing to the early systemic spread of esophageal cancer) are clinically relevant anatomic findings that relate directly to the embryogenesis of the mediastinum.

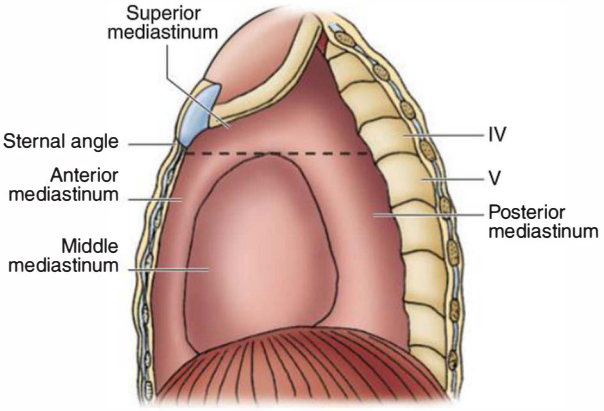

**FIGURE 17-1** Mediastinal compartments. The plane defining the inferior border of the superior mediastinum runs from the sternal angle to the junction of T4 and T5. For the purpose of discussion, the anterior and superior mediastinum are often combined.

# NONMALIGNANT MEDIASTINAL DISEASE

## Mediastinal Infections

### PNEUMOMEDIASTINUM

Pneumomediastinum may derive from injury or perforation of the proximal tracheobronchial tree or the esophagus. It is an emergent condition given the risk of rapid progression to life-threatening mediastinitis with contamination of the confined space lying between the pleurae.

Limited, spontaneous pneumomediastinum (SPM) in the absence of symptoms of systemic infection is generally managed conservatively with bedrest, analgesics, and cough suppressants, as well as prophylactic antibiotics to reduce the possibility of secondary mediastinitis. In general, spontaneous pneumomediastinum does not require surgical intervention. Complications, such as tension pneumomediastinum, delayed pneumothorax, or airway compromise, are rare. The challenge is to differentiate cases of benign spontaneous pneumomediastinum from those associated with more ominous diagnoses such as transmural tears of the esophagus or tracheal injury. The key differentiator lies in the absence of symptoms referable to a finding that is effectively an incidental radiologic observation.[2]

***Outcomes.*** Comparisons of patients with different etiologies of SPM have not been published, nor are there studies analyzing risk factors in patients with SPM. Patients developing pneumomediastinum secondary to barotrauma in the ICU have been noted to have 27 times higher mortality risk compared with other underlying conditions. Ventilator-induced barotrauma is an independent prognostic factor for hospital mortality. Secondary pneumomediastinum resulting from blunt force thoracic trauma has a more favorable outcome in comparison with pneumomediastinum associated with prolonged ventilation, poorly compliant lungs, and subsequent barotrauma.[3]

***Prognosis.*** Mortality rates of 10 and 13 percent have been noted among trauma patients with pneumomediastinum.[2] In ventilator-induced barotraumas, mortality rates of 55 and 65 percent have been noted in patients with mediastinal emphysema and pneumothorax, respectively.[3]

### ACUTE MEDIASTINITIS

***Treatment.*** Acute mediastinitis is a surgical emergency for which medical therapies serve an adjunctive role only. Surgical correction of the source of the mediastinal contamination, debridement of infected tissues, and, in certain cases, diversion of the esophagus are the keys to a successful outcome. Antibiotic administration, fluid resuscitation, invasive monitoring, and hemodynamic support are principal nonsurgical measures.

***Outcomes.*** Outcomes are dependent on host risk factors that might contribute to the development of deep surgical site infections, including obesity, diabetes mellitus, ischemia (following the use of bilateral internal thoracic artery grafts, for example), advanced age, female sex, chronic lung disease, active smoking, prolonged mechanical ventilation, the use of steroids, and preoperative hospital stay longer than 5 days.[1]

***Prognosis.*** Postoperative mediastinitis occurs in 1 to 3 percent of patients undergoing median sternotomy, and its associated mortality has been reported to be as high as 40 percent.[2]

### CHRONIC MEDIASTINITIS

Once symptoms for both granulomatous and fibrosing (also known as sclerosing) mediastinitis have ensued as a result of obstruction and compression of mediastinal structures, no medical therapy has been shown to be of uniform benefit, nor have surgical corrections been met with much success. Antifungal agents, steroids, and immunosuppressive agents are used for both etiologies, while studies have shown that tamoxifen can be effective in the medical treatment of fibrosing mediastinitis. The effectiveness of steroid therapy has been controversial.[4]

### SUPERIOR VENA CAVA OBSTRUCTION

***Treatment.*** Treatment is directed at either symptomatic alleviation or the underlying cause. First-line therapy is classically surgery or stenting procedures. Traditional medical treatment has included systemic steroids (prednisolone or dexamethasone) and diuretics. For patients with SVC obstruction due to malignancy, chemoradiotherapy is used. Steroids are generally given in conjunction with radiotherapy

because of the concern for radiation-induced edema. Radiotherapy can take two to four weeks to show effect and has significant rates of complications, including radiation-induced esophagitis and pneumonitis. A systematic review by Rowell et al. found complete relief of the symptoms of SVC obstruction in 77 percent of patients with small-cell lung cancer and 60 percent with non–small-cell lung cancer at two weeks.[5] For patients with SVC obstruction due to intravascular thrombus associated with an indwelling catheter, removal of the catheter and anticoagulation is standard. However, the efficacy of short- or long-term anticoagulation therapy is unclear. Although thrombolytic agents have been used effectively in patients with vena caval thrombosis, most experts recommend anticoagulation after thrombolysis (to prevent disease progression and recurrence) and aspirin after stent placement in the absence of thrombosis.

***Outcomes.*** Outcomes are dependent on the underlying cause. Despite treatment with radiotherapy or chemotherapy, some patients fail to respond and symptoms persist. Systematic analysis noted a 17 percent recurrence rate.[5]

***Prognosis.*** Reported recurrence rates are 18 to 20 percent. Recurrence can be due to either persisting tumor mass or SVC thrombosis.[6] In some patients, SVC obstruction may relapse after a period of time despite a good initial response.

### CASTLEMAN DISEASE

Castleman disease or benign B-cell hyperproliferation, often associated with HIV infection, involves lymphadenopathy within the mediastinum.

***Treatment.*** Surgery is the mainstay of treatment for both multicentric and unicentric disease. For multicentric Castleman disease, variable treatment modalities have been used, including lymphoma-based chemotherapeutic regimens such as cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP), immunotherapies such as interferon alpha, and monoclonal antibodies such as rituximab. For unicentric Castleman disease, chemotherapy is usually unnecessary.[7,8] For locally advanced, unresectable, unicentric Castleman disease, neoadjuvant radiotherapy of 40 to 50 Gy is used to facilitate radical resection. No randomized controlled trials have been conducted to definitively characterize optimal treatment because of the infrequency of the diagnosis; case reports are predominant in the literature.[7,8]

***Outcomes.*** For unicentric disease, complete resection has been reported to be curative and recurrence is rare. For multicentric disease, outcomes are significantly worse, but the true difference is unclear because treatment strategies vary.[9]

***Prognosis.*** For patients with resectable unicentric disease, treatment is curative. For patients with multicentric disease, the median survival is two to three years.[9]

## MEDIASTINAL DISEASE BY COMPARTMENT

### Anterior Mediastinal Masses

The anterior–superior compartment is the most common site for mediastinal masses, and the majority of these masses are malignant. Lymphomas, thymomas, and germ cell tumors are the leading diagnoses in this compartment. Less frequently, masses may be of endocrine origin, lipomas, infections, vascular malformations, or other rare neoplasms.

Characteristics of the masses on imaging may suggest a diagnosis, but a complete history and physical examination add valuable information. Symptomatic patients are more likely to have a malignant mass than asymptomatic patients. Constitutional symptoms suggest lymphoma or an endocrine tumor. Weakness with repetitive muscle use suggests myasthenia gravis (MG) with associated thymoma. Cardiothoracic symptoms such as chest pain, cough, dysphagia, or hoarseness suggest compression by the tumor. On physical examination, findings of neck masses, lymphadenopathy, evidence of SVC syndrome, or testicular masses all add valuable information to the working diagnosis. Laboratory evaluation for endocrine disease, paraneoplastic syndromes, or tumor markers such as beta human chorionic gonadotropin (β-hCG) and alpha-fetoprotein (AFP) may have a role. The standard imaging of a chest x-ray and CT scan may be supplemented with nuclear imaging by SESTAMIBI or positron emission tomography (PET) scanning for endocrinologically active tumors such as thyroid masses, parathyroid adenomas, and thymic carcinoid.

The role of biopsy for anterior mediastinal masses, particularly thymomas, is controversial because of the possibility of tumor seeding. In addition, even with CT or ultrasound guidance, the fine-needle aspiration (FNA) may produce a false-negative biopsy. Finally, the pathologist may not be able to differentiate thymoma from lymphoma on the basis of an FNA sample. Core biopsy allows more tissue for evaluation, and despite earlier concerns about the use of cutting needles for mediastinal biopsies, it is now generally accepted as safe. Surgical biopsy, which can often be obtained through a small anterior mediastinotomy (Chamberlain incision), permits accurate diagnosis when clinical history, radiographs, and percutaneous biopsy are not determinant.

### LYMPHOMA

Lymphomas are the most common neoplasm of the mediastinum, although primary mediastinal lymphomas are rare and account for less than 10 percent of lymphomas. The most common types of lymphomas found in the mediastinum include Hodgkin, non-Hodgkin, and lymphoblastic lymphomas. B-cell lymphomas arise when errors occur during critical processes of B-cell development, such as V(D)J recombination, somatic hypermutation, and class switch recombination, which are involved in light- and heavy-chain formation and DNA modification. Largely curable, Hodgkin lymphoma (HL) is most common in the third decade of life

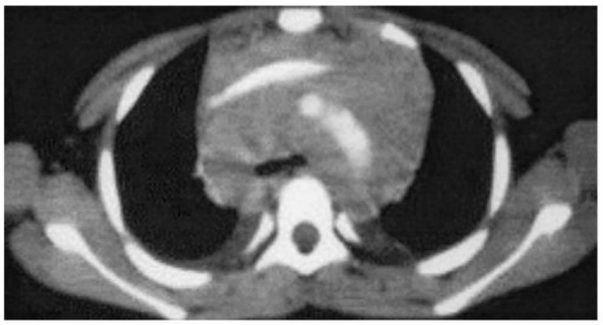

**FIGURE 17-2** Computed tomography of a lymphoma in the anterior mediastinum.

but has a bimodal peak at 15 to 34 years and over 60 years. Hodgkin lymphoma outcomes are predicted according to the International Prognostic Score. The most common histologic types in order of incidence are classical Hodgkin lymphoma (nodular sclerosis, mixed cellularity, lymphocyte-predominant, and lymphocyte-depleted types) and nonclassical Hodgkin lymphoma (nodular lymphocyte-predominant). Non-Hodgkin lymphoma (NHL) is a heterogeneous group of malignancies seen at all ages but is most concentrated in patients greater than 50 years of age. In addition, patients with HIV/AIDS are at increased risk for NHL. Lymphoblastic lymphoma is a rare and aggressive neoplasm of immature B-cells committed to the B-cell or T-cell lineage that primarily affects children but can also be seen in adults with a median age of 39 years (Fig. 17-2).

***Treatment.*** Patients with early-stage Hodgkin lymphoma are treated with two to four cycles of doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) followed by involved-field radiotherapy (IF-RT) with 30 Gy.[2-5] In advanced HL, administration of six to eight cycles of chemotherapy optionally followed by radiotherapy of residual disease is the treatment of choice. Recently bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP) are being used, particularly for high-risk patients. An optimal treatment regimen for Hodgkin lymphoma has not been determined; at this time, chemotherapy alone or various combinations of chemotherapy and radiotherapy are associated with high overall survival rates. Meta-analysis has suggested chemotherapy plus radiotherapy is superior to chemotherapy alone, although side effects and the development of secondary malignancies in younger patients continue to be a concern.[4-5] Currently, ABVD remains the gold standard of chemotherapy although increasing data note that using the aggressive BEACOPP regimen has improved survival in advanced stages. Mustargen, oncovin, procarbazine, and prenisone (MOPP) and MOPP/ABVD have been replaced due to concerns for toxicity, while European groups are increasingly using BEACOPP.[10]

NHL treatment strategies are based on histology and World Health Organization staging criteria. The current standard of care for first-line chemotherapy is cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP). For patients with follicular NHL or diffuse large B-cell lymphoma, the addition of anti-CD20 rituximab is considered standard therapy. Monoclonal antibodies and integration of radioimmunotherapy as part of initial therapy are being investigated at this time.

***Outcomes.*** The five-year survival rate for patients with early-stage Hodgkin lymphoma has consistently been greater than 90 percent, with complete remission occurring in more than 70 percent.[11] ABVD-based treatments have noted five-year recurrence rates of 61 to 66 percent and five-year overall survival rates of 73 to 83 percent. Unfortunately, 30 to 40 percent of patients with advanced stage Hodgkin lymphoma experience treatment failure requiring salvage high-dose chemotherapy or autologous stem cell transplantation.[12] Patients presenting with mediastinal manifestations, despite the lack of a unified system of categorization, are defined as high risk according to most standards. For patients older than 60 years, treatment options have been limited due to increased susceptibility to the toxic effects of intensive therapy and often comorbid conditions.[13]

Patients with low-grade NHL are likely to respond to standard treatment regimens with subsequent relapse, although the duration of relapse decreases with each subsequent treatment. For patients with low-grade NHL, autologous bone marrow transplantation can lead to complete remission although long-term follow-up is required for determination of cure rate. For patients with intermediate- to high-grade NHL that does not go into remission or relapse, the prognosis is poor.[15]

***Prognosis.*** In accounting for all stages of HL, the five-year survival rate is greater than 90 percent. However, more patients die from treatment-related complications than from progressive or recurrent lymphoma. Secondary malignancies occur at roughly one percent per year for 30 years after treatment and are particularly high among young women (age <30 years) who received thoracic radiation. Between 30 and 40 percent of these women will develop breast cancer in the 25 years posttreatment.[14] In addition, cardiac disease due to radiotherapy and chemotherapy has been noted to be significantly increased for more than 25 years posttreatment, with increased rates of coronary artery disease, myocardial injury, valvular disease, and pericardial fibrosis.

For diffuse large B-cell lymphoma, the original International Prognostic Index (IPI) created in 1993 is still used to predict outcomes for patients. For patients in low, low-intermediate, high-intermediate, and high risk categories, the five-year overall survival rates are 73, 51, 43, and 26 percent, respectively. A revised version was created by Sehn et al. to account for the introduction of rituximab. For patients in very good, good, and poor risk categories, the four-year estimated progression-free and overall survival rates are >90, >80, and >50 percent, respectively. Currently, the original IPI remains the validated and definitive measure for assessing risk.

## THYMOMA

***Epidemiology and Pathology.*** The thymus plays an important role in immunologic development in early life and then begins to involute in adolescence. Thymic tumors are rare in children, and are most common in middle-aged adults. About 20 percent of anterior mediastinal masses are of thymic origin. The term thymoma refers to neoplastic growth of the thymic epithelial cells. The vast majority of thymomas are well-encapsulated neoplasms that are considered benign and cause clinical disease as a result of compression of surrounding structures or through a variety of neoplastic syndromes. There are two main types of malignant thymomas that are histologically and biologically different. The first type is histologically identical to a benign thymoma except it has violated its capsule and is capable of invasion of surrounding tissues or distant metastasis. Despite this spread, the tissue lacks features commonly associated with malignancy including increased mitotic activity. The second type is a thymic carcinoma and is histologically different from the encapsulated thymomas. These tumors are rare and aggressive, and they have a poor prognosis. The most frequently used classification system is one based on the scale developed by Masaoka and colleagues in 1981. This system stages the tumor on the basis of histologic examination of the capsule and does not consider the size of the tumor. An intact capsule is stage I, transcapsular invasion with or without invasion of adjacent tissues is stage II, invasion of adjacent organs is stage III, and involvement of the pleura, pericardium, or distant metastasis is stage IV. The World Health Organization has developed a staging system based on tumor cell type.

***Clinical Presentation.*** The clinical presentation of thymomas varies. The majority of patients are asymptomatic with an incidentally discovered mass. Some patients may be symptomatic due to local compression or invasion, whereas others have a mass discovered during an evaluation for paraneoplastic syndromes. The most common association is thymoma with MG. About half of patients with thymoma have MG, but the vast majority of patients with MG do not have thymoma.

***Investigation.*** Classic thymomas have a characteristic appearance on chest computed tomography; they are smooth contoured masses that are well defined and encapsulated, and some may have cystic changes. Invasion of an encapsulated mass into nearby structures suggests a malignant thymoma. Thymic carcinoma is characterized by irregular borders, and metastases are frequently present at the time of presentation.

All patients with thymoma should be evaluated for MG. A careful history and physical examination looking for progressive muscle weakness with repetitive exertion should be performed. The role of preoperative biopsy remains controversial. The main concern is seeding the tumor along the needle track or into the mediastinum as drop metastases. In addition, small amounts of tissue or specimens obtained by FNA may be insufficient to distinguish thymoma from lymphoma. In the absence of invasion into local structures, resection alone is generally offered. For a larger mass, a careful biopsy may assist with operative planning or neoadjuvant therapies (induction chemotherapy or chemoradiation).

***Treatment.*** The treatment of choice in a patient with thymoma is removal of the entire thymus gland. An expanding number of surgical approaches exist for resection. The traditional median sternotomy (partial or full) provides ideal exposure and a minimum of morbidity. Recently, smaller well-encapsulated tumors have been resected via camera-guided minimally invasive approaches including robot-assisted thymectomy. For larger tumors or tumors with local invasion, an anterior thoracotomy or even a bilateral anterior thoracotomy with transverse sternotomy (clamshell incision) is employed. Larger malignant tumors (>8 cm) may benefit from neoadjuvant chemotherapy to improve the chances of complete resection. Debulking operations are unlikely to provide significant benefit and should generally not be performed. An exception occurs when bilateral phrenic nerve entrapment is found intraoperatively. To avoid bilateral vocal cord paralysis, residual tumor adjacent to one recurrent laryngeal nerve may be left in hopes that postoperative radiotherapy or chemotherapy may provide local control.

The Masaoka and WHO staging systems both correlate with prognosis and outcomes. Stage-specific overall survival for patients with stage III cancers is significantly lower than that for patients with stage I or II disease. However, in patients with stage III disease who undergo successful, microscopically margin-negative (R0) surgical resection, five-year survival rates approach that of patients with stage I disease (80 vs. 75 percent for stage III disease).[16] For patients with more advanced disease (stage III or greater), complete surgical extirpation (including contiguous resection of lungs, pericardium, and/or great vessels) with negative margins is more challenging. Most patients with early-stage disease undergo R0 resection, but only 50 to 60 percent of patients with stage III thymomas taken directly to surgery actually achieve microscopically negative margins. If not, additional therapy as an adjunct to surgery plays a role.[16]

A reasonable approach how and best to use multidisciplinary care is based on the National Comprehensive Cancer Network Guidelines (version 2.2011) for thymic malignancies.[17] Patients with stage I to IIB disease undergo immediate surgical resection, with adjuvant radiotherapy reserved for pathologic capsular invasion or microscopically positive margins (R1 resection). If the final pathology reveals a thymic carcinoma, adjuvant chemotherapy should also be included. Patients who present with stage III to IVA disease proceed to surgery if deemed eligible for resection by a multidisciplinary team of experts. However, if it seems unlikely that R0 resection can be achieved initially, an induction chemotherapy or chemoradiation should be used, followed by restaging and consideration of surgical resectability. If eligible for resection, the patient proceeds to surgery and adjuvant therapy can be considered as described for the early-stage patients; if the thymoma is unresectable, definitive chemoradiation is performed.[17]

## MYASTHENIA GRAVIS

Initial treatments for MG are the acetylcholine (ACh) esterase inhibitors, such as pyridostigmine, which inhibit the breakdown of ACh at the neuromuscular junction, thus increasing the availability of ACh to stimulate ACh receptors (AchR) and facilitate contraction. AChR antibody-positive early-onset patients with generalized MG and insufficient response to pyridostigmine therapy should be considered for thymectomy, ideally within one year of disease onset. Patients with associated thymoma should have a thymectomy. In general, patients with MG and thymomas do not respond as well to thymectomy as do patients with MG without thymomas.[18] In addition, immunosuppressive medication should be considered in all patients with progressive MG symptoms. Patients are usually started on prednisolone, as well as bisphosphonate, antacids, and azathioprine to prevent osteoporosis and gastrointestinal complications. Observational studies over the past 30 years have noted remission or marked improvement in 70 to 80 percent of patients with MG treated with oral corticosteroids, usually prednisolone.[19] For patients intolerant of this regimen, treatment with another immunosuppressive drug should be considered. Short-term immunotherapy, specifically plasmapheresis and intravenous immunoglobulin (IVIG), has been noted to have short-term benefit although there are no adequate randomized controlled trials to quantify its benefit. Retrospective studies have shown that plasmapheresis is valuable in lessening symptoms during initiation of immunosuppressive drug therapy, during an acute crisis, and as a short-term treatment in severe cases to induce remission and in preparation for surgery. However, there is currently insufficient evidence on the efficacy of plasmapheresis in the treatment of myasthenic crisis or MG before thymectomy. IVIG has been noted to have a positive effect in the acute phase of MG. However, in mild or moderate MG, no significant different in efficacy between IVIG and placebo, or between IVIG and methylprednisolone, was found at 6 weeks. Currently, there is not sufficient evidence for definitive selection of second-line drug therapy. In general, azathioprine may be used if insufficient remission is achieved with steroids, followed by cyclosporine and mycophenolate, while rituximab and cyclophosphamide are used only in severely drug-resistant patients. Azathioprine is recommended with steroids to allow tapering of the steroids to the lowest dose possible. Its onset of therapeutic response may take 4 to 12 months, and its maximal effect is at 6 to 24 months. Cyclophosphamide, an alkylating agent, is also effective.

## GERM CELL TUMORS

***Epidemiology and Pathology.*** Both seminomas and nonseminomas, including teratomas, occur in the mediastinum and compromise approximately 20 percent of anterior mediastinal masses. All forms of these tumors have a peak incidence in young adults. These tumors are thought to be the result of pluripotent germ cells that fail to migrate from the mediastinum to the gonads during early development.

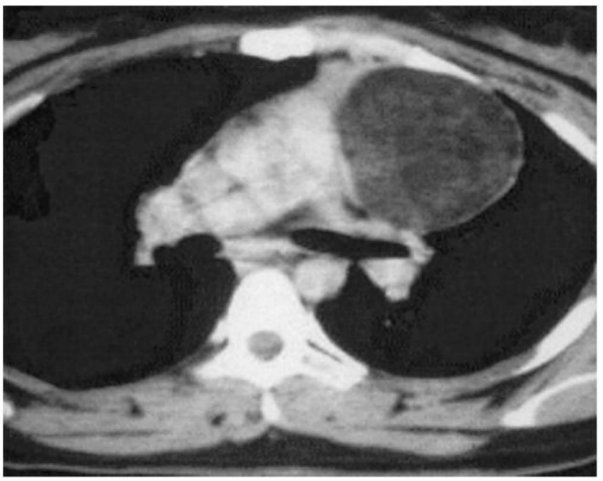

**FIGURE 17-3** Computed tomography of a mediastinal germ cell tumor.

Mediastinal germ cell tumors are pathologically identical to the gonadal germ cell tumors. Extragonadal germ cell tumors are rarely primary tumors, and the mediastinum is a frequent site of metastasis. The other common extragonadal sites are the retroperitoneum and the brain. Therefore, any mediastinal germ cell tumor, except mature teratomas, should prompt a search for an occult primary in the gonads, retroperitoneum, or brain (Fig. 17-3).

## SEMINOMAS

Seminomas are rare, occur exclusively in men, and are generally malignant but highly responsive to treatment. The tumors are composed of cells that appear similar to spermatogonia but are nonfunctional. Most patients are symptomatic at time of presentation. Some of these tumors contain syncytiotrophoblastic cells that secrete β-hCG, although serum levels may be undetectable. These tumors never secrete AFP.

***Treatment.*** The established treatment according to the International Germ Cell Cancer Collaborative Group (IGCCCG) criteria consists of three to four cycles of cisplatin-based chemotherapy, either four cycles of neoadjuvant etoposide and cisplatin, or three cycles of bleomycin, etoposide, and cisplatin (BEP). These regimens have durable response rates of 81 to 92 percent and favorable toxicity profiles.[20,21] For intermediate seminomas, defined as those tumors with nonpulmonary visceral metastasis, the standard regimen is four cycles of BEP.[22] For patients who relapse after initial chemotherapy, standard doses of three-drug combinations based on ifosfamide and cisplatin or high-dose chemotherapy with autologous stem-cell support are used. No randomized controlled trials have been conducted to compare treatment modalities, but improved outcomes have been noted with paclitaxel, ifosfamide, and cisplatin, plus either vinblastine or etoposide.[23] Post-chemotherapy

surgical resection of seminomas is technically difficult due to the desmoplastic reaction induced by chemotherapy and in general is not done.[24]

***Outcomes.*** A large retrospective study by Bokemayer et al. from 11 United States and European cancer centers noted no significant difference in progression-free and overall survival between mediastinal and retroperitoneal seminomas. Five-year objective remission rate (ORR) and overall survival rate were 92 and 88 percent, respectively. The presence of nonpulmonary visceral metastases significantly decreased overall survival, with five-year progression-free and overall survival rates of 67 and 72 percent, respectively.[22]

## NONSEMINOMAS

Nonseminomas arise from embryonal tissue and include embryonal carcinoma, teratocarcinoma, choriocarcinoma, yolk sac tumors, and benign teratomas. If a tumor has components of both seminoma and embryonal tissue it is called a mixed germ cell tumor and is included in this category as well. With the exception of benign teratoma, these tumors are more frequent in men, are almost always malignant, and are more likely to have metastasized to nearby tissue and lymph nodes than seminomas. Histologically, many of these tumors contain either yolk sac cells that secrete AFP, syncytiotrophoblastic cells that secrete β-hCG, or both. Most patients will have elevated serum levels of these hormones, which are useful for both diagnosis and following response to treatment.

Teratomas are the most common of the germ cell tumors and have a different epidemiology, histology, and biology than the others. These tumors occur equally in men and women, are generally benign and consist of at least two of the three embryologic layers: endoderm, mesoderm, and ectoderm. A mature teratoma has differentiated into mature somatic structures such as skin, bone, teeth, fat, and epithelial tissue. Less than one percent undergo malignant transformation. An immature teratoma also contains tissue from multiple embryonic layers, but the tissues are similar to fetal tissue and are at greater risk of being malignant. Benign mature teratomas should be surgically removed and pathologically examined for evidence of occult cancer within the tumor (Fig. 17-4).

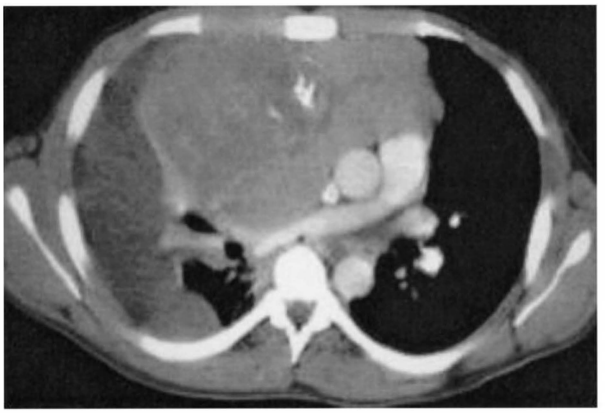

**FIGURE 17-4** Computed tomography of a mediastinal teratoma containing a well-differentiated structure (tooth).

***Clinical Presentation.*** Benign teratomas often come to attention either through compression of nearby structures, or through a connection with a bronchus that leads to expectoratation of contents of the teratoma. Seminomas and nonseminomatous tumors may present with symptoms of local compression or with symptoms of systemic endocrine changes such as gynecomastia. Nonseminomatous tumors have a known association with Klinefelter syndrome.

***Investigation.*** Any man with an anterior mediastinal mass should have serum β-hCG and AFP levels drawn. In addition, once the diagnosis of germ cell tumor is made, a thorough investigation for an occult primary tumor and other metastases should be undertaken, including physical examination of the testes or ovaries for masses, and imaging of the retroperitoneum and brain.

***Treatment.*** Treatment consists of four cycles of BEP followed by surgical resection. After cisplatin-based chemotherapy for primary mediastinal nonseminomatous germ cell tumors (PMNSGCT), a residual mass in the mediastinum is usually present; only infrequently does pathology demonstrate complete tumor necrosis. Surgical removal of residual disease after chemotherapy has been advocated due to the poor results noted with salvage chemotherapy. Currently, using etoposide, ifosfamide, and cisplatin (VIP) is being investigated for initial chemotherapy due to the significant pulmonary toxicity and therapeutic equivalency of BEP.[25]

***Prognosis.*** PMNSGCT, although histologically identical to their more common testicular counterparts, have a distinctly worse prognosis and therefore have been designated as poor-risk nonseminomatous germ cell tumors along with other subsets of testicular nonseminomatous germ cell tumors. In addition, the presence of nonpulmonary metastases, β-hCG >50,000, AFP >10,000, or LDH >10-times normal all suggest a poor prognosis.[22] Patients with retroperitoneal or gonadal primary sites have better prognosis than patients with primary mediastinal GCT. With the incorporation of four cycles of cisplatin-based chemotherapy, retrospective analyses have noted ORR of 40 to 80 percent and a survival rate of 30 percent. Two prospective studies of 31 and 41 patients noted a long-term survival of greater than 50 percent after cisplatin-based chemotherapy plus surgery, while Bokemeyer et al. noted a long-term survival rate of 48 percent.[26]

***Outcomes.*** For mediastinal nonseminomas, prognosis is poor compared to primary gonadal and retroperitoneal nonseminomas, with five-year overall and progression-free

survival of 45 and 44 percent, respectively. For patients with recurrence, the salvage rate has been noted to be less than 10 percent with cisplatin-based chemotherapy. Consequently, surgical resection plays an important role in salvage treatment when no effective chemotherapy is available.[25]

## THYMOLIPOMA

This rare tumor is a neoplasm of the thymic fat and is usually benign. Its classic appearance on chest imaging is a large mass of fat with areas of normal thymus tissue scattered throughout. This tumor does not invade surrounding tissue, but can grow quite large and compress surrounding structures. Large tumors should be resected for this reason.

## THYMIC CARCINOID

***Treatment.*** Surgical resection is the primary treatment modality for thymic carcinoids with additional chemotherapy and radiotherapy used as needed for advanced disease. Due to the relative rarity of the disease and lack of randomized controlled trials, standardized treatment has not been established. For patients with early-stage disease, chemotherapy either before or after adjuvant radiotherapy deserves strong consideration considering the aggressive nature of the disease (Fig. 17-5). For patients with locally advanced disease, neoadjuvant treatment with chemoradiation may offer the potential for downstaging and increased resectability. There are no studies investigating the use of neoadjuvant chemoradiation followed by aggressive resection, but there are case reports establishing feasibility.[18] For patients with advanced thymic carcinoids that cannot be completely resected, neoadjuvant or adjuvant systemic treatment is required, often in combination with radiotherapy. A case report by Filosso et al. describes treating a patient with bulky thymic carcinoid with 45 Gy radiation concurrently with four cycles of cisplatin and etoposide; complete resection was achieved.[27] Cisplatin-based regimens, such as cisplatin, adriamycin, and cyclophosphamide (PAC), are used most often. Evidence supporting radiotherapy in the adjuvant, neoadjuvant, or definitive setting is limited; case series and case reports suggest that the addition of postoperative radiotherapy may improve local control following complete resection. Tiffet et al. published a case series of 12 patients, of whom nine patients had an R0 resection. Three of the nine patients received adjuvant radiotherapy, and none had a local recurrence. Six of the nine patients did not receive adjuvant radiotherapy, and four had a local recurrence.[28] Surgery followed by radiation offers a reasonable probability of local control, but these patients remain at high risk for metastatic disease. A multimodality approach to treatment is worth considering. Targeted molecular therapy is increasingly being used; inhibitors of c-kit, epidermal growth factor receptor (EGFR), and various receptor tyrosine kinases have been reported in small studies with mixed results.[29]

**FIGURE 17-5** Computed tomography of a thyroid carcinoma in the superior mediastinum.

***Prognosis.*** Thymic carcinoids have a poor prognosis, are locally aggressive, and have demonstrated metastatic rates ranging from 40 to 82 percent.[30] Completeness of resection is a strong prognostic indicator. In the largest series to date, overall five- and 10-year survival was 28 and 10 percent, respectively.[18]

***Outcome.*** Outcome data are limited due to the small series of patients studied; relapses or progressive disease can be expected to occur in 10 to 30 percent of patients. In 20 to 30 percent of these patients, objective remissions can be achieved by cisplatin-based regimens after relapse-free intervals. Approximately 50 percent of patients with an advanced malignant thymoma or thymic carcinoma will be candidates for second-line treatment.[18]

## THYROID

Substernal goiter is the most common mass in the superior mediastinum and can be found in up to 20 percent of goiter operations. These masses are generally benign. Most patients come to attention for treatment of a neck mass that extends substernally. The extent of the mass can be determined by CT scan or nuclear imaging. Complications from the mass include compression of the trachea or esophagus, compression of the recurrent laryngeal nerve, or compression of the neck veins impeding drainage of blood from the head and neck. Surgical treatment is indicated if there is compression of important structures and if radioactive iodine treatment fails. Rarely, a partial median sternotomy is required if removal of the substernal goiter cannot be accomplished through the traditional cervical approach.

### PARATHYROID

Ectopic parathyroid glands may be located in the mediastinum, including the pericardium and the recurrent laryngeal nerve. Patients come to attention because of hyperparathyroidism, and may have had a failed parathyroidectomy in the neck. Ninety-nine percent of parathyroid adenomas are benign, but surgery is indicated to cure the hyperparathyroidism. The surgical approach will be dictated by location of the active gland, which is determined by nuclear imaging; most can be accessed through a cervical incision. Intraoperative and postoperative measurements of parathyroid hormone can assist with determining whether all affected glands have been removed. On gross examination, parathyroid adenomas will be enlarged but well encapsulated. In contrast, parathyroid carcinoma is characterized by a larger-than-expected firm gland that is unencapsulated and adheres to surrounding tissues.

## Middle Mediastinal Masses

Because the categorization of compartments of the mediastinum does not reflect true anatomic divisions, any of the masses of the anterior or posterior mediastinum can present as a middle mediastinal mass. However, the most common masses of the middle mediastinum are benign cysts that form during early development associated with the pulmonary system, pericardium, or esophagus. Mediastinal lymphadenopathy may appear as a mass in this compartment and may be related to primary tumors such as lymphoma, lymphatic metastases of primary lung or esophageal cancers, or other processes related to infection or inflammation. In addition, large vessels in the mediastinum may develop aneurysms that can appear as mediastinal masses on chest imaging. Using intravenous contrast with CT imaging or performing angiography will identify these structures as vascular.

Symptoms are common with masses in this compartment as cysts may cause compression or obstruction of important structures, or may become infected. Children are symptomatic more often than adults because of their smaller intrathoracic volume. Laboratory tests are generally normal. After the initial chest x-ray and CT scan of the chest, there is often a role for transthoracic or transesophageal ultrasound. Ultrasound may further characterize whether the cysts are simple or complex, and biopsies or drainage may be accomplished using this technology.

### BRONCHOGENIC CYSTS

Bronchogenic cysts are formed during one of two abnormalities of fetal development. Most commonly, they form as aberrant budding from the foregut's ventral surface and are located posterior to the carina or a main stem bronchus. Otherwise, they form as abnormal budding from the tracheobronchial tree. They are usually simple cysts, lined with respiratory epithelium, filled with serous or mucus fluid, and surrounded by smooth muscle and cartilage that limit their growth. Generally they are discrete and do not communicate with the respiratory tree, but communication is possible and it increases the risk of the cyst becoming infected. Because of their limited intrathoracic space, neonates are more likely to present symptomatically than older children or adults with cysts of the same size. Cysts in adults are often discovered incidentally. These cysts are generally benign, although there is a small risk of malignant transformation.

Evaluation includes a CT scan of the chest to further characterize the cyst. A simple fluid-filled cyst in the expected location is classic. Evidence of a septated cyst or one with aberrant features needs further evaluation. An air–fluid level suggests communication with the tracheobronchial tree or infection. If there are concerns about a cyst, transbronchial biopsy and aspiration of cyst contents for pathologic analysis is an option prior to surgery.

***Treatment.*** Traditionally, all cysts were removed via thoracotomy for three main reasons: (1) a substantial percentage of asymptomatic patients eventually become symptomatic, (2) if the cyst becomes infected, the formation of adhesions complicates removal, and (3) there is a small but finite risk of malignant transformation. Currently, many cysts can be removed by minimally invasive techniques such as video-assisted thoracic surgery, which reduces operative morbidity. In addition, small simple cysts that are asymptomatic may be observed and removed if symptoms develop.

If the cyst is removed surgically, the entire cyst should be removed. Any remnant cyst wall that cannot be removed should be cauterized if possible to avoid recurrence. For a poor surgical candidate, the cyst can be drained through a transbronchial aspiration, and then filled with alcohol or bleomycin to promote fibrosis and prevent reaccumulation of fluid.

### PERICARDIAL CYSTS

Pericardial cysts are the second-most common type of mediastinal cysts and form during embryologic development as a discrete cyst composed of a single layer of mesothelial cells. They are most commonly located at the right costophrenic angle and are often asymptomatic. Rarely, pericardial cysts rupture into the pericardial cavity and cause cardiac tamponade. Even more rarely, these cysts grow to a size that impairs the right ventricular outflow tract, causing critical hypotension and death. If patients are asymptomatic, the cyst may be observed. If patients are symptomatic, the cyst can be treated by aspiration under fluoroscopy, or operative decompression. Because of the typical location of the cysts, minimally invasive techniques will generally be useful.

### ESOPHAGEAL DUPLICATION CYSTS

Esophageal duplication cysts are the least common of the mediastinal cysts. Whereas bronchogenic cysts bud from

the ventral aspect of the developing foregut, esophageal duplication cysts bud from the dorsal aspect. The cyst lining is composed of acid-secreting digestive tract epithelium, and the cyst may be outside of the esophageal wall or encompassed within it. Rarely, the duplication cyst buds from dorsal foregut under conditions that place it in proximity to the developing spinal cord, creating a "neurenteric cyst" that integrates both enteric and neural tissue in the cyst structure.

The clinical presentation of patients with symptomatic esophageal cysts includes chest pain or dysphagia as a result of esophageal compression. Possible complications of esophageal cysts include infection, esophageal perforation, and hemorrhage. Patients with neurenteric cysts may also have neurologic symptoms related to involvement of the spinal cord. Investigation of a suspected esophageal cyst is by chest CT and endoscopy. If a neurenteric cyst is suspected, an MRI may offer better imaging of any spinal cord involvement.

Treatment is surgical resection of the entire cyst and is offered to all patients who are appropriate surgical candidates. In contrast to bronchogenic cysts that may be observed, esophageal duplication cysts have a serious risk of complications, making surgical resection the standard of care. A neurenteric cyst resection involves coordination between thoracic surgeons and neurosurgeons.

## Posterior Mediastinal Masses

The posterior compartment contains the paravertebral gutters and masses in this location are most often of neurogenic origin. Other masses include esophageal cysts, including neurenteric cysts, esophageal malignancy, and diaphragmatic hernia. In children, this compartment is by far the most common site for mediastinal masses, which are likely to be symptomatic and malignant. In adults, masses in this compartment are less common than anterior mediastinal masses, and they are more likely to be benign.

### NERVE SHEATH TUMORS

Nerve sheath are generally of two types: the more common schwannomas and less common neurofibromas. Schwannomas, also known as neurilemmomas, are benign tumors of the Schwann cells that are firm and encapsulated. They grow slowly, are generally only found in adults, and are unlikely to undergo malignant transformation into neurofibrosarcomas. In contrast, neurofibromas are slow-growing tumors of the peripheral nerve sheath, involve multiple cell types including Schwann cells and fibroblasts, and are soft and not encapsulated. They are associated with neurofibromatosis type 1 (NF1), also known as von Recklinghausen disease. Malignant peripheral nerve sheath tumors may occur spontaneously or as a result of transformation of a benign tumor. Risks for malignant transformation include NF1 or prior irradiation of the area. These tumors are poorly differentiated sarcomas and may invade locally as well as spread hematogenously.

Patients with these tumors present with radiculopathy and neurologic symptoms from spinal cord compression. Patients with malignant tumors may have episodes of hypoglycemia arising from the release of an insulin-like hormone from the tumor. Multiple neurofibromas are a strong indicator of underlying NF1 disease. MRI may offer additional information over the CT images.

Benign peripheral nerve sheath tumors are treated surgically through either posterior thoracotomy or a minimally invasive technique. The primary treatment of malignant peripheral nerve sheath tumors continues to be surgical resection, but active research into possible chemotherapeutic treatments holds promise for these patients.

### NEUROBLASTOMA

Neuroblastoma is a congenital malignancy of neural crest cells that arises from the adrenal medulla or sympathetic ganglia. Tumors may develop anywhere along the spine, and approximately 20 percent are in the posterior mediastinum. The tumor is a malignancy of infants and young children, with most patients being diagnosed before five years of age. It is the most common extracranial solid tumor in children. The clinical course is varied and spontaneous remission is possible, but aggressive disease is not uncommon. Extraadrenal tumors, especially posterior mediastinal tumors, tend to be less aggressive. Children diagnosed before 12 months of age have better survival at all stages of disease than do older children, and they are more likely to undergo spontaneous regression.

Clinical presentations vary, and most children present with a palpable mass in the abdomen. For children with a posterior mediastinal mass, respiratory distress may be prominent. The tumors often have neuroendocrine activity, and diarrhea may occur if the tumor is releasing vasoactive intestinal peptide. A paraneoplastic syndrome associated with neuroblastoma is opsoclonus myoclonus syndrome, also called "dancing eyes and feet" syndrome, and some children have persistent neurologic deficits after treatment. Both diarrhea and opsoclonus myoclonus syndrome are rare, but are associated with improved prognosis.

Neuroblastoma often appears on imaging as a paravertebral shadow that may contain calcifications. Specifically in the posterior mediastinum, the tumor may cause splaying of the posterior ribs that is visible on chest x-ray. Evidence of vertebral pedical erosion may be present and suggests that the tumor may have extended into the spinal cord. Chest CT is the standard preoperative imaging, but MRI may be valuable if there is a concern about central nervous system involvement. PET scans offer useful information about presence of metastases.

The treatment for neuroblastoma is influenced by the biologic features of the tumor, the age of the child, and the stage of disease. Treatment protocols have been developed and generally follow the schema of surgery alone for

low-risk disease; surgery with chemotherapy for moderate-risk disease; and neoadjuvant chemotherapy, surgery, and myeloablative treatment followed by autologous stem cell transplant for high-risk disease. Radiation is not standard treatment, but may be offered to palliate symptoms for low- and moderate-risk disease.

### GANGLIONEUROMA

This tumor of neural crest origin is composed of mature ganglion cells that are well-differentiated and benign. The most common location is in the sympathetic ganglia of the posterior mediastinum. It is a disease of older children and young adults. Treatment is surgical and is expected to be curative.

### PARAGANGLIOMA

Tumors of the paraganglia are extraadrenal pheochromocytomas, and may occur in the posterior mediastinum. They are rare, usually benign, solitary, and may be associated with multiple endocrine neoplasia. Not all paragangliomas are functional, but those that are secrete catecholamines that cause the clinical syndrome of episodic hypertension, palpitations, sweating, and severe headache. Levels of serum or urine catecholamine metabolites are usually elevated. The majority of these masses are apparent on CT scanning, and appear vascular if intravenous contrast is given. Tumor invasion of adjacent structures suggests malignancy. Complete surgical resection is the treatment, and may be done with a minimally invasive approach. Because of the vascular nature of these tumors, intraoperative bleeding may be significant. Patients with functional tumors should receive α- and β-blocking agents preoperatively in the same manner as adrenal pheochromocytoma patients do.

## MEDIASTINAL DISEASE BOARD REVIEW QUESTIONS (CHAPTER 17)

1. Which of the following is true regarding thymomas?
   A. Thymoma classification is based on tumor size.
   B. The presence of myasthenia gravis is a risk factor for poor outcome.
   C. Neoadjuvant therapy can be used for large malignant tumors.
   D. Debulking operations are a mainstay of thymoma treatment.
   E. Fine-needle aspiration is the preferred method of diagnosis.

2. Which of the following is true concerning mediastinal anatomy?
   A. The junction of the superior vena cava and the right atrium is located in the anterior-superior mediastinum.
   B. The mediastinal space arises from a combination of the ventral and dorsal esophageal mesenteries.
   C. Neurogenic tumors commonly occur in the middle mediastinum.
   D. The lungs and pericardium arise from the dorsal mesoesophagus.
   E. Bronchogenic cysts are the result of aberrant budding from the dorsal foregut.

3. Which is true regarding neurogenic tumors of the mediastinum?
   A. The peak incidence of neuroblastoma is in early adulthood.
   B. Extraadrenal neuroblastomas are typically aggressive.
   C. Surgical resection of a neuroblastoma is usually not curative.
   D. The posterior mediastinum is the most common location for neuroblastoma.
   E. Paragangliomas are, by definition, nonfunctional tumors.

4. Which of the following is true regarding germ cell tumors?
   A. The mediastinum is the most common site of primary germ cell tumors.
   B. Nonseminomatous tumors are associated with Klinefelter's syndrome.
   C. Surgical removal of residual disease in nonseminomas is not indicated after chemotherapy.
   D. Malignant seminomas are highly resistant to treatment.
   E. Serial β-hCG and AFP levels are not useful after initial therapy.

5. Which of the following is correct?
   A. Prophylactic antibiotics are contraindicated in spontaneous pneumomediastinum.
   B. Treatment of acute mediastinitis is primarily medical, with surgery reserved for failure of medical therapy.
   C. Corticosteroid therapy has been shown to be highly effective for sclerosing mediastinitis.
   D. Anticoagulation after thrombolysis and aspirin after stent placement are recommended treatment guidelines for vena caval thrombosis.
   E. The majority of patients with superior vena cava syndrome have an underlying benign process.

## ANSWERS

1. **Answer: C.** Neoadjuvant chemotherapy is recommended for large malignant thymomas. Thymoma classification is based on histologic examination of the capsule and invasion. The presence of myasthenia gravis is not a risk factor for poor outcome. Debulking operations do not provide significant benefit in the absence of complete resection. Fine-needle aspiration is controversial and may fail to distinguish a thymoma from a lymphoma.
2. **Answer: B.** The mediastinal space arises from the ventral and dorsal esophageal mesenteries. The junction of the SVC and right atrium is located in the middle mediastinum. Neurogenic tumors most commonly occur in the posterior mediastinum. The lungs and pericardium arise from the ventral mesoesophagus. Bronchogenic cysts are the result of aberrant budding from the ventral foregut.
3. **Answer: D.** The posterior mediastinum is the most common location for neuroblastoma. The peak incidence of neuroblastoma is in infancy and early childhood. Extraadrenal neuroblastomas are typically less aggressive and surgical resection is usually curative. Some paragangliomas can secrete catecholamines.
4. **Answer: B.** Nonseminomatous tumors are associated with Klinefelter's syndrome. The mediastinum is the most common site of metastatic germ cell tumors. Serial β-hCG and AFP levels are useful after initial therapy, particularly for nonseminomatous tumors, and surgical removal of residual disease in nonseminomas is indicated if levels remain elevated. Malignant seminomas are highly responsive to treatment.
5. **Answer: D.** Anticoagulation after thrombolysis and aspirin after stent placement are recommended treatment guidelines for vena caval thrombosis. Prophylactic antibiotics are indicated in the initial treatment of spontaneous pneumomediastinum. Treatment of acute mediastinitis is primarily surgical. Corticosteroids have variable efficacy in sclerosing mediastinitis. The majority of patients with SVC syndrome have an underlying malignant process.

# 18 Chest Wall Tumors

*Robert A. Meguid*
*Malcolm V. Brock*

**KEY CONCEPTS**

- Epidemiology
  - Chest wall tumors constitute 5 percent of thoracic tumors and less than 1 percent of all primary tumors; between 40 and 60 percent are malignant. Tumors may originate primarily in the chest wall, may metastasize to it, or extend into it via local invasion from adjacent structures. Morbidity and mortality are specific to the particular tumor type.
- Clinical features
  - Chest wall tumors often present as painless enlarging masses, with pain developing with progressive growth. Constitutional symptoms may also develop.
- Diagnosis
  - After initial history and physical examination, radiographic imaging can reveal anatomic location, tissue of origin, involvement or invasion of adjacent structures, and ultimately the response to therapy or recurrence. Computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography-CT (PET-CT) are useful, dependent on the tissue type and location. Needle, incisional, or excisional biopsy is usually necessary to determine tissue type and aids in further management.
- Treatment
  - Multidisciplinary management is helpful given the rarity and diverse nature of chest wall tumors. Medical treatment varies with different tumor types. Chemotherapy and radiation therapy may be used.
  - Surgical treatment varies with different tumors types. In general, malignant tumors should be resected to negative margins including the uninvolved rib above and below the tumor. Chest wall reconstruction is necessary for defects greater than 5 cm and those resulting in exposure of vulnerable underlying structures, and aims at stabilizing the chest wall during respiration and excursion.
- Outcome/prognosis
  - Outcomes of the treatment are tumor-dependent. Long-term surveillance is accomplished with serial examination and imaging.

## INTRODUCTION

Tumors involving the chest wall are uncommon, constituting 5 percent of all thoracic masses and less than 1 percent of all primary tumors.[1] Tumors may originate primarily in the chest wall, may metastasize to it, or extend into it via local invasion from adjacent structures. As a group, chest wall tumors can be organized by their tissue of origin or occurrence and further divided into malignant and benign tumors. Chest wall tumors are listed in Table 18-1. In characterizing these tumors, we have identified them based on the tissue of origin in the chest wall, moving from the parietal pleura through the chest outward to the skin.

Malignant and benign primary chest wall tumors are roughly equally distributed with malignant lesions representing 40 to 60 percent of all chest wall tumors.[1,2] Of primary malignant chest wall tumors, chondrosarcomas occur with the most frequency, constituting approximately 35 percent.[3] Presenting with decreasing frequency are solitary myelomas (plasmacytomas) (25 percent), Ewing sarcomas (15 percent), osteosarcomas (15 percent), and lymphomas (10 percent).

The most common benign tumor of the chest wall is fibrous dysplasia, accounting for approximately 40 percent of cases. Chondromas are also common, constituting 30 percent of cases. Other, less frequently occurring benign chest wall tumors include osteochondromas, lipomas, desmoid tumors, neurofibromas, and giant cell tumors.

Metastases more commonly seen involving the chest wall include melanoma, breast carcinoma, lung carcinoma, renal cell carcinoma, and mesothelioma. Details of each tumor type and specific management strategies are discussed at the end of this chapter.

**TABLE 18-1: Chest Wall Tumor Types by Tissue of Origin**

| Tissue of Origin | Benign | Malignant |
|---|---|---|
| **Soft-tissue tumors** | | |
| Parietal pleura | Benign localized solitary fibrous tumor | Malignant localized solitary fibrous tumor<br>Mesothelioma |
| Bone, cartilage, and connective tissue | Fibrous dysplasia<br>Chondroma<br>Osteochondroma<br>Chondromyxoid fibroma<br>Langerhans cell histiocytosis<br>Aneruysmal bone cyst<br>Ossifying fibromyxoid tumor<br>Giant cell tumors | Chondrosarcoma<br>Osteosarcoma<br>Ewing sarcoma and primitive neuroectodermal tumor<br>Primary pleuropulmonary synovial sarcoma<br>Adamantinoma |
| Muscle | Leiomyoma<br>Rhabdomyoma | Leiomyosarcoma<br>Rhabdomyosarcoma |
| Nerve | Neurofibroma<br>Schwannoma (benign peripheral nerve sheath tumor)<br>Paraganglioma<br>Ganglioneuroma | Neurofibrosarcoma<br>Malignant peripheral nerve sheath tumor (malignant schwannoma)<br>Ganglioneuroblastoma<br>Neuroblastoma |
| Lymphovascular | Cavernous hemangioma<br>Glomus tumor<br>Lymphangioma | Angiosarcoma |
| Soft tissue | Desmoid tumor<br>Lipoma<br>Spindle cell lipoma<br>Elastofibroma<br>Other benign soft-tissue tumors<br>Cutaneous nevus | Malignant fibrous histiocytoma<br>Liposarcoma<br>Soft-tissue sarcoma<br>Proximal-type epithelioid sarcoma<br>Radiation-induced sarcoma<br>Skin cancer |
| Hematologic | | Lymphoma (primary)<br>Myeloma (plasmacytoma) |
| Common metastases to or invasion into chest wall | | Lung cancer<br>Breast cancer<br>Melanoma<br>Mesothelioma<br>Lymphoma (metastatic)<br>Renal cell carcinoma |

Infectious etiology is also possible, with primary pulmonary infections sometimes invading into the chest wall. These are most commonly due to fungal diseases, such as nocardia and actinomyces. Discussion of these infections is outside the scope of this chapter.

The clinical presentation of chest wall tumors varies from an incidentally found asymptomatic mass to a painful visible lesion. Initially, often chest wall tumors are asymptomatic, but as they continue to grow and invade the chest wall, pain is almost inevitable especially in malignant lesions. Workup begins with a history and physical examination, and includes axial imaging and often biopsy to establish tissue diagnosis. Management of rarely encountered tumors is aided by a multidisciplinary oncologic approach.

The aims of chest wall tumor resection are to achieve cure or control of the disease and to leave the chest wall stable enabling the patient to engage in the normal physiology of respiration, with a good quality of life. Management of chest wall tumors often poses the surgical challenge of resection, followed by closure or reconstruction of defects greater than 5 cm or involving two or more ribs. Reconstruction of the latter can be aided through the employment of composite prosthetic materials and techniques of rotational, advancement and free flaps with the assistance of surgeons trained in plastic reconstructive techniques.

## CLINICAL FEATURES

The presentation of chest wall tumors ranges from incidentally discovered painless lesions to painful enlarging masses. They are asymptomatic in 20 percent of patients, and local trauma is frequently the inciting event drawing attention to the presence of a lesion. The remaining 80 percent of patients present with

enlarging masses, local or adjacent pain, dyspnea, cough, and symptoms of neurologic or vascular involvement.[4] As these lesions involve a dynamic structure of the chest wall, patients may complain of exertion-related pain. Patients may also experience nonspecific symptoms including fatigue, muscle aches, night sweats, and weight loss. Painful chest wall masses are more likely to be malignant in nature due to more rapid growth of the former, as well as invasion into adjacent structures, rather than displacement of them.

## DIAGNOSIS

Suspicion of the presence of a chest wall tumor begins with obtaining a history and performing a physical examination of the patient. Patients may describe a history of chest or shoulder pain, dyspnea, new-onset cough, constitutional symptoms, swelling of the neck or head, ipsilateral ptosis, myosis, anhidrosis, and enophthalmos (Horner syndrome). History may also reveal prior malignancy.

Additional history should include temporal onset of the lesion, associated symptoms such as the quality and nature of the pain, presence of radiating pain, history of environmental exposures, such as asbestos or radiation, and history of constitutional symptoms including weight loss, change in appetite, dyspnea with or without exertion, fevers, chills, and night sweats.

Physical examination is focused on the area of interest, but it should also include examination for regional adenopathy, neural involvement, and musculoskeletal deficits. This includes location, size, appearance, and quality on palpation of the lesion, presence of any satellite lesions, ulcerations, or sinuses. Neurologic involvement may include nerves of the brachial plexus, the long thoracic nerve (with resulting winged scapula), or the sympathetic chain (with resulting Horner syndrome as already described). Auscultation of the chest may reveal diminished breath sounds or the presence of a rub associated with an effusion.

Although chest wall tumors are rare and varied, a combination of clinical information with appropriate imaging can suggest a specific diagnosis. Imaging can reveal anatomic location, tissue of origin, involvement or invasion of adjacent structures, and ultimately response to therapy or recurrence.

Following the history and physical examination, our workup algorithm proceeds to chest radiograph and computed tomography (CT), with the selective use of magnetic resonance imaging (MRI) for soft-tissue masses and concern for vascular or neurologic involvement by the tumor. The use of positron emission tomography-CT (PET-CT) is becoming more widespread in diagnosis of malignancies. We have included optimal modalities of imaging and characteristic radiographic findings of different chest wall tumors with the descriptions of each tumor type at the end of this chapter. In general, slow-growing, benign tumors displace adjacent tissues, with maintenance of well-defined tissue planes. More aggressive malignant tumors tend to invade adjacent tissues.

Chest radiography is commonly the first imaging modality performed in diagnosis and evaluation of patients with chest wall tumors, and is often performed prior to referral for evaluation by the thoracic surgeon. It may help characterize chest wall or pulmonary lesions, and may also identify incidental lesions. Although the value of the chest radiography in diagnosis and operative planning is limited, it may help characterize the location, size, and nature of the lesion, involvement of bony versus soft tissue, and presence of ossification or calcification. It also can be useful for following the growth of a chest wall lesion.[5] The use of ultrasound to define borders of tumors has been described but this is not our preferred modality.[6]

CT is useful in determining the location and size of the lesion as well as providing information on presence, and extent, of invasion of adjacent structures. It is more accurate than chest radiography in the assessment of tumor morphology. Additional techniques to elucidate tumors in the plane of the ribs include off-axial imaging with an angled gantry, or the use of thin-sectioning with breath-holding.[5] A contrast CT can provide information on the vascularity of a tumor, and help differentiate tissue planes and types.

The use of MRI for characterizing chest wall tumors is increasing. MRI has the ability to provide distinction of anatomic involvement, revealing subtle tissue planes, and can differentiate between tumor and adjacent inflammation. Information on invasion or encasement of vascular and neurologic structures, as well as characterization of the nature of the lesion, can be determined. It is specifically useful for characterization of soft-tissue masses. The use of cardiac gating and respiratory compensation can improve image resolution by minimizing motion artifact associated with respiratory excursion of the chest wall. Additional techniques include prone positioning of patients.[5] Due to these advantages, MRI is our preferred modality for evaluating chest wall tumors.

PET-CT is a useful adjunct for evaluating metabolic activity, especially in the setting of metastatic malignancies, and to assess lymph node involvement. It can also be used to stage soft-tissue sarcomas. In the setting of benign and slow-growing tumors, the degree of $^{18}$F-fluoro-2-deoxy-D-glucose (FDG) uptake may be mild as compared with faster-growing tumors. These data may aid in differentiating between tumor types and can assist in both the diagnosis as well as tumor staging.[7,8]

PET-CT is 96 percent accurate in the diagnosis of T-stage, N-stage, and M-stage of patients with bone and soft-tissue sarcomas. Accuracy of diagnosis of T-stage is increased to 99 percent using a combination of PET-CT, CT, MRI, Technetium-99m-hydroxymethylene diphosphonate bone scintigraphy, and plain radiography studies. Accuracy of diagnosis of N-stage and M-stage is increased to 97 percent using a combination of PET-CT with the other imaging modalities. PET scanning without the combination of CT imaging is accurate only in 80 percent of T-staging, 93 percent of N-staging, and 91 percent of M-staging of patients with bone and soft-tissue sarcomas. The overall accuracy

in diagnosis of PET-CT combined with other imaging modalities was 87 percent in the patients with bone and soft-tissue sarcomas.[8] Therefore, we use the combined modality PET-CT to aid in staging of bone and soft-tissue sarcomas.

Tissue diagnosis, in conjunction with staging, guides management of chest wall tumors. Diagnosis of smaller tumors, generally less than 5 cm in diameter, is confirmed by excisional biopsy with 1- to 2-cm margins. For larger lesions, and in tumors with involvement of adjacent structures, incisional biopsy is used. Principles for soft-tissue sarcomas apply in regards to positioning and orientation of the initial incision so that it may be included with the tumor specimen, should re-excision be necessary. Fine-needle aspiration can help in the diagnosis of some chest wall tumors, as noted later in the chapter, but is not reliably useful for determination of malignant potential and tumor grade of soft-tissue masses. Although core-needle biopsy can provide insight into tumor architecture, it is our experience that to obtain enough tissue to provide an accurate diagnosis and stage, which may require immunohistochemical staining in addition to histologic examination, excisional and incisional biopsies are preferable.

## STAGING AND PREOPERATIVE TESTING

There is currently no uniform staging system for all primary tumors occurring in the chest wall. The staging of chest wall tumors is based on the staging classification of the primary tumor type involved. Staging workup, therefore, is diagnosis-specific, and may entail additional imaging studies (CT or ultrasound of the abdomen, CT or MRI of the head), invasive studies (bronchoscopy, esophagoscopy, colonoscopy), and laboratory evaluation to rule out nodal and metastatic diseases.

Preoperative pulmonary function tests are routinely obtained, in this event, pulmonary resection is necessary to achieve tumor-free margins with en bloc resection. In addition, routine preoperative workup is performed to rule out comorbidities that may compromise a patient's ability to tolerate treatment or posttherapeutic outcome.

## MANAGEMENT

We favor a multidisciplinary approach to the management of malignant, complicated, and rare chest wall tumors. Regular review of patients with chest wall tumors at institutional tumor boards facilitates diagnosis and management, drawing on the experience of pathologists, radiologists, medical oncologists, radiation oncologists, and surgical oncologists. This is critical when considering the rare nature of chest wall tumors, given the overall scarcity of retrospective experience and prospective data on their management. We also find that it aids in the identification of patients who will most likely benefit from neoadjuvant and adjuvant chemotherapy and radiation therapy.

## INDICATIONS FOR RESECTION

Surgical management remains the mainstay of therapy for chest wall tumors. This is in part, to cure benign and limited malignant lesions, and in part, to aid in diagnosis and guide additional therapy. Specific recommendations for the management of different chest wall tumors are outlined later, accompanying the review of each tumor type.

Surgical therapy of malignant lesions typically necessitates wide local excision with confirmation of histologically negative tissue margins. In general, full-thickness resection, including skin, if involved, is performed. Resection often includes ribs and soft tissues from the interspace above and below the lesion. In the case of local invasion into adjacent tissues, including lung, heart, liver, kidney, spleen, diaphragm, and major neural and vascular structures, resection is indicated where possible, but involvement of "vital structures" may limit the ability to achieve tumor-free margins. Adhesions between chest wall and lung parenchyma are resected en bloc with the tumor, with preservation of as much adjacent lung parenchyma as possible while still achieving an adequate tumor-free margin. Therefore, the judgment of the surgeon is critical in the complex management of chest wall tumors.

## NONSURGICAL MANAGEMENT

Although the mainstay of curative therapy for chest wall tumors is margin-negative surgical resection, specific tumor types are treated primarily with chemotherapy and radiotherapy, and chest wall tumors presenting in advanced local stage are frequently treated with either adjuvant or even neoadjuvant therapy.

In addition, evidence of extension of disease into adjacent organs or cavities, or presence of metastases, may prohibit safe surgical resection or prevent it from achieving control of symptoms or cure. Consideration of the utility of surgery is especially critical for several circumstances, including patients with a large-tumor burden when it is unclear if the patient will tolerate the extent of resection such as pulmonary invasion necessitating large or bilateral lung resections, patients with distant metastases, or patients who are severely malnourished.

## CHEST WALL RECONSTRUCTION

The goal of reconstruction is to recreate a stable, nonparadoxically functioning chest wall, which will afford the patient minimal additional work to engage in efficient respiration, as well as efficient and comfortable excursion during activity. Reconstruction beyond primary tissue coverage is usually not necessary for defects involving a single rib, less than 5 cm in diameter, lying beneath the scapula or occurring posteriorly on the rib cage. However, following resection of anterior and lateral lesions with resulting chest wall

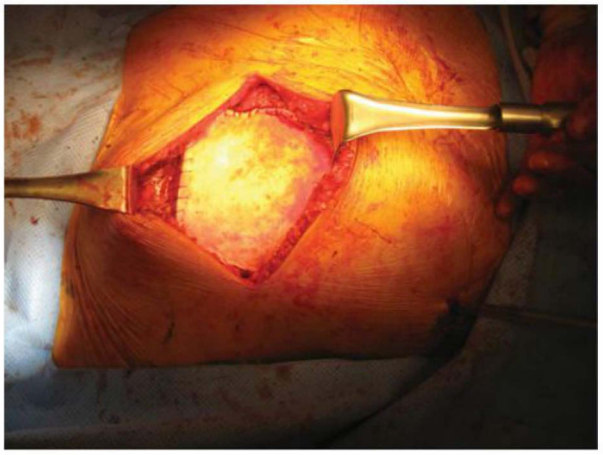

**FIGURE 18-1** Photograph of the reconstructed chest wall following resection of an 11.4-cm grade I chondrosarcoma with resection of medial aspects of the fourth through sixth ribs. Reconstruction was performed with 2 mm Gore Tex sutured to the borders of the defect. (Image courtesy of Douglas Wood, MD.)

**FIGURE 18-2** Reconstruction of the chest wall in a patient undergoing resection of recurrent chest wall sarcoma on the right chest. Right chest wall following initial resection and recurrence of tumor, with intraoperative planning and marking of landmarks. (Image courtesy Dan Suver, MD.)

defects greater than 5 cm in diameter, chest wall reconstruction should be performed. This also applies to defects resulting from the resection of two or more adjacent ribs, which can lead to chest wall instability. In addition, vulnerability of underlying structures should be considered. Specifically, sternal resections and those leading to exposure of the heart and great vessels should be reconstructed.

The chest wall is a dynamic structure with complex three-dimensional movement with respiration. Reconstruction using rigid material can lead to paradoxical movement. To maintain physiologic respiratory movement following chest wall reconstruction, nonelastic, pliable, permanent material such as polypropylene mesh (Marlex, Chevron Phillips Chemical Company LLC, The Woodlands, Texas, USA) or Gore Tex (W. L. Gore & Associates, Inc., Newark, Delaware, USA), with the advantage of being fluid impermeable, can be affixed to the ribs to fill defects (Fig. 18-1).[6] In addition, ribs can be replicated using metal plates anchored to the existing rib margins (Strasbourg Thoracic Osteosyntheses System—STRATOS™; MedXpert GmbH, Heitersheim, Germany), with polypropylene mesh affixed to them using nonabsorbable suture material, and the reconstructed chest wall covered with myocutaneous or muscle rotational flap. It is important to return the patient to a neutral position on the operating table during reconstruction, so that the mesh is not secured with the rib spaces expanded.

More rigid chest wall reconstruction can be achieved with methyl methacrylate sandwiched between two pieces of nonabsorbable mesh (Figs. 18-2, 18-3, 18-4, and 18-5). Reconstruction of a resected sternum may be accomplished with this polypropylene mesh–methyl methacrylate sandwich or with polypropylene reinforced with omentum.[9,10] This is useful when the heart or great vessels are exposed following medial costal or sternal resection. The use of steel wire mesh as a foundation for reconstructing large defects has been described in the past, but we do not favor its use.[11,12]

It is important to consider the location of the reconstruction relative to more dynamic areas of the chest wall. For example, posterior resections may allow the tip of the scapula to hang up on resected or adjacent ribs. In this instance, posterior reconstruction is necessary to preserve function of mobility of the arm and the scapula. Another example is in the inferior costal border. Here, we have found that rigid prostheses may be poorly tolerated when patients bend over onto them, and preferentially use Gore Tex or a flexible mesh.

**FIGURE 18-3** Reconstruction of the chest wall in a patient undergoing resection of recurrent chest wall sarcoma on the right chest. Reconstruction of resulting chest wall defect with polypropylene mesh-methyl methacrylate sandwich. (Image courtesy Dan Suver, MD.)

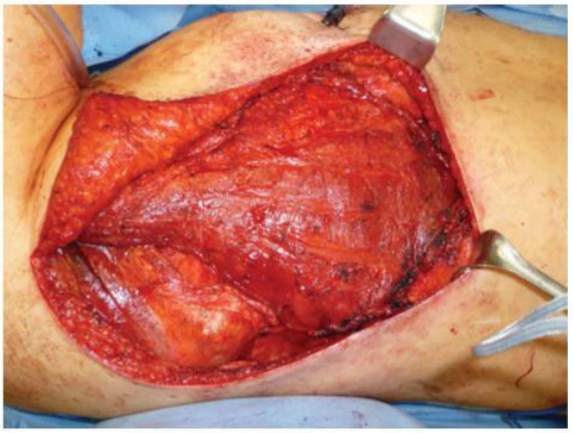

**FIGURE 18-4** Reconstruction of the chest wall in a patient undergoing resection of recurrent chest wall sarcoma on the right chest. Latissimus dorsi muscle flap overlying chest wall reconstruction. (Image courtesy Dan Suver, MD.)

The use of tissue transfer techniques, such as advancement skin flaps, skin grafting, rotational muscle flaps, and myocutaneous flaps, may aid in closure or coverage of large soft-tissue defects, especially when skin is involved, or in irradiated tissue beds. Based on location and extent of resection, useful muscle flaps include the pectoralis major, latissimus dorsi, and rectus abdominus (Figs. 18-6, 18-7, 18-8, and 18-9). We prefer to enlist the help of an experienced plastic reconstructive surgeon for large, complex repairs.

Reoperation for recurrences of chest wall tumors, following initial resection and reconstruction, poses a particular challenge. Not only must the further loss of chest wall tissue be managed, but also the adhesion between reconstructive prostheses and adjacent structures. Therefore, great care must be taken during dissection.

**FIGURE 18-5** Reconstruction of the chest wall in a patient undergoing resection of recurrent chest wall sarcoma on the right chest. Split-thickness skin graft overlying muscle flap. (Image courtesy Dan Suver, MD.)

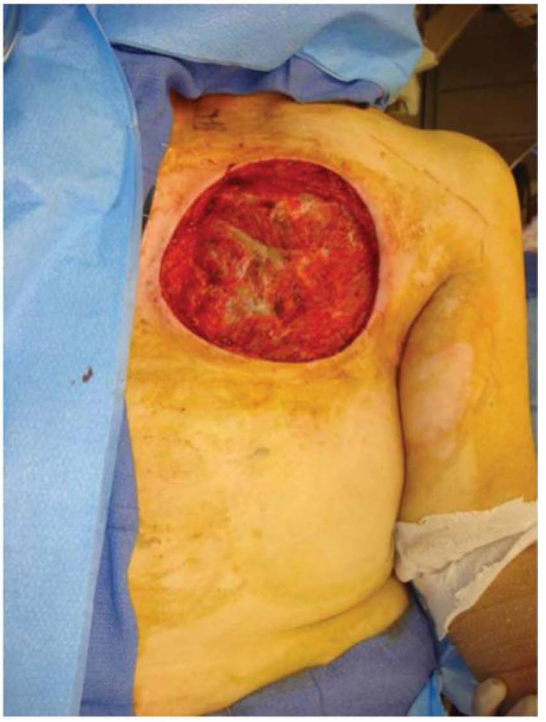

**FIGURE 18-6** Resection of recurrent chest wall sarcoma and reconstruction of anterior chest wall using a latissimus dorsi myocutaneous flap: resulting defect prior to reconstruction. (Image courtesy of Merhan Habibi, MD.)

**FIGURE 18-7** Resection of recurrent chest wall sarcoma and reconstruction of anterior chest wall using a latissimus dorsi myocutaneous flap: planning flap procurement. (Image courtesy of Merhan Habibi, MD.)

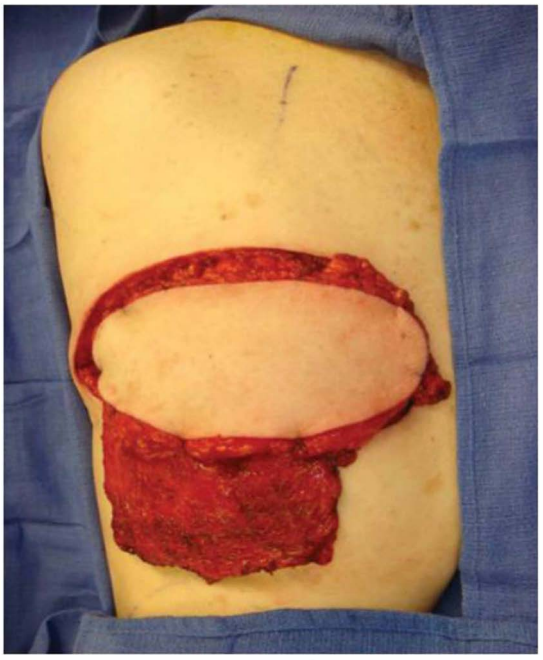

**FIGURE 18-8** Resection of recurrent chest wall sarcoma and reconstruction of anterior chest wall using a latissimus dorsi myocutaneous flap: preparation of latissimus dorsi myocutaneous flap. (Image courtesy of Merhan Habibi, MD.)

We have encountered various complications associated with chest wall reconstruction, including generalized inflammation, seroma formation, herniation of pneumatoceles, development of pleuroparenchymal fistulae, infection of the surgical site and prostheses, persistent drainage from sinuses associated with prostheses, and presence of enlarged lymph nodes that may be inflammatory or indicative of cancer recurrence.

Management of these can be challenging for the surgeon as well as the patient. In the setting of cancer cachexia, patients may not tolerate indolent complications or complex operations to treat them.

## SURVEILLANCE

Most primary chest wall tumors recur locally. Some also metastasize to the lungs, liver, or elsewhere, as described later. Long-term surveillance is achieved by serial examination of the patient and axial imaging. We generally see patients 2 to 4 weeks after the surgery, followed by clinic visits at 4- to 6-month intervals for 2 years, and then yearly for an additional 8 years, with a noncontrast chest CT obtained annually for 10 years. We engage in more frequent observation for aggressive tumors, and longer surveillance for more indolent tumors.

## TUMORS OF THE CHEST WALL

### Parietal Pleura

#### BENIGN

***Benign Localized Solitary Fibrous Tumor.*** Solitary fibrous tumors are spindle cell neoplasms, commonly of pleural origin, and lacking epithelial differentiation. Thoracic solitary fibrous tumors constitute two-thirds of solitary fibrous tumors, the remainder being extrathoracic in location.[13] Between one-quarter and one-third occur in the parietal pleura of the chest wall, diaphragm, or mediastinum, while the majority occur in the visceral pleura (Figs. 18-10, 18-11, 18-12, and 18-13).[14,15] Solitary fibrous tumors of the pleura are characterized by combinations of cellular, fibrous, and

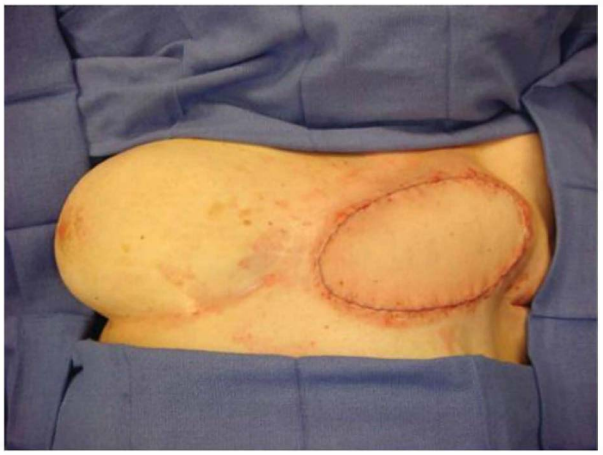

**FIGURE 18-9** Resection of recurrent chest wall sarcoma and reconstruction of anterior chest wall using a latissimus dorsi myocutaneous flap: following reconstruction with flap. (Image courtesy of Merhan Habibi, MD.)

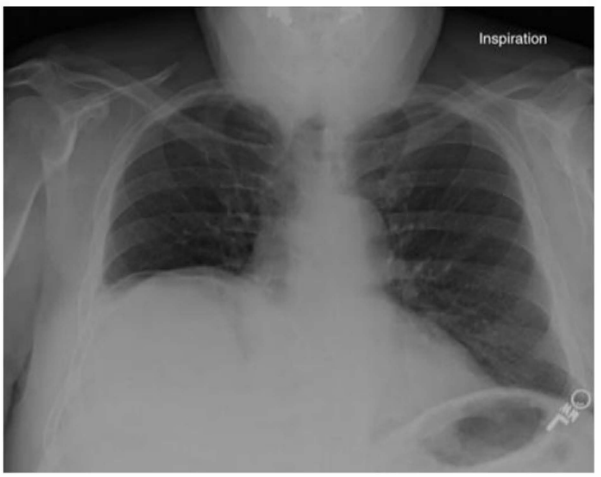

**FIGURE 18-10** PA chest radiograph of a 68-year-old man with a large right chest mass. Subsequent biopsy determined this to be a solitary fibrous tumor. (Image courtesy Douglas Wood, MD.)

**FIGURE 18-11** Lateral chest radiograph of a 68-year-old man with a large right chest mass. Subsequent biopsy determined this to be a solitary fibrous tumor. (Image courtesy Douglas Wood, MD.)

hemangiopericytomatous components, with fibrotic, thickened investing pleura.

Localized solitary fibrous tumors of the pleura occur equally in men and women, in all age groups but with preponderance to presentation in the sixth and seventh decades

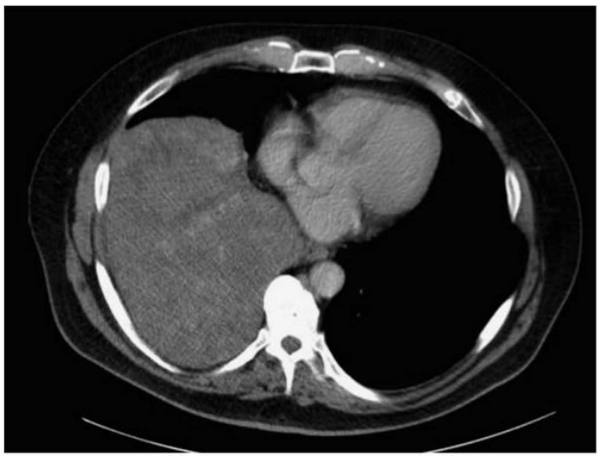

**FIGURE 18-12** Abdominal CT image of a 68-year-old man with a large right chest mass. This image demonstrates the size and location of the chest wall solitary fibrous tumor. Extirpation of the tumor required resection of adjacent lung parenchyma as well as diaphragm and a wedge of the right lobe of the liver, into which there was superficial invasion. (Image courtesy of Douglas Wood, MD.)

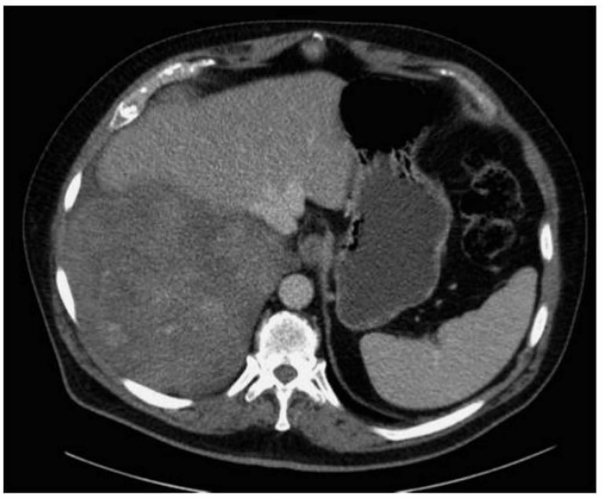

**FIGURE 18-13** Abdominal CT image of a 68-year-old man with a large right chest mass. This image demonstrates the size and location of the chest wall solitary fibrous tumor, with involvement of the liver. Extirpation of the tumor required resection of adjacent lung parenchyma as well as diaphragm and a wedge of the right lobe of the liver, into which there was superficial invasion. (Image courtesy of Douglas Wood, MD.)

of life. Patients with localized fibrous pleural tumors most commonly present with ipsilateral chest pain, dyspnea, and cough. They may rarely have ipsilateral pleural effusions, or vena cava compression with associated symptoms. Approximately one-quarter of patients are asymptomatic at diagnosis. On chest radiography, tumors may be evident as sharply circumscribed masses in the periphery of the lung fields, with homogeneous appearance on chest CT.[14] Following tissue diagnosis via core-needle biopsy or incisional biopsy, treatment is complete resection, which is usually curative.

## MALIGNANT

***Malignant Localized Solitary Fibrous Tumor.*** Malignant localized solitary fibrous tumors of the pleura are a subgroup of localized solitary fibrous tumors of the pleura, and for the most part share histologic features, presentation, and workup, with their benign counterparts, except as noted later. Localized solitary fibrous tumors of the pleura demonstrate malignant behavior in 10 to 36 percent of cases, with malignancy associated with larger tumors, tumors with increased cellularity, and nonpedunculated tumors, emphasizing the importance of adequate tissue sampling in cases of tumors with mixed components.[14]

Their presentation is also comparable with that of benign localized solitary fibrous tumors of the pleura. However, the presence of an ipsilateral pleural effusion is associated with approximately one-third of malignant localized solitary fibrous tumors of the pleura, which is significantly greater than that in their benign counterparts.[14]

Approximately half of all malignant localized solitary fibrous tumors of the pleura recur, with a single site of recurrence in three-quarters of patients. Two-thirds of recurrent localized solitary fibrous tumors originate from the parietal pleura.[14] The disease-free interval varies widely, between 6 months and 13 years following surgical resection.[15] Metastatic disease is treated with palliative chemotherapy, including doxorubicin and ifosfamide.[13]

### MESOTHELIOMA

Mesotheliomas are diffuse malignant tumors of the pleura, with epithelial differentiation. These are addressed in-depth in a separate chapter.

## BONE AND CARTILAGE

### Benign

#### FIBROUS DYSPLASIA

The majority of benign chest wall lesions are due to fibrous dysplasia of the bone, accounting for approximately 40 percent of benign chest wall lesions. These most commonly present in the third and fourth decades of life, with an equal distribution between men and women. In children, they are the most common benign lesion of the ribs.

Fibrous dysplasia is the result of failure of differentiation of mesenchymal osteoblasts. Presenting findings commonly include pain due to pathologic fracture or bone deformity. On CT imaging, fibrous dysplasia has an amorphous calcified appearance. On both T1- and T2-weighted MR imaging, they have heterogeneous signal intensity.[5] Treatment is surgical excision to both relieve symptoms and rule out malignant disease.

#### CHONDROMA

Similar to fibrous dysplasia of bone, chondromas are the most common benign tumor of cartilage. They account for between 10 and 30 percent of benign chest wall lesions.[3,16] These most commonly present in the second and third decades of life, with an equal distribution between men and women. Their appearance on radiographic studies is similar to that of malignant chondrosarcomas. As a result, surgical biopsy, and often resection, is necessary to rule out malignancy and treat symptomatic lesions.

#### OSTEOCHONDROMA

Osteochondromas generally present in adulthood. Patients typically present with masses associated with fractures or rib deformities. On imaging, they appear as masses with eccentric growth patterns at the costochondral junction. CT imaging of osteochondromas is characterized by a cartilaginous mass with a calcified cap. On T2-weighted MRI, osteochondromas have a high signal intensity.[5] Osteochondromas can undergo malignant transformation, but most complications are associated with a mass effect and displacement of adjacent structures. Malignant lesions may have an irregular appearance on imaging. Surgical resection is necessary to rule out malignancy and to treat symptomatic lesions.

#### CHONDROMYXOID FIBROMA

Chondromyxoid fibromas are tumors consisting of chondroid, myxomatous, and fibrous components. Occurring in long bones around the knee in approximately half of all cases, these rarely occur in bones of the chest wall. When occurring in the chest, they typically present in early adulthood, with equal distribution between men and women, and have been reported to occur in the rib, spine, scapula, and sternum.[17] They are usually lobular with sclerotic bands of tissue-separating lobules.

Chondromyxoid fibromas appear on radiographs as well as demarcated masses with scalloped sclerotic borders, lacking internal calcification. On CT imaging, they characteristically appear as an expansile mass with diffuse or heterogeneous enhancement, bone destruction, lobulated margins with septations, and a sclerotic rim. On T2-weighted MRI, they have high signal intensity.[5] Treatment is surgical resection, in part to rule out malignant disease.

#### LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis, or dendritic cell histiocytosis (also previously known as histiocytosis X), is a rare disease resulting from clonal proliferation of dendritic Langerhans cells. It may present as unifocal, multifocal unisystem, or multifocal multisystem disease. Affecting children, with a peak incidence between 5 and 10 years of age, unifocal disease carries a favorable prognosis.[18] Langerhans cell histiocytosis most commonly presents in the skull and long bones of the upper extremity, but has been reported to occur in ribs.[19] Lesions present as painful bone swelling. Histologic diagnosis is made by identification of Langerhans cells, and can be confirmed by demonstration of characteristic Birbeck granules on electron microscopy. Treatment is surgical resection, in part to rule out malignant disease, or radiation therapy if the diagnosis has been confirmed. Systemic disease is treated with chemotherapy.

#### ANERUYSMAL BONE CYST

Aneruysmal bone cysts are blood-filled cysts that may develop rapidly and typically present in early adulthood. They are characterized by a network of blood-filled cysts lined with fibroblasts and multinucleated giant cell osteoclasts. In the chest, these commonly develop in the posterior elements of the spine, but may occur in the ribs or clavicles.

On axial imaging, they characteristically appear as expansile masses with cortical thinning and well-defined

inner margins. On both T1- and T2-weighted MRI, they have a heterogeneous signal, with fluid–fluid levels, and may appear septated.[5] Fluid–fluid levels are the appearance of two different density fluids, usually water-density fluid layering over blood. Surgical resection is indicated for symptomatic lesions.

### OSSIFYING FIBROMYXOID TUMOR

Ossifying fibromyxoid tumors are composed of chords or nests of small, round cells, with a hyaline fibrosis-like myxoid matrix, usually surrounded by an incomplete bone shell. They typically present in adulthood, with a median age of 50 years, occurring with a 2:1 male-to-female ratio. Approximately 15 percent occur in the chest wall, most frequently involving the ribs.[20]

Patients present with a slow-growing, nontender mass, progressing over several years. On CT imaging, they characteristically appear as a vascularized, bubble-shaped, intracortical, osteolytic lesion surrounded by a sclerotic band of tissue with confluent contours. They are contrast enhancing, and on T2-weighted MRI, they have high signal intensity.[5] Treatment is wide resection, as recurrence is reported in a quarter of all patients treated with local excision.[20]

### GIANT CELL TUMORS

Giant cell tumors are benign tumors arising from the metaphyses and epiphyses of bones, accounting for approximately 5 percent of primary bone tumors.[21] Although approximately 80 percent arise from long bones, with 55 percent occurring in the lower extremities, they occasionally arise from the epiphysis of the head or tubercle of ribs.[22–28] Giant cell tumors most commonly present in the third and fourth decades of life, but can present in children, with a slight increase in incidence in females, and may be mistaken for giant cell reparative granulomas, brown tumors of hyperparathyroidism, aneurismal bone cysts, or fibrous dysplasia. Giant cell tumors exist in a spectrum of patterns, and the aggressive variant is associated with invasion of surrounding soft tissues. Patients may present with lytic lesions encompassing the adjacent bone, and approximately 20 percent have an overlying soft-tissue mass on presentation.

CT imaging may reveal cortical thinning of the rib and disruption. On T1-weighted MRI they have low signal intensity. On T2-weighted MRI, they have high signal intensity, and fluid–fluid levels may be present.[5] Technetium-99m-hydroxymethylene diphosphonate bone scintigraphy reveals increased uptake by these lesions. Giant cell tumors metastasize approximately 5 percent of the time, with metastases most commonly to the lungs.[21] Metastases usually occur within 3 years of resection, but these have been reported to happen up to 8 years following resection of the primary tumor.[29]

Treatment is resection, when possible. Use of curettage with ablation of residual tumor via phenol, alcohol, or liquid nitrogen has been reported, as has been done for platinum-based chemotherapy for metastases.[21] The recurrence rate is approximately 50 percent, and adjuvant chemotherapy may be indicated to decrease this. Radiation therapy may be useful for treatment of these lesions; however, it is thought to impart a risk of malignant transformation, which may also occur rarely without radiation exposure.[30] Disease-free survival from pulmonary metastases from giant cell tumors of the bone is 56 percent at an average follow-up time of 8 years from diagnosis.[31]

## Malignant

### CHONDROSARCOMA

Chondrosarcomas are the most commonly occurring malignant primary tumors of the chest wall. They constitute approximately 24 to 40 percent of sarcomas of the chest wall in most large series.[3,32] They most commonly arise in the pelvis or long bones, and less frequently in the chest wall. However, when occurring in the chest wall, most develop in the anterior chest, arising from the costochondral arches of the ribs in 80 percent of occurrences and from the sternum in 20 percent of occurrences.[16] Although this tumor is thought to be related to prior chest wall trauma, 10 percent of chondrosarcomas develop from benign tumors of the cartilage. Extraosseous chondrosarcomas develop infrequently.[33] Chondrosarcomas occur in a bimodal distribution in patients younger than 20 years of age and in patients older than 50 years of age, with a male-to-female ratio of 2:1.

When large enough, chondrosarcomas are visible on chest radiograph.[34] They vary in degree of differentiation, resulting in a spectrum of appearances, with characteristics of various density and various patterns of calcification, irregular borders, and bone destruction. They are best visualized on CT (Fig. 18-14); however, on T1-weighted MRI chondrosarcomas have a signal intensity similar to muscle, with varying degrees of calcifications throughout.

**FIGURE 18-14** Representative image from CT scan of the chest of an 80-year-old man presenting with a slow-growing mass involving his right fourth through sixth ribs. Needle biopsy failed to confirm diagnosis. Surgical pathology revealed grade I chondrosarcoma. (Image courtesy of Douglas Wood, MD.)

**FIGURE 18-15** Photograph of the resected 11.4-cm grade I chondrosarcoma specimen from the chest of an 80-year-old man presenting with a slow-growing mass involving his right fourth through sixth ribs. Area of resection extends from the superior border of the third intercostals space superiorly, to the upper border of the seventh rib, medially from the sternal border to a clearly uninvolved margin laterally, and from the subcutaneous tissue to the adjacent pericardial fat pad including a deep border of a wedge resection of the right lower lobe. The overlying skin was preserved. Note the smooth surface of the mass. (Image courtesy of Douglas Wood, MD.)

On T2-weighted MRI, they have signal intensity similar to, or greater than, that of fat. The myxoid variant of chondrosarcomas lacks bone formation and calcifications, and may appear to have an increased signal intensity on T2-weighted MRI.[35]

Pathologic diagnosis can be made by core-needle biopsy. Chondrosarcomas are resistant to chemotherapy and radiation therapy. Treatment is surgical resection with negative tissue margins of at least 4 cm.[3,36] Local recurrence is reported in 17 percent of patients who were treated with wide resection, with a 96-percent 10-year disease-specific survival. Worse outcome is associated with incomplete or local excision, advanced tumor grade, and increased tumor size.[36] Evidence of invasion during resection can help differentiate low-grade chondrosarcomas from chondromas (Fig. 18-15).

## OSTEOSARCOMA

Osteosarcomas are one of the more commonly presenting chest wall sarcomas. In conjunction with chondrosarcomas, they constitute approximately 40 percent of sarcomas of the chest wall.[32] In the chest, osteosarcomas most frequently occur in the ribs, scapula, and clavicle. They most frequently present in young adults, commonly as a painful mass. Extraosseous osteosarcomas present in the sixth decade of life. Thoracic osteosarcomas spread locally and have a greater preponderance to recur and metastasize than extremity osteosarcomas. They may have cystic components in addition to heterogeneous bone matrix.

On chest radiograph, osteosarcomas appear as a mass with calcifications, lytic lesions, or sclerotic bone, described as a "sunburst" appearance. On CT, osteosarcomas appear to have calcifications in their centers, with heterogeneous enhancement on intravenous contrast studies. Osteosarcomas have a signal intensity greater than muscle on T1-weighted MRI, and high signal intensity on T2-weighted MRI.[35]

Osteosarcomas are treated with neoadjuvant chemotherapy followed by surgical resection. Prognosis is predicted by tumor response to chemotherapy.

## EWING SARCOMA AND PRIMITIVE NEUROECTODERMAL TUMOR

Characteristically presenting in children and adolescents, Ewing sarcoma makes up approximately 6 percent of malignant chest wall tumors.[3] Although constituting only 10 percent of cases of all Ewing sarcomas, Ewing sarcoma of the chest wall is the most common malignant lesion of the ribs in children. Ewing sarcoma and primitive neuroectodermal tumors, the latter of which constitutes less than 1 percent of chest wall sarcomas, are related along the continuum of cell differentiation as Ewing's sarcoma develops from neural crest cells as a solitary mass or multiple masses.[37] In the chest, they can occur in bones or as extraosseous lesions. They are aggressive tumors, which may displace or invade adjacent tissues, including the lung.

On chest radiograph, Ewing sarcoma classically has an "onion peel" appearance. On axial imaging, it appears as an ill-defined mass, with cystic degeneration, necrosis, and sometimes with calcifications. On T1-weighted MRI, Ewing sarcoma has a signal intensity equal to or greater than muscle, a high signal intensity on T2-weighted MRI, and it is contrast enhancing.[35]

The 5-year overall survival is equal to the 5-year cause-specific survival, at 44 percent in patients with nonmetastatic Ewing sarcoma following surgical resection, with or without adjuvant chemotherapy.[38] Chemotherapeutic agents used are generally vincristine, doxorubicin or adriamycin, and cyclophosphamide-based agents; however, etoposide and ifosfamide are gaining use.[39,40] Radiation therapy is used preoperatively for tumors considered "borderline" for successful resection and postoperatively for control of local disease in the setting of positive margins and local invasion into adjacent structures. Favorable local control rates indicate that patients primarily succumb to metastatic disease despite success of local resection.

## PRIMARY PLEUROPULMONARY SYNOVIAL SARCOMA

Synovial sarcomas, which have a mesenchymal origin, predominantly occur at para-articular locations in the extremities of young patients, but rarely occur in the chest wall, pleura, lung, or heart. These soft-tissue masses infiltrate adjacent structures if not diagnosed early.[41] Patients usually present in the second to fifth decade of life. Disease can

progress rapidly as these malignancies tend to be aggressive when occurring in the chest wall.

On CT imaging, synovial sarcomas appear as ill-defined masses with attenuation slightly greater than muscle, and calcifications may be present in approximately one-third of tumors. On T1-weighted MRI, synovial sarcomas have signal intensity equal to muscle, and may reveal foci of hemorrhage or fluid–fluid levels. On T2-weighted MRI, synovial sarcomas appear heterogeneous and may have internal septation visible.[35]

Treatment is comparable to that of other sarcomas, with wide resection. Case reports detail local recurrence within 1 year of initial resection, with mixed response to chemotherapy and radiation therapy.[42–44]

### ADAMANTINOMA

Adamantinomas are intraosseous epithelial neoplasms of low-grade malignancy. They are of uncertain histopathogenesis. Adamantinomas are rare, constituting 0.3 to 0.4 percent of all primary bone tumors.[45] Although most of these occur in long bones, with 60 to 90 percent occurring in the tibia, cases have been reported of primary adamantinomas occurring in the ribs.[45–47] They are slow-growing tumors, composed of epithelial and osteofibrous components in varying proportions, and have characteristic solid cell nests. They can invade adjacent tissues and become metastatic, with one of the three described primary rib tumors metastasizing to the liver.[47]

Adamantinomas present throughout life, with a mean age of 30 years. Patients present with a slow-growing mass on the rib, which may be painless or associated with dull pain. On radiologic imaging, adamantinomas appear as medullary, osteolytic, eccentric lesions with sclerotic margins.[47] On pathologic examination, adamantinomas may be confused with epithelial metastatic neoplasms and sarcomas. They can be differentiated from other tumor types via immunohistochemical staining for markers of epithelial origin. Treatment is wide resection, with recurrences and metastases most commonly to lungs and abdominal viscera occurring up to 15 years after resection. Postoperative survival of patients with adamantinomas, irrespective of tumor site, is 82.5 percent after 4 years.[48]

## MUSCLE

## Benign

### LEIOMYOMA

The development of leiomyomas, benign tumors originating from smooth muscle, in the chest wall is exceedingly rare. In the only recent case report, a leiomyoma arose from the microvascular smooth muscle in the extrapleural chest wall of a 55-year-old female, and was successfully treated with resection.[49]

### RHABDOMYOMA

Rhabdomyoma of the chest wall has only been reported as isolated case reports, treated with surgical resection.

## Malignant

### LEIOMYOSARCOMA

Leiomyosarcoma of the chest wall represents between 1 and 5 percent of primary soft-tissue chest wall sarcomas.[3,32,37,50] It most commonly presents in men, in the sixth to eighth decade of life, as a painful mass, or is incidentally found on imaging studies. Epstein–Barr virus is associated with the development of leiomyosarcomas as well as leiomyomas, in patients with AIDS, and leiomyosarcoma may develop secondary to exposure to cyclophosphamide.[51,52] In advanced cases, leiomyosarcoma may present with cutaneous or hepatic metastases.

On CT imaging, these malignancies lack calcification, but may have central necrosis or a cystic appearance, and may displace adjacent vascular structures. On MRI, they present as spindle-shaped lesions. On T1-weighted MRI, they have low signal intensity, while on T2-weighted MRI, they have high signal intensity. With intravenous contrast, leiomyosarcomas typically have a rim-enhancing appearance (Figs. 18-16, 18-17, and 18-18).[35] Pathologic diagnosis can be confirmed via the presence of spindle cells, staining positive for vimentin. Treatment and outcomes are comparable with that of other soft-tissue sarcomas discussed later in this chapter.

### RHABDOMYOSARCOMA

Rhabdomyosarcoma constitutes approximately 11 percent of malignant chest wall tumors, and represents the second

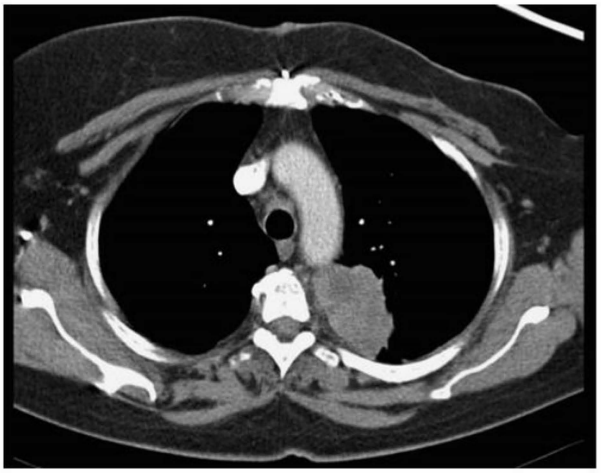

**FIGURE 18-16** CT image of a 59-year-old woman with a 4.5 × 3.6 × 3.4 cm chest wall leiomyosarcoma that had invaded into adjacent chest wall structures as well as adjacent lung parenchyma. (Image courtesy of Douglas Wood, MD.)

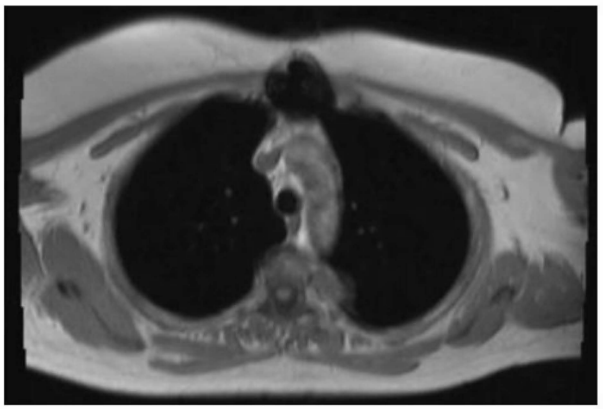

**FIGURE 18-17** The same chest wall leiomyosarcoma from Figure 18-16 imaged with T1-weighted MRI. (Image courtesy of Douglas Wood, MD.)

most commonly identified malignant chest wall tumor in children.[3] It is a high-grade sarcoma with differentiated skeletal muscle. Rhabdomyosarcoma presents before middle age with a rapidly growing mass, or with symptoms related to mass effect. Bone invasion occurs in a fifth of patients with rhabdomyosarcoma. Different subtypes of rhabdomyosarcoma exist, with the alveolar subtype occurring the most frequently in the chest wall.[53] On CT and MRI, it lacks calcifications, may have central necrosis, and has a heterogeneous appearance on T1- and T2-weighting.[35]

Treatment is comparable with that of other sarcomas, with wide resection being the mainstay of therapy. Chemotherapy is used based on institutional experience and preference. Radiation therapy is reserved for tumor-positive margins following surgical resection. Metastases occur in two-thirds of patients with rhabdomyosarcoma of the chest wall.[37]

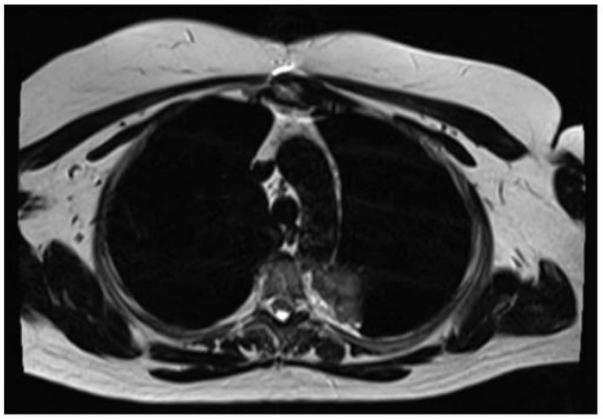

**FIGURE 18-18** The same chest wall leiomyosarcoma from Figure 18-16 imaged with T2-weighted MRI. (Image courtesy of Douglas Wood, MD.)

# NERVE

## Benign

### NEUROFIBROMA

Neurofibromas originate from a nerve and are slow-growing in nature. They typically present in patients in their third to fourth decade of life. They may or may not be encapsulated. Sixty to ninety percent of patients with neurofibromas have neurofibromatosis type 1 (NF-1) or multiple plexiform neurofibromas.

On axial imaging, they present as well-defined lesions with plexiform contours, calcifications, and may have adjacent rib erosion. They have variable contrast enhancement on intravenous contrast CT imaging. On T1-weighted MRI, neurofibromas have low signal intensity, while in T2-weighted imaging, they have high signal intensity peripherally due to enhancement of the peripheral stromal architecture and lack of enhancement by the central cellular component, resulting in a target-like appearance.[5] When gadolinium is administered, the center of the tumor is enhanced on MRI.[54] Rarely they may progress to malignant degeneration. Treatment is surgical excision for symptomatic lesions and to rule out malignant disease.

### SCHWANNOMA

Schwannomas develop from schwann cells, which form nerve sheaths and facilitate nerve-signal conduction. In the chest, schwannomas typically arise from intercostal nerves and spinal nerve roots (Fig. 18-19). They are characteristically encapsulated, well circumscribed, firm, spheroid, or ovoid masses (Fig. 18-20). Malignant schwannomas, or malignant peripheral nerve sheath tumors, constitute less than 10 percent of chest wall schwannomas, and therefore, suspicion of

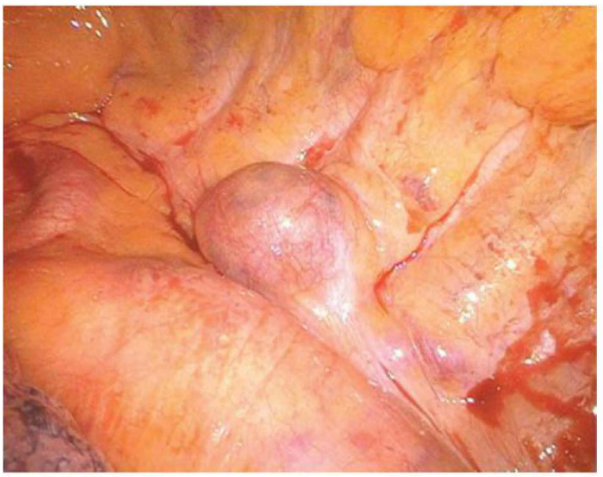

**FIGURE 18-19** Intraoperative photograph of a schwannoma occurring on the left chest wall just lateral to the aortic arch. (Image courtesy of Leah Backhus, MD.)

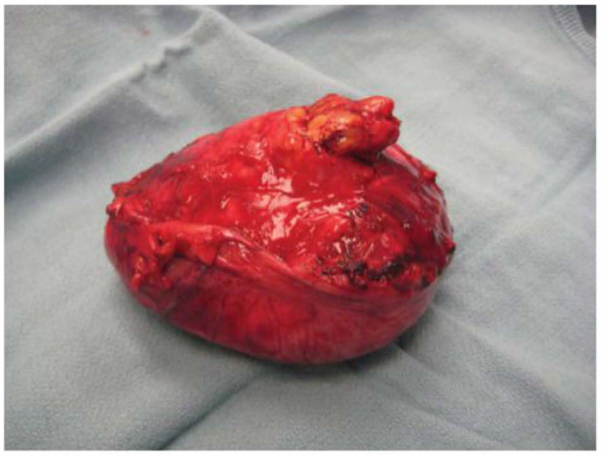

FIGURE 18-20 Photograph of resected 10.5 × 9.6 × 5.5 cm schwannoma specimen from a 34-year-old man identified initially on chest radiograph for pain. Note the intercostal nerve root protruding from the tumor. (Image courtesy Douglas Wood, MD.)

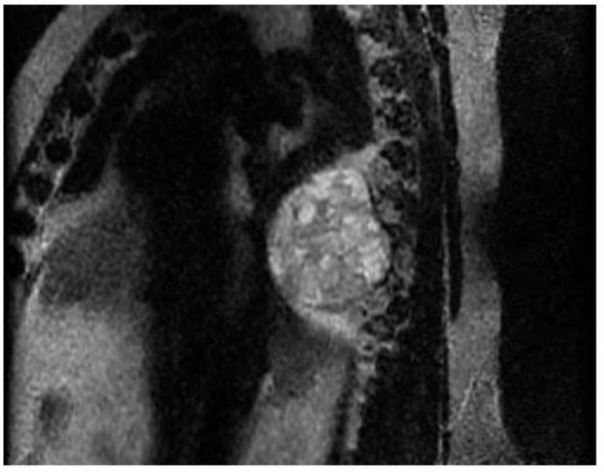

FIGURE 18-22 Sagittal view of a chest wall Schwannoma imaged with T2-weighted MRI. (Image courtesy of Douglas Wood, MD.)

malignancy should be maintained during workup and initial resection.[55]

Schwannomas are slow-growing and typically present in patients in their third through sixth decades of life. On axial imaging, schwannomas appear as well-defined lesions adjacent to nerves. Nonenhancing central necrosis may be present in larger lesions, and bone erosion may be present as well, indicating the presence of smaller lesions. On both T1- and T2-weighted MRI, larger schwannomas have a heterogeneous signal due to cystic change within the tumor, whereas smaller lesions are homogeneous. However, although their signal intensity on T1-weighted MRI is slightly more than that of muscle, it is greater than muscle on T2-weighted MRI (Figs. 18-21, 18-22, and 18-23).[5] Of note, they are painful to biopsy percutaneously. Treatment is surgical excision for symptomatic lesions and also serves to rule out malignant disease. Due to possible central neural involvement, we advocate resection in conjunction with a neurosurgeon who has evaluated the patient preoperatively.

## PARAGANGLIOMA

Paragangliomas of the chest wall arise from paraganglial cells of the aorticosympathetic or aorticopulmonary paraganglia, in the paravertebral region of the fifth, sixth, or seventh ribs. They occur on the right more than in the left, and present in late childhood to early adulthood. Although approximately 95 percent are nonfunctioning, they may rarely be functional pheochromocytomas, producing excess catecholamines. Patients may present with synchronous or metachronous extrathoracic paragangliomas.

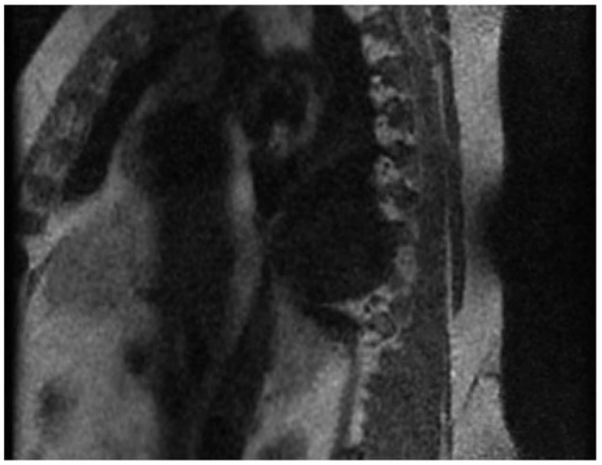

FIGURE 18-21 Sagittal view of a chest wall Schwannoma imaged with T1-weighted MRI. (Image courtesy of Douglas Wood, MD.)

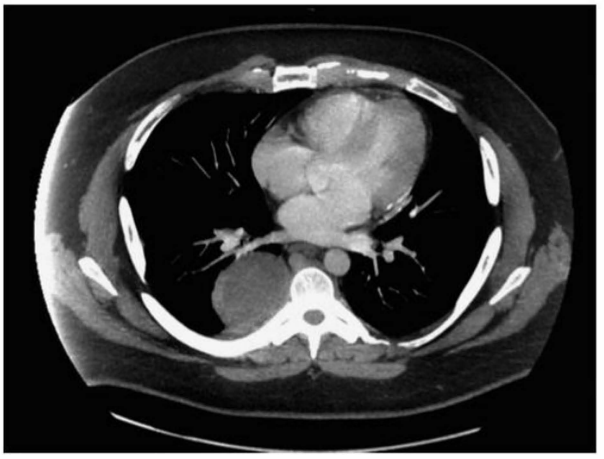

FIGURE 18-23 Axial view of a chest wall Schwannoma imaged with CT. (Image courtesy of Douglas Wood, MD.)

On axial imaging, paragangliomas appear as well-defined lesions in a midthoracic location. They are homogeneous in appearance and have intravenous contrast enhancement.[56] On T1-weighted MRI, paragangliomas have low signal intensity, whereas on T2-weighted imaging they have high signal intensity.[5]

Workup includes a 24-hour urine metanephrine test to determine if tumors are metabolically functional. Although both nonfunctioning and functioning tumors should be excised, the preoperative treatment algorithm for pheochromocytomas holds true for those occurring in the chest. This entails 2 weeks of preoperative alpha-blockade, with volume resuscitation on the order of several kilograms of gained weight, followed by beta-blockade. Treatment is surgical resection for symptomatic lesions and to rule out malignant disease.

### GANGLIONEUROMA

Ganglioneuromas of the chest wall arise from sympathetic chain ganglia in the chest wall, are composed of mature ganglion cells as well as Schwann cells, and are located paravertebrally and in the posterior mediastinum. They present in early adulthood, with a median age at diagnosis of 7 years, with a slight female preponderance.[57]

Ganglioneuromas are slow-growing and encapsulated. As such, they are most commonly found incidentally on radiographic study for other purposes (e.g., trauma evaluations), but patients may present with dyspnea or cough. On axial imaging, they appear as well-defined lesions, with calcifications present in approximately one-quarter of patients. On CT imaging, they may have either heterogeneous or homogeneous attenuation. On T1- and T2-weighted MRI, ganglioneuromas have areas of low signal intensity, creating a whorled appearance.[5]

They rarely metastasize, with reported metastatic ganglioneuromas likely representing neuroblastomas or ganglioneuroblastomas that have matured to ganglioneuromas, and confer an excellent prognosis in comparison with the more undifferentiated neuroblastic tumors. Rarely, ganglioneuromas may be metabolically active, necessitating workup and management as discussed for paraganglioma-pheochromocytomas earlier. Treatment of ganglioneuromas is complete surgical resection, in part to minimize risk of recurrence, and in part to enable thorough pathologic examination to rule out malignant neuroblastic tumors, such as neuroblastoma and ganglioneuroblastoma, which would possibly necessitate additional therapy.

## Malignant

### NEUROFIBROSARCOMA AND MALIGNANT PERIPHERAL NERVE SHEATH TUMOR (MALIGNANT SCHWANNOMA)

Previously known as malignant schwannomas, and alternately known as neurogenic sarcomas, malignant peripheral nerve sheath tumors occur throughout the body, along the course of peripheral nerves, and present during adulthood. They constitute less than 10 percent of chest wall tumors and approximately 9 to 13 percent of chest wall sarcomas.[3,32,37] Fifty percent of cases are associated with NF-1, where they occur in a male-to-female ratio of 4:1 and present in younger patients. Patients with NF-1 have a lifetime risk estimated at 10 percent of developing malignant peripheral nerve sheath tumors.[55,58,59] These tumors may develop de novo, or from preexisting neurofibromas. Although these are the most common mediastinal neurogenic tumors, they may involve any myelinated nerve, and therefore, approximately 5 percent of thoracic malignant peripheral nerve sheath tumors occur in the chest wall, usually from intercostal nerves.[59]

Patients with malignant peripheral nerve sheath tumors of the chest wall present with localized pain. Masses are slow-growing and may project into the thoracic cavity. On CT, malignant peripheral nerve sheath tumor appears as a well-circumscribed heterogeneous mass and may be associated with adjacent boney destruction if occurring on an intercostal nerve. On T1-weighted MRI, these have heterogeneous signal intensity greater than that of muscle, while on T2-weighted MRI, they have heterogeneous high signal intensity. They are difficult to distinguish from benign neurofibromas.[35] Four-quadrant open biopsies are preferable to percutaneous needle biopsies for definitive diagnosis.[60]

For localized tumors, treatment is wide resection. Features associated with poor prognosis including tumor size greater than 5 cm, advanced histology, higher tumor grade, and association with NF-1. Malignant peripheral nerve sheath tumors carry a high risk of local recurrence as well as distant metastases, and therefore, a staging CT or MRI of the chest and abdomen is useful, as well as localized imaging studies for specific symptoms (e.g., CT of the head). The current management algorithm is surgical resection to negative margins, plus neoadjuvant or adjuvant radiation therapy, with optional addition of adjuvant chemotherapy. The role of tyrosine kinase inhibitors in treatment of malignant peripheral nerve sheath tumors is currently being studied. Overall 5-year survival is between 34 and 64 percent.[55,60]

### NEUROBLASTOMA AND GANGLIONEUROBLASTOMA

Neuroblastomas and ganglioneuroblastomas rarely occur in the chest wall, most frequently in children, in the extra-adrenal sympathetic ganglia, resulting in paraspinal tumors. They represent the undifferentiated continuum of tumors arising in the sympathetic ganglia from a neural crest cell origin. Neuroblastomas are composed of neuroblasts, undifferentiated neural crest cells. Ganglioneuroblastomas are composed of mature gangliocytes and immature neuroblasts. The presence of undifferentiated tissue predisposes these tumors to potentially malignant behavior, with that of neuroblastoma being greater than that of ganglioneuroblastoma. Their mature counterparts, ganglioneuromas, are of low malignant potential.

Neuroblastoma is one of the most common pediatric malignancies in the United States, with a median age of presentation of 22 months, regardless of tumor site. Presenting symptoms include chest and shoulder pain, Horner syndrome, a painless mass, and opsoclonus-myoclonus, or jerking of the extremities and eyes most commonly associated with thoracic primary neuroblastomas.[57,61]

Chest wall neuroblastomas and ganglioneuroblastomas appear as poorly defined tumors, often with calcifications. On T1-weighted MRI, these have heterogeneous low signal intensity, while on T2-weighted MRI, they have heterogeneous high signal intensity.[35] Approximately 15 percent of neuroblastomas arising from the paraspinal sympathetic chain extend intrathecally, which can be seen on noncontrast MRI.[62] Therefore, at surgical resection, we prefer to seek the assistance of an experienced neurosurgeon, should there be spinal involvement. The aim of surgical extirpation is resection with macroscopically negative margins.

Disease-free and overall survival is related to tumor stage. Treatment of stage III tumors may benefit from neoadjuvant chemotherapy. More advanced-stage tumors should be treated with definitive chemotherapy, with radiation therapy added for node-positive disease. Metastases most commonly occur to bone and have varying degrees of response to chemotherapy.[57]

# LYMPHOVASCULAR

## Benign

### CAVERNOUS HEMANGIOMA

Cavernous hemangiomas occur in utero and present at birth or before the third decade of life. They present as a mass of dilated, tortuous, thin-walled vessels usually in the skin, but in the chest wall they are associated with intercostal locations and resulting erosion into adjacent bone, namely, the ribs and sternum.[63]

Hemangiomas of the chest wall are typically found incidentally on radiographic chest imaging, or as a palpable mass. On CT imaging, cavernous hemangiomas characteristically appear with ill-defined contours and enhancement on intravenous contrast studies. One-third develop phleboliths, which are visible on CT.[64] On MRI, they may appear to have heterogeneous signal intensity, fluid–fluid levels, and areas of high signal intensity on both T1- and T2-weighted images.[5]

Because many chest wall tumors with a similar presentation are malignant, to avoid risk of seeding tumor cells along a needle-biopsy tract, needle biopsy should be avoided. Preoperative biopsy should only be performed when tissue diagnosis will dictate management, for example, on lesions larger than 5 cm, where complex reconstruction following complete resection is anticipated, and when lymphoma, multiple myeloma, or tumor metastases are suspected. Otherwise, excisional biopsy should be performed. Nonsurgical treatment options include observation, and embolization, specifically where hemangiomas are superficial.[65]

### GLOMUS TUMOR (GLOMANGIOMA)

Glomus tumors are rare tumors that develop in adulthood, with equal frequency in women and men. They are often intramuscular and present with a solitary painful lesion, but may also present as multiple painless lesions.[66] They develop from the glomus body, specialized smooth muscle cells involved with thermoregulation at arteriovenous anastomoses.

CT imaging characteristically reveals well-defined contours around an enhancing soft-tissue mass with feeding vessels and associated bone erosion. MRI is characterized by heterogeneous signal intensity on both T1- and T2-weighted images; the tumor displaces vessels and is surrounded by feeding vessels and hence is well-defined on contrast studies.[5] Treatment is surgical resection for symptomatic lesions and to rule out malignant disease.

### LYMPHANGIOMA (CYSTIC HYGROMA)

Lymphangiomas are benign congenital lymphomatous malformations. They most commonly present in the neck, but may involve the chest wall, in neonates. Large lesions may be visualized on prenatal ultrasonography.[67] Differentiation from solid masses and diagnosis is aided by the ability to transilluminate characteristically balotable lesions, and by the presence of a multiloculated cystic mass on ultrasound. Although benign, lymphangiomas may develop complications when they become large and compress adjacent anatomy, if they hemorrhage, fistulize, or become infected. Surgical resection is indicated for large lesions, when there is risk of complication, and may require multiple stages. Lymphangiomas may recur with incomplete resection.[68]

## Malignant

### ANGIOSARCOMA

Angiosarcoma constitutes approximately 4 percent of chest wall sarcomas.[3,32] These malignant endothelial neoplasms present as painful, enlarging masses, with a peak incidence in the seventh decade of life. In a series of 80 patients with angiosarcoma, 14 percent had lesions involving the trunk wall including the chest wall.[69] Angiosarcomas are associated with chronic lymphedema, and radiation and chemical exposure (specifically arsenic, thorium dioxide, and polyvinyl chloride). They rarely occur in the chest, but can occur in proximity to the breast in men and women, usually following radical-surgical or radiation therapy for carcinoma of the breast.

As these lesions are highly vascular, they enhance on CT and MRI with intravenous contrast administration, when feeding vessels may be visualized. The associated

lymphedema is characterized by soft-tissue nodules and fluid collections adjacent to muscle, and increased attenuation of fatty tissue.[35] Complications include anemia, hemorrhage, and coagulopathy.

Treatment is similar to that of soft-tissue sarcomas, discussed in detail later, and entails wide resection. Local recurrences occur in approximately 20 percent of patients, with a median disease-free interval of 7 months. Metastases occur in 49 percent of patients. Overall 50 percent survival is 20 months.[69]

## SOFT TISSUE (FAT AND SKIN)

### Benign

#### LIPOMA

Lipomas are encapsulated benign growths of adipocytes. They commonly present in a wide age range of adulthood. On CT imaging, they characteristically appear as well-defined nonenhancing homogeneous masses. On T1- and T2-weighted MRI, they have high signal intensity, with low signal intensity of thin septa that may be present.[5] A key point of surgical management is extracapsular resection to minimize the likelihood of local recurrence. Seldom is reconstruction required following resection of lipomas, as overlying skin and adjacent tissue can be preserved.

#### ELASTOFIBROMA

Elastofibromas are common, slow-growing benign chest wall lesions that characteristically develop deep to the scapula. They are considered "pseudotumors" as they form due to fibroblastic proliferation. They are reported in approximately 10 to 25 percent of cadavers on autopsy. They occur in the inferior subscapular region, deep to the serratus anterior, latissimus dorsi, and rhomboid muscles. Ten percent occur bilaterally.[70]

Although most elastofibromas are asymptomatic, symptomatic patients present with shoulder discomfort or pain. On CT imaging, they appear as poorly circumscribed soft-tissue masses with signal intensity similar to muscle. On T1- and T2-weighted MRI, they have low signal intensity, with intervening high signal fat strands. On PET-CT, elastofibromas have increased metabolic activity with FDG uptake, which may lead to misdiagnosis of malignancy. Core-needle biopsy may be diagnostic.[70]

Treatment of symptomatic lesions is excision, and radiologic and tissue diagnosis should be confirmed prior to radical resection for misdiagnosis of malignancy.

#### OTHER BENIGN SOFT-TISSUE TUMORS

Other benign soft-tissue tumors have been described as involving the chest wall. These are usually reported as solitary cases. Included among these are chondroid syringoma, a benign, slow-growing tumor of the eccrine and apocrine glands, with mixed epithelial and mesenchymal elements. Although these more commonly arise from salivary glands, they may occur in the axilla. These usually present as slow-growing, painless nodules of the head and neck, most commonly seen in middle-aged or older men. Rarely, these may undergo malignant transformation or metastasis.[71]

Diagnosis of these rare tumors presents a challenge, and is often made after surgical biopsy or resection. Treatment is margin-negative excision, and wide local resection if suspicion exists for malignancy and for tumors larger than 3 cm. Regional lymph nodes should be sampled if they are clinically palpable or suspicious.

### Malignant

#### SOFT-TISSUE SARCOMA

Sarcomas of the chest wall are rare. Presentation is typically due to development of a nonpainful mass, and less frequently a painful mass, pain alone, or as an incidental finding on radiographic imaging.[37] In addition to infiltration of adjacent structures, symptoms may be due to local compression and present as limb paresthesias, range of motion defects, and distal swelling of a compromised upper extremity.[72] Diagnosis is made by core-needle biopsy or open biopsy. For superficial lesions less than 5 cm in diameter, excisional biopsy is used. Contrast enhanced MRI is our preferred method of evaluation of extent of the tumor (Fig. 18-24). In addition, CT of the chest should be obtained during workup for staging to rule out pulmonary metastases and regional and mediastinal lymphadenopathy. In cases of the latter, either mediastenoscopic lymph node sampling or PET scan is useful for lymph node staging.

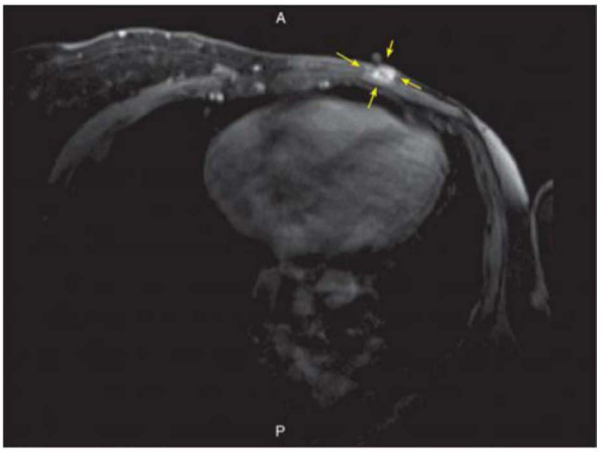

**FIGURE 18-24** Representative image from MRI scan of the chest of patient with recurrent sarcoma of the chest wall. The arrows mark the site of chest wall recurrence. (Image courtesy Merhan Habibi, MD.)

The goal for surgical extirpation of soft-tissue sarcomas is en bloc full-thickness chest wall resection with a 1-cm margin of normal tissue to achieve tumor-free (R0) margins. On definitive resection, the biopsy tract, including overlying skin incision site, should be excised with the specimen. The achievement of a 1-cm tumor margin may pose a technical challenge, based on anatomic relation of the tumor to adjacent structures. Grossly, tumor-positive (R2) margins necessitate reresection. When technically feasible, reresection should be performed for microscopically positive (R1) margins. Regional lymph nodes should be examined for metastases, as this may affect postoperative treatment and prognosis.

Neoadjuvant radiation therapy (50 Gy) can be used to diminish burden of disease with large tumors and improve the ability to obtain tumor-free margins for tumors involving vital structures (nerves and blood vessels). Intraoperative radiation therapy and brachytherapy may be considered for some situations, highlighting the utility of multidisciplinary management of soft-tissue sarcomas from early on in patient management.

Radiation therapy (50–60 Gy) is added postoperatively for residual disease, tumor margins less than 1 cm, tumors larger than 5 cm, or highly invasive tumors.[73,74] In the instance of intracompartmental tumors treated via compartmental resection, radiation therapy is not strictly indicated.

No consensus has been reached on the utility of chemotherapy for the primary treatment of soft-tissue sarcomas. Chemotherapy is used for recurrent disease and for metastatic disease. Intraoperative brachytherapy is used selectively to sterilize deep close margins.

Local recurrence of soft-tissue sarcomas occurs in up to two-thirds of patients, and should be treated with reresection when possible, and radiation therapy should be considered.[37,75] In a large series of chest wall soft-tissue sarcomas, approximately 7 percent of patients presented with synchronous metastases, and ultimately 35 percent experienced metastases.[37] Lung metastases from sarcomas should be treated with chemotherapy, especially in the setting of synchronous lesions in the absence of extrapulmonary disease.[73] However, isolated pulmonary lesions can be treated with wedge resection. In select populations, the latter confers up to 20 percent 5-year survival.[76]

Rapidity of disease recurrence is a function of malignancy grade and response to, and completeness of, definitive therapy. Recurrence is seen within 2 to 3 years in high-risk patients. To achieve early detection of local or pulmonary recurrence, we advocate regular follow-up visits with CT of the chest at 4-month intervals for the first 2 to 3 years after treatment, then every 6 months up to 5 years, and yearly thereafter.

Overall 5-year survival of chest wall soft-tissue sarcomas is 66 percent, with significantly poorer 5-year survival for those with high-grade sarcomas (49 percent) as compared with those with low-grade sarcomas (90 percent).[37] In a series of patients treated with chest wall resection for high-grade sarcomas, either primary, metastatic, or recurrent, 5-year disease-free survival was 40 percent and overall 5-year survival was 59 percent, suggesting that aggressive surgical resection to establish tumor-free margins should be performed for chest wall sarcomas.[50] Another study reported similar results with a 50 percent 5-year survival following chest wall resection for recurrent sarcomas.[32]

## DESMOID TUMOR

Desmoid tumors involving the chest wall account for between 20 and 50 percent of low-grade chest wall sarcomas.[2,3,37,77–81] Desmoid tumors, also known as fibromatosis, are fibroblastic and myofibroblastic neoplasms. These histologically benign tumors arise from the connective tissue of the muscular aponeurosis, and are locally aggressive, invading adjacent structures, but usually confined to musculature and fascia. Although they most commonly occur in the abdomen, the retroperitoneum, and the extremities, approximately 20 percent of desmoid tumors occur in the chest wall and intrathoracically.[82,83] On histologic examination, desmoid tumors have characteristic spindle cells separated by thick bands of collagen. These are associated with beta-catenin, adenomatous polyposis coli germline, or somatic mutations.[82] They more frequently occur in females, patients with familial adenomatous polyposis, and at sites of prior trauma or scaring, such as rib fractures.[81] They characteristically present as an enlarging mass, which becomes painful due to compression and invasion of local structures, including the lungs.[84]

Radiologic appearance varies and is based on collagen content of the tumor, and may be infiltrative or nodular in nature. Desmoid tumors are best characterized by T1-weighted MRI, where they have a signal intensity less than or comparable to muscle, and T2-weighted MRI, which can elucidate soft-tissue infiltration (Figs. 18-25 and 18-26).[35]

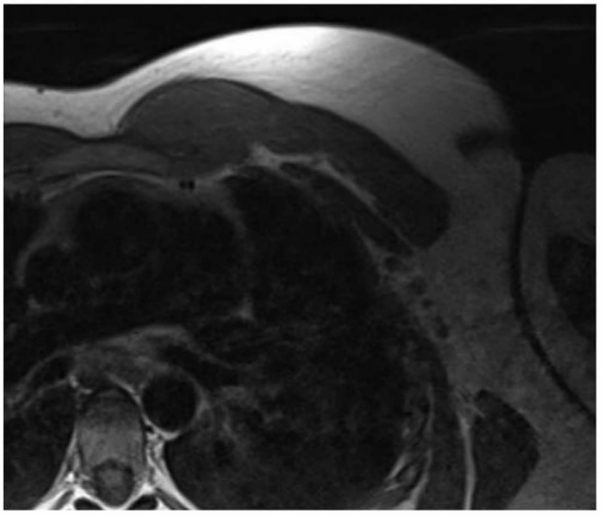

**FIGURE 18-25** T1-weighted MRI of left chest wall desmoid tumor in a 20-year-old woman. (Image courtesy of Douglas Wood, MD.)

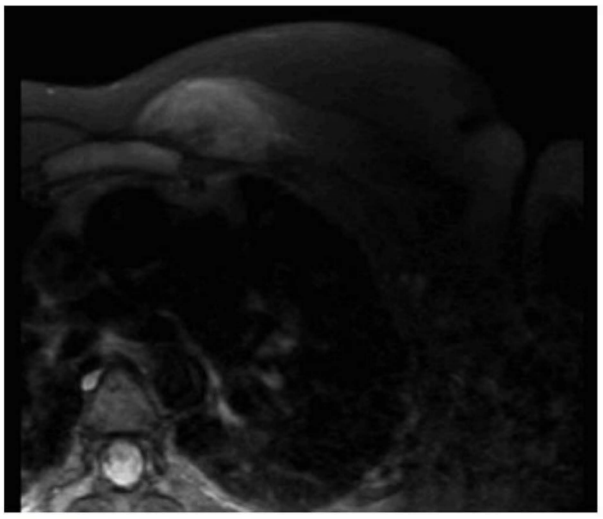

**FIGURE 18-26** T2-weighted MRI of left chest wall desmoid tumor in a 20-year-old woman. (Image courtesy of Douglas Wood, MD.)

However, desmoid tumors may not be well characterized on CT imaging (Fig. 18-27). In addition, open biopsy may not yield a correct diagnosis.

Treatment is radical resection with microscopically negative margins (R0) of 2 to 4 cm.[82,85] The inability to achieve microscopically negative tissue margins may result in the need for radiation, which may be given pre- or postoperatively, or in lieu of surgery due to the inability to resect lesions based on anatomic constraints. Chemotherapy, anti-inflammatory therapy, and hormone therapy are reserved for situations where surgical resection is not an option, such as widespread tumor infiltration. No single agent or combination chemotherapy has been identified that elicits a response in all patients. Agents noted to induce a partial or complete response in patients include doxorubicin and dacarbazine, interferon-alpha with or without tretinoin, vinorelbine or vinblastine and methotrexate, and tamoxifen.[82,86]

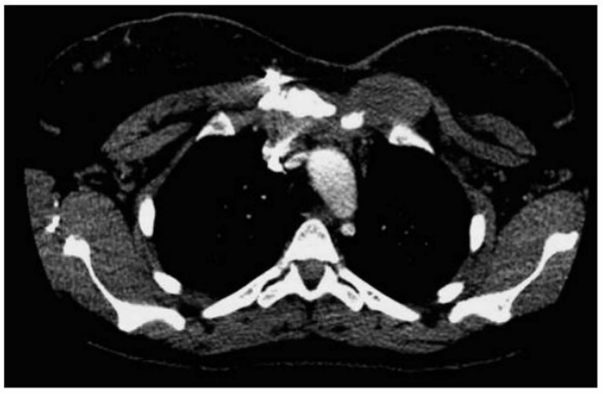

**FIGURE 18-27** Chest CT of the same patient in Figures 18-25 and 18-26 one year after initial resection of chest wall desmoid tumor and medial head of left clavicle, and subsequent reconstruction. Recurrence of the desmoid tumor is evident, as is hardware from initial reconstruction. (Image courtesy of Douglas Wood, MD.)

Although between one-quarter and one-half of desmoid tumors recur locally following resection, they do not metastasize. Recurrence is associated with degree of resection. In a series of 53 patients who underwent surgery for chest wall desmoid tumors, 89 percent recurrence rate was reported in patients with micro- or macroscopically positive resection margins. Fifty percent of patients who underwent reresection developed local recurrence, as opposed to only 8 percent of those who underwent margin-negative primary resection. The 5-year local recurrence rate is between 29 and 37.5 percent, with 5-year survival of 93 percent.[87,88] Lifelong follow-up with imaging and biopsy of suspicious lesions is necessary to rule out recurrence and malignancy.

## PROXIMAL-TYPE EPITHELIOID SARCOMA

Although proximal-type epithelioid sarcoma, an undifferentiated soft-tissue sarcoma, characteristically occurs in the extremities, attached to tendon, tendon sheaths, or fascia, they may occur in the chest wall.[89] These present as a subcutaneous or deep dermal mass. Proximal epithelioid sarcomas, occurring in the trunk and thighs, are more aggressive than those occurring in the distal extremities. Histologically, they resemble poorly differentiated carcinoma with sheets of large cells with characteristic prominent nucleoli, and frequently have a rhabdoid phenotype.

On CT imaging, approximately one-third of these tumors have stippled calcification. On T1-weighted MRI, proximal-type epithelioid sarcomas have signal intensity equal to muscle. On T2-weighted MRI, they appear as heterogeneous masses with high signal intensity. They are intravenous contrast enhancing.[35] Immunohistochemistry is necessary to differentiate proximal-type epithelioid sarcoma from other epithelioid lesions.

Treatment is wide local excision. Chemotherapy and radiation therapy have been used pre- and postoperatively. In a series of 20 patients, with mean follow-up of 4 years and 5 months, there was a 65 percent local recurrence rate, and a mean disease-free survival of 10 months. The same authors report a 75-percent rate of metastases, with metastases to lymph nodes, the lung, bone, and skin.[89] Larger tumor size at presentation was correlated with poorer prognosis but not occurrence of metastasis.

## RADIATION-INDUCED SARCOMA

Radiation-induced sarcoma of the chest wall is an aggressive tumor, occurring in patients who have undergone radiation therapy for, and survived, breast cancer and lymphoma. Tumor types described include chondrosarcomas, osteosarcomas, fibrosarcomas, malignant fibrous histiocytomas (MFHs), malignant schwannomas, and undifferentiated sarcomas. In a series of 15 patients, interval between

radiation therapy and occurrence of radiation-induced sarcoma ranged between 6 and 27 years, with a median of 14 years.[90] Treatment entails aggressive wide local en bloc resection, including involved skin and soft tissue, previously irradiated tissue and surgical sites, with an R1 margin of 4 cm. Rib margins include the unaffected rib above and below the tumor, and involved viscera including lung and mediastinal structures are resected. High-grade tumors are treated with adjuvant chemotherapy. Median survival of surgically managed radiation-induced sarcoma is approximately 5 years.[90]

### MALIGNANT FIBROUS HISTIOCYTOMA

Extrapleural MFH tumors are rare tumors of mesenchymal origin, accounting for 0.6 percent of soft-tissue tumors, and between 7 and 27 percent of malignant chest wall tumors in several large series.[3,37,91] They typically originate in skeletal muscle and fascia. MFH tumors develop malignant features in approximately 50 percent of cases.[13] Although they predominantly occur in the pleura, extrapleural locations include chest wall, head and neck, endocrine glands, intraperitoneally, and in the retroperitoneum. Extrapleural solitary MFH tumors have a higher rate of locoregional recurrence, as well as the possibility of metastasis. When occurring in the chest wall, they are more commonly located presternally.[37] Of the chest wall soft-tissue sarcomas, MFH are the least likely to metastasize, occurring in only 18 percent in one large series.[37]

On CT imaging, MFH appear as a heterogeneously enhancing mass in muscle or fascial planes (Fig. 18-28). The myxoid type of MFH has a characteristic appearance of central low attenuation of the myxoid matrix surrounded by enhancing nodular tissue on CT. Appearance on MRI may be variable, but on T1-weighted MRI, most MFH tumors have an appearance similar to muscle, while on T2-weighted MRI, they have the signal intensity equal or greater to that of adipose tissue.[35]

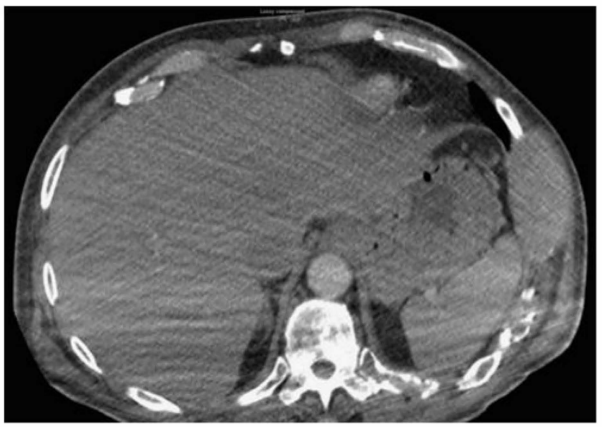

**FIGURE 18-28** Representative image from CT scan of the chest of 62-year-old man with an 8.5 × 4.1 cm malignant fibrous histiocytoma encompassing the left seventh through ninth ribs prior to resection. Following resection, reconstruction of the chest wall was achieved with 2 mm Gore Tex. (Image courtesy of Michael S. Mulligan, MD.)

As with other rare sarcomas, diagnosis of MFH should be confirmed by a pathologist experienced in soft-tissue tumors and well-established pathologic criteria of malignancy exist. Treatment is resection with negative margins, with adjuvant chemotherapy and radiation therapy for malignant disease, or for margin-positive disease where additional surgical resection is not an option. Extended long-term follow-up is warranted.

### LIPOSARCOMA

Liposarcoma constitutes 15 to 20 percent of adult chest wall sarcomas, and less than 10 percent of malignant chest wall tumors.[3,37] Three distinct clinicopathologic subtypes of liposarcoma exist: pleomorphic, myxoid, and well-differentiated or dedifferentiated liposarcoma. The latter is the most common subtype, accounting for 40 to 45 percent. Ten percent of liposarcomas present in the chest wall.[32] A recent series of 12 dedifferentiated liposarcomas reported one involving the chest wall, the majority occurring in the retroperitoneum.[92] On radiologic imaging, the different subtypes differ in appearance due to their histopathology. In general, as liposarcomas contain fat and soft tissue, they appear slightly more dense than fat on CT.[35] Treatment and outcomes are comparable with that of other soft-tissue sarcomas of the chest wall, which is already discussed.

### OTHER SARCOMAS

For other, rare soft-tissue malignancies, diagnosis should be confirmed by a pathologist experienced in soft-tissue tumors, as well-established pathologic criteria of malignancy exist for many tumors. These include spindle cell sarcomas, tenosynovial sarcomas, hemangiopericytomas, alveolar soft-part sarcomas, dermatofibrosarcoma protuberans, and giant cell sarcomas, each of which constitute less than 3 percent of chest wall soft-tissue sarcomas in a large series.[37]

### SKIN CANCER

Skin cancer may occur on the chest wall, with melanoma occurring particularly in areas of high sun exposure. Treatment is beyond the scope of this chapter and is discussed in-depth in other forums.

## HEMATOLOGIC

## Malignant

### LYMPHOMA

Primary lymphomas of the chest wall are rare in comparison with metastatic lymphoma, and account for approximately

1 percent of malignant chest wall tumors.[3] Primary lymphoma of the bone, accounting for approximately 5 percent of primary bone tumors, is usually diffuse histiocytic non-Hodgkin lymphoma. Secondary skeletal involvement occurs in up to 25 percent of patients with Hodgkin lymphoma, and approximately 20 percent of patients with non-Hodgkin lymphoma.[93]

Boney invasion may occur from hematogenous dissemination or spread from adjacent diseased lymph nodes. Sternal involvement is commonly due to direct extension from internal mammary lymph nodes. Differentiation between primary disease and metastatic disease is critical to staging and treatment, with metastatic lesions conferring stage IV disease.

Lymphoma involving muscle of the chest wall can occur as a discrete mass or as diffuse tumor infiltration. Again, this may represent primary lymphoma, or more commonly, contiguous extension from an adjacent site.[93]

Malignant T-cell lymphoma of the skin, mycosis fungoides, manifests as erythema and eczema of the skin, progressing to indurated plaques with lymphadenopathy, finally progressing to ulcerated skin lesions. Advanced malignant T-cell lymphoma involves abdominal viscera, and has a very poor prognosis.[93]

Patients with chest wall lymphoma present most commonly in their sixth decade of life, and may have immunosuppression, associated with solid organ transplantation or AIDS. Lesions may infiltrate along neurovascular bundles and extend into subcutaneous tissues. On CT imaging, tumors have similar attenuation to muscle, with slight contrast enhancement. On T1-weighted MRI, lymphomas have signal intensity slightly less than muscle, and high signal intensity on T2-weighted MRI.[35]

Treatment of primary lymphoma of the bone is resection, with radiation therapy for positive margins. However, treatment is stage-dependent, and chemotherapy is the mainstay of treatment as most lymphoma presents in advanced stage.

### SOLITARY MYELOMA (PLASMACYTOMA)

Myeloma of the chest wall constitutes approximately 3 percent of malignant chest wall tumors.[3] The plasma cell tumor myeloma can develop either as a solitary lesion (plasmacytoma) or with a diffuse bone marrow infiltrate as multiple myeloma. In addition, solitary myeloma can progress to multiple myeloma. Solitary myeloma, which may present as a multicystic boney mass, or as an extraosseous lesion, typically presents in the sixth decade of life. Extraosseous solitary myeloma less commonly progresses to multiple myeloma. Both can occur in the chest wall, with osseous solitary myeloma more frequently involving the breast.

Chest wall myeloma typically appears as a lytic lesion on chest radiography. On T1-weighted MRI, myelomas have low signal intensity and high signal intensity on T2-weighted MRI.[35]

For biopsy-proven solitary lesions confined to the chest, radiation therapy can be employed for local control. Surgical resection can augment this should local control be difficult to achieve. In a large series of solitary myelomas, 69 percent 10-year survival was reported following treatment. However, there was an 85 percent local recurrence rate and 58 percent of patients progressed to multiple myeloma over 10 years.[94]

## COMMON METASTASES TO, OR INVASION OF, THE CHEST WALL

Overall, most patients who present with tumors involving the chest wall have local invasion of, or metastases to, the chest wall from nonprimary chest wall tumors. Several malignancies have a predilection to metastasize to the chest wall, or to invade it via growth from adjacent structures. These include lung cancer, breast cancer, melanoma, mesothelioma, lymphoma, and renal cell carcinoma. Lung cancer, of which approximately 5 percent undergoing resection have chest wall invasion, and mesothelioma are discussed elsewhere in-depth.

When considering surgical management for metastases to the chest wall, one must consider the role of resection for control of local symptoms versus curative intent. Each patient should be evaluated individually, including consideration of local control, prognosis, and quality of life following chest wall resection. We advocate surgical management when definitive local control has been achieved and there is no evidence of further metastases.

## SUMMARY

Chest wall tumors are rare, constituting a small portion of thoracic tumors. They include primary malignant and benign lesions, as well as metastases and locally invasive neoplasms.

Patient presentations vary, with most presenting with a painful mass, dyspnea, or other symptoms but one-quarter presenting with a painless, incidentally found lesion. Diagnosis rests on a combination of history, physical examination, axial imaging, and tissue biopsy.

Treatment is largely wide resection, with nuances in magnitude of resection, margins, and use of neoadjuvant and adjuvant chemotherapy and radiation therapy, based on diagnosis.

Resection may create a tissue defect in the chest wall, a dynamic structure. Therefore, reconstruction following resection may be simple or complex and involve tissue rearrangement or use of prosthetics.

The diagnosis and management of tumors of the chest wall remains a challenge for the thoracic surgeon. The engagement of a multidisciplinary team approach to diagnosis and management, including experienced assistance in the operating room, will lead to improved care and outcomes for patients with chest wall tumors.

## CHEST WALL TUMORS BOARD REVIEW QUESTIONS (CHAPTER 18)

1. A 76-year-old man presents with a gradually enlarging mass involving the costochondral arch of his ninth rib anteriorly; core-needle biopsy is inconclusive. Which of the following statements is correct?

   A. Evidence of invasion indicates this is a chondrosarcoma.
   B. Homogeneous signal intensity on T1-weighted MRI indicates this is fibrous dysplasia.
   C. Lack of calcifications indicates this is an osteosarcoma.
   D. Heterogeneous appearance indicates this is a benign localized solitary fibrous tumor.

2. An 11-year-old boy presents with a tender left eighth rib lesion after being hit by a baseball. On CT imaging, this lesion has an amorphous calcified appearance. Which of the following does this most likely represent?
   A. Fibrous dysplasia
   B. Giant cell tumor
   C. Neurofibroma
   D. Rhabdomyosarcoma

3. Biopsy of a chest wall mass in a 63-year-old woman is consistent with diffuse B-cell lymphoma. Complete workup fails to identify any other sites of disease. Which is the correct treatment plan?
   A. Chemotherapy with cytoxan, adriamycin, vincristine, and prednisone.
   B. External beam radiation therapy
   C. Observation
   D. Surgical resection with radiation therapy for positive margins

4. Which of the following is the most common chest wall sarcoma in adults?
   A. Angiosarcoma
   B. Chondrosarcoma
   C. Ewing's sarcoma
   D. Osteosarcoma
   E. Rhabdomyosarcoma

5. A 6-year-old boy presents with a 3-cm, tender, right fourth rib mass. The lesion has an onion peel appearance on chest radiography. Which of the following does this most likely represent?
   A. Ewing's sarcoma
   B. Multifocal Langerhans cell histiocytosis
   C. Neuroblastoma
   D. Rhabdomyosarcoma
   E. Schwannoma

## ANSWERS

1. **Answer: A.** Evidence of invasion differentiates this as a chondrosarcoma as opposed to a chondroma. Fibrous dysplasia has a heterogeneous signal on T1-weighted MRI. Osteosarcomas are calcified. Benign localized solitary fibrous tumors have a homogeneous appearance on CT imaging.
2. **Answer: A.** Fibrous dysplasia is the most common benign rib lesion in children and has an amorphous calcified appearance on chest CT. Although giant cell tumors of the rib can occur in children, these are characterized by cortical thinning and rib disruption on CT imaging. Neurofibromas typically present in adults in their 30s and 40s. Rhabdomyosarcomas are the second most common malignant chest wall tumor in children, but lack calcifications on CT and MRI.
3. **Answer: D.** Primary lymphomas of the chest wall with no evidence of metastatic disease are managed by surgical resection with radiation therapy for positive margins. Chemotherapy (CHOP protocol) is reserved for systemic lymphoma. External beam radiation alone and observation are inappropriate management strategies.
4. **Answer: B.** Chondrosarcoma is the most common chest wall sarcoma in adults, followed by osteosarcoma. Angiosarcoma is rare, representing only 4 percent of adult chest wall sarcomas. Ewing's sarcoma is the most common malignant rib lesion in children, followed by rhabdomyosarcoma.
5. **Answer: A.** Ewing's sarcoma of the chest wall has a characteristic onion peel appearance on chest radiography. Multifocal Langerhans cell histiocytosis of the ribs is extremely rare. Neuroblastomas occur more commonly in infants than children. Rhabdomyosarcomas and schwannomas lack calcifications on imaging.

# 19 Congenital Chest Wall Anomalies

*Ibrahim Sultan*
*Stephen C. Yang*

## KEY CONCEPTS

- Epidemiology
  - Pectus excavatum occurs in about 1:400 live births, with a male predominance of up to 5:1. No genetic abnormalities or chromosomal aberrations have been associated with pectus excavatum, although a familial tendency has been described. Up to two-thirds of children with Marfan's syndrome and a large proportion of Ehlers–Danlos patients develop pectus excavatum deformities. The incidence of pectus carinatum is about one-tenth that of pectus excavatum, with a similar male predominance and 25 to 30 percent reported family history. Scoliosis and other spinal deformities or a family history of these are associated with pectus carinatum.
- Pathophysiology
  - Pectus excavatum is a concave depression of the sternum resulting from abnormal growth, lengthening, rotation, or increased elasticity of the costal cartilages. Reduced cardiovascular performance has been linked to this defect. Pectus carinatum results from anterior displacement of the costal cartilages due to rotation and lengthening, leading to sternal protrusion. No significant cardiopulmonary abnormalities have been demonstrated with this lesion.
- Clinical features
  - In pectus excavatum, the sternum is posteriorly retracted and differential growth of the costal cartilages often results in an asymmetric chest wall with a common right-sided rotation of the sternum and an elevated left side. Other characteristic findings include sloped ribs, rounded shoulders with a classic stooped posture, and a protuberant abdomen. It is most commonly discovered in the first few years of life. Decreased stamina and endurance during exercise and excessive tachycardia/palpitations are commonly observed with this disorder. Pain is occasionally associated with this defect. Pectus carinatum is associated with pain, respiratory symptoms, ease of injury, and psychosocial body image concerns.
- Diagnostics
  - The best radiographic imaging modality for pectus deformities is the computed tomographic scan of the chest, which provides precise information regarding cardiac displacement, lung volumes, the degree of deformity, and any associated malformations.
- Treatment
  - Surgical correction of pectus excavatum includes the modified Ravitch repair (subperichondrial resection of all abnormal costal cartilages and wedge osteotomy to correct the posterior depression of the sternum by bringing it to a more anterior and neutral position) and the Nuss repair (using a precurved substernal bar to bend the sternum and cartilages to a corrected position). Surgical correction for pectus carinatum utilizes the basic principles employed in the open Ravitch repair, namely excision of all abnormal cartilages and return of the sternum to a neutral straight position.
- Outcomes/prognosis
  - The modified Ravitch or Nuss repairs represent the "gold standard" corrective operation for pectus excavatum. Hospitalization rarely exceeds 3 days, and 97 percent of patients experience a good result from the operation. Similar success rates are reported for Ravitch-type repairs of pectus carinatum. Complications include recurrence, pneumothorax, wound infection, atelectasis, and local tissue necrosis.

## INTRODUCTION

Children with congenital chest wall anomalies present from infancy to adolescence with cosmetic, psychological, or physiologic concerns. The spectrum of major anomalies of the chest wall includes pectus excavatum, pectus carinatum, Poland's syndrome, sternal clefts, and Jeune's syndrome.[1,2] The most common anomaly, pectus excavatum, is a concave depression of the sternum that comprises of majority of referrals seen by a pediatric surgeon for chest wall defects. Genetic or chromosomal associations with chest wall deformities are rare and include connective tissue disorders such as Marfan's and Ehlers–Danlos syndromes.[3,4] This chapter reviews the embryology of chest wall development as well as the pathophysiology, diagnosis, and treatment of the various congenital chest wall anomalies.

## HISTORICAL HIGHLIGHTS

The first reported repair of the pectus excavatum deformity, by Meyer, occurred in 1911.[5] Several reviews followed, but the benchmark repair, including costal cartilage excision and sternal osteotomy, was described by Ravitch in 1949 and has undergone only minor modifications in over 50 years of use.[6] Recently, experience has been growing with a minimally invasive technique for pectus excavatum repair described in 1998 by Donald Nuss.[7] Ravitch is also credited with the first repair of a pectus carinatum defect in 1952.[8] Jeune and colleagues described the syndrome of asphyxiating thoracic dystrophy in 1954,[9] and Cantrell, in 1958, described the pentalogy that includes lower sternal clefts.[10]

## EMBRYOLOGY

The chest wall consists of muscles derived from myotomes and ribs, costal cartilages, and components of the sternum from the axial skeleton. Shortly after the fifth week of development, dermomyotomes in the thoracic region split and form myotomes, from which the chest wall musculature arises. The mesenchymal costal processes of the developing thoracic vertebrae give rise to the ribs starting at week 5 after fertilization.[11,12] During the embryonic period, the costal processes become cartilaginous and finally undergo endochondral ossification to become ribs. The synovial costovertebral joints arise from the embryonic junction between the vertebrae and the costal processes. During week 6 of development, a pair of vertical mesenchymal structures, known as sternal bars, develops ventrolaterally along the body wall. These bars gradually fuse craniocaudally in the median plane as they chondrify to form precursors of the manubrium, sternebral segments of the sternal body, and xiphoid process. Ossification of the sternum also occurs in a craniocaudal fashion and is complete by 60 days postfertilization except for the xiphoid, which ossifies after birth. Incomplete sternal fusion is not uncommon and can lead to bifid xiphoid or a spectrum of sternal clefts.

## PECTUS EXCAVATUM

Abnormal growth, lengthening, rotation, or increased elasticity of the costal cartilages leads to the relatively common depression of the sternum known as pectus excavatum. Clinical findings usually begin to manifest by 2 to 3 years of age, but—given the risk of acquired thoracic dystrophy or recurrence after correction in younger patients—operative intervention should occur in older children or adolescents. The physiologic benefit of pectus excavatum repair is frequently discussed but remains controversial and is based mostly on retrospective data. Two repairs are most commonly performed, an open repair, first described by Ravitch, and a less invasive bar repair, described by Nuss. The type of repair is chosen based on the surgeon's experience and the complexity of the deformity. Both techniques have demonstrated good results when the appropriate patient is selected at the appropriate age for repair. The latter approach described by Nuss has become more popular in many centers across the world. These patients are not only referred for the Nuss procedure by primary care physicians, but majority of such patients are self-referred because of information available on the World Wide Web.[13]

## DEVELOPMENT

There is no known cause for pectus excavatum. Cartilaginous growth appears to be abnormal, which causes either posterior depression of the sternum in the case of abnormal lengthening of the cartilages or rotation of the sternum in the case of differential cartilaginous growth. The sternum itself does not appear to play a causative role in excavatum or carinatum. A study of the biomechanical, morphologic, and histochemical properties of cartilage from children with pectus excavatum shows decreased tension, compression, and flexure, with disrupted type II collage patterns in the deep zones of the cartilage.[14]

## EPIDEMIOLOGY

Pectus excavatum is relatively common, occurring in approximately 1:400 live births, with a male predominance of up to 5:1.[15] No genetic abnormalities or chromosomal aberrations have been associated with pectus excavatum, although a familial tendency has been described.[15,16] Up to two-thirds of children with Marfan's syndrome and a high frequency of Ehlers–Danlos patients develop pectus excavatum deformities.[3,4] Children with connective tissue disorders can present later in life, have more progressive defects, and suffer from

more complicated postoperative courses, but successful cosmetic and functional results can be achieved even in these patients.[4] Other associations include cardiac disorders[17] and scoliosis.[18]

## PATHOPHYSIOLOGY

Pediatric surgeons performing pectus excavatum repair argue that children with pectus excavatum seem to enjoy an increase in stamina and cardiovascular performance after surgical correction. However, it is unclear whether the cardiopulmonary advantages are conferred on these patients after undergoing repair of their pectus excavatum. These advantages quoted in the literature are mostly based on retrospective data.[19,20]

Two organ systems have been examined for physiologic differences in pectus excavatum: pulmonary and cardiovascular. Static pulmonary function tests performed at rest seem to show few abnormalities in children with pectus.[21,22] Other studies have confirmed the lack of difference in static lung volumes and baseline resting pulmonary function before and after both Ravitch and Nuss repairs,[23,24] while some even argue for a possible worsening of lung function after chest wall reconstruction.[25–28] In reviewing these studies, the majority of children are at the lower end of the "normal range" of pulmonary function, suggesting a defect. Interestingly, decreased postoperative pulmonary function testing in some studies has been found in contrast to subjective improvement in exercise stamina.[27] In some studies, including those that show no difference in resting pulmonary tests, exercise pulmonary function shows significant differences in lung volumes in preteen and teenaged pectus patients.[21,29] A recent study by Haller and coworkers shows a lower forced vital capacity (FVC) in pectus patients before surgery, with over half complaining of exercise limitation; significant improvement was found in 66 percent of these patients after repair.[30] Patients with abnormal ventilation/perfusion scintigraphy scans have demonstrated improvement after surgical correction of pectus deformity.[31] Although vital capacities were reported as only mildly reduced or normal in pectus patients, a nonlinear increase in oxygen uptake was seen when compared with controls, possibly indicating an abnormal work of breathing during exercise.[32] In another study, all pectus patients experienced improvement in maximal voluntary ventilation and exercise tolerance.[33] Some authors believe that the improvement of pulmonary function after pectus repair can be appreciated only in children who have severe deficits preoperatively.[34]

Reduced cardiovascular performance, rather than ventilatory limitations, has been the focus of a number of studies in an effort to understand the physiologic manifestations of pectus excavatum.[35,36] Right ventricular filling seems to be diminished with this condition and somewhat alleviated after repair.[37] Kowalewski and colleagues showed increased right ventricular systolic, diastolic, and stroke volumes after surgical correction of pectus excavatum.[38] A lower heart rate and expanded cardiac stroke volume have been described after pectus repair,[27,28,33] as has a higher oxygen pulse and cardiac output.[29,30] For this reason, routine cardiology evaluation in patients with known rhythm abnormalities, right atrial and ventricular hypertension, and mitral valve prolapse is prudent. Studies have indicated a significantly higher proportion of patients with mitral valve prolapse in patients with pectus excavatum when compared with control children in the same age group.[13]

In addition to the apparent cardiopulmonary advantages of pectus repair, the psychological and psychosomatic aspects associated with this disease cannot be underestimated. School-aged children with pectus excavatum suffer from embarrassment, social anxiety, orientation toward failure, marked depressive reactions, feelings of stigmata, reduced tolerance of frustration, and limited capacity for work.[39] In many children, these body image issues alone merit surgical intervention; when combined with the apparent cardiopulmonary advantages of correction, these considerations should clearly urge all health care providers to be supporters and advocates of treatment of pectus excavatum.

## CLINICAL FEATURES

Figure 19-1 illustrates the classic physical features of a child with pectus excavatum. Most children who present for surgical evaluation are active and healthy-appearing, with the chief complaint of a visible anatomic defect. Several relatively younger patients may also present to the office with their parents who clearly recognize the anatomic defect but is not obvious to the child. Physical examination of such children may demonstrate sloped ribs, rounded shoulders with a classic stooped posture, and a protuberant abdomen. When the excavatum defect is severe, the cardiac point of maximal impact can be shifted laterally beyond the midclavicular line. Pectus excavatum is most commonly discovered in the first few years of life, although it can be apparent in the newborn period or in a delayed fashion later in development. In newborns, pectus excavatum can be associated with paradoxical chest wall movement with ventilation. Although pectus excavatum may present at birth, most patients present after prepubertal spurt. These are typically boys in majority of the case. 20 to 30 percent of such patients may have accompanying scoliosis. Marfarnoid features may be seen in up to 20 percent of such patients.[13] Many of these anomalies can resolve spontaneously during the early years and should not be considered for surgical repair until ages 8 to 12.

Physically active children often complain of shortness of breath during exercise or decreased exercise tolerance when compared with their peers, but they generally have no symptoms at rest. Excessive tachycardia or palpitations during mild exercise can also be seen in patients with this disorder.[15] In a 30-year review of 375 patients undergoing pectus repair, 67 percent reported preoperative decreased stamina and endurance during exercise, 32 percent had frequent respiratory infections, 8 percent had chest pain, and 7 percent had

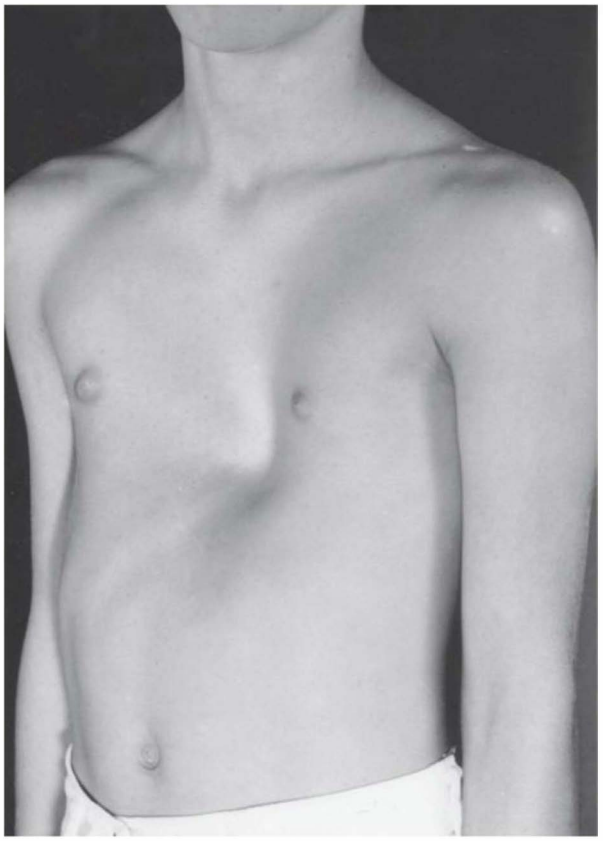

FIGURE 19-1 Child with pectus excavatum. Note the rounded shoulders, central defect, and "pot belly."

asthma.[40] Another 30-year study found, at initial presentation, 56 percent of subjects with dyspnea on exertion, 29 percent with shortness of breath at rest, 10 percent with chest pain, and 10 percent with palpitations.[41] Table 19-1 summarizes the signs and symptoms of pectus excavatum.

**TABLE 19-1: Signs and Symptoms of Pectus Excavatum**

| |
|---|
| Physical signs |
| Visible depression of lower sternum |
| Right-sided rotation of sternum with asymmetrical chest wall |
| Sloped ribs |
| Rounded shoulders |
| Protuberant abdomen |
| Laterally displaced cardiac point of maximal impact |
| Associated findings of connective tissue disorders |
| Symptoms |
| Nonspecific parasternal chest pain |
| Decreased subjective exercise tolerance, work capacity |
| Frequent respiratory infections, exercise-induced asthma |
| Embarrassment reactions, social anxiety, depression, suicidal thoughts |

## IMAGING STUDIES

Many centers will begin the workup with a preoperative chest radiograph. Apart from being readily available and inexpensive, it allows measurement of severity index. In children with recurrent pectus excavatum, it helps detect the extent of abnormal calcification of cartilages. Regardless of the surgical approach selected, the best radiographic test for preoperative evaluation of a patient with pectus excavatum is computed tomography (CT) of the chest.[42–44] This study provides precise information regarding cardiac displacement, lung volume, and, most importantly, the most accurate measurement of the depth of the sternal defect and its relationship to the overall width of the thorax.[45] The Haller index can be obtained by measuring the ratio of the AP distance between the vertebral bodies and the sternum at its narrowest point and the transverse diameter of the chest. This can be performed on physical exam or more reliably by a CT scan. Although age and gender-related variability exists in the Haller index,[46] normal children should not have a Haller index greater than 2.5, while the severity index of those with pectus excavatum generally ranges from 3 to 6 (Figs. 19-2 and 19-3A and B). Magnetic resonance imaging (MRI) has been used in patients where radiation exposure is a concern, particularly in those children that are cooperative and do not need sedation or general anesthesia for MRI.

## INDICATIONS FOR OPERATION

Factors determining candidates for repair of pectus excavatum defects include anatomic, physiologic, psychological, considerations as well as proper timing (Table 19-2). A CT scan can accurately define the anatomic defect, including the severity index of the sternal depression as well as its effects on cardiac and pulmonary anatomy. A Haller index of 3 or greater is associated with the presence of pectus excavatum.

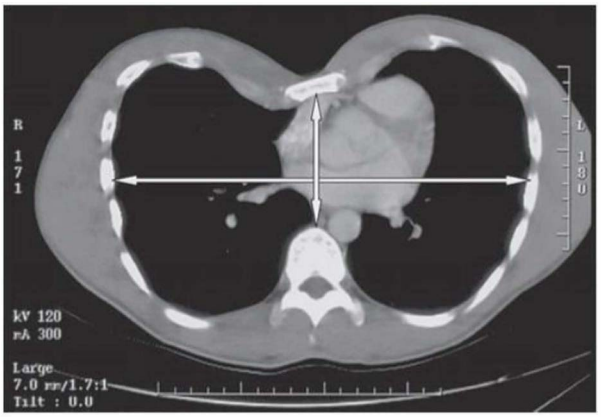

FIGURE 19-2 Cross-sectional CT scan to measure the Haller index. CT scan taken at the deepest part of defect. The Haller index is equal to the transverse diameter of the thorax divided by the anteroposterior dimension.

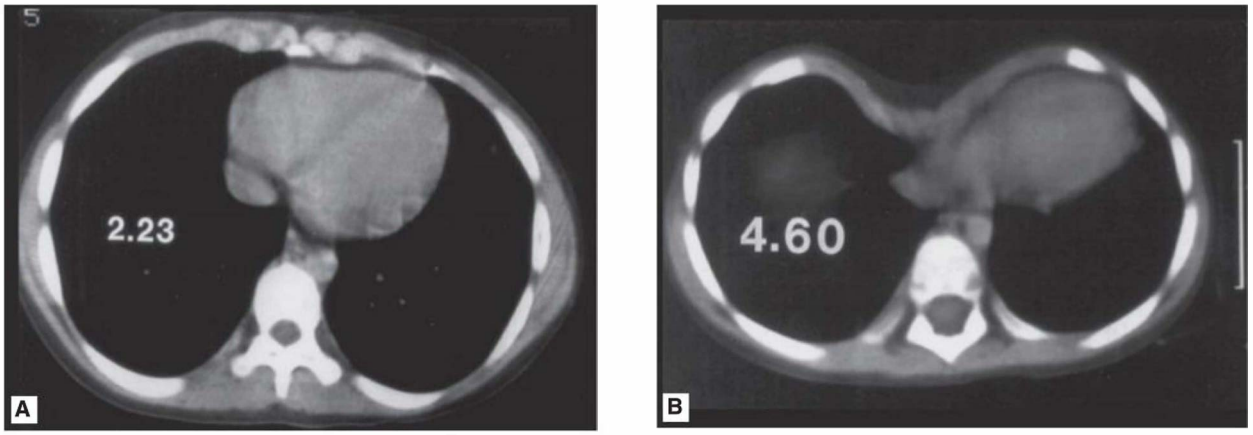

**FIGURE 19-3** **A.** Chest CT scan of a normal child. The Haller index should be <2.5. **B.** Chest CT scan of a patient with severe pectus excavatum.

All candidates should undergo stress pulmonary function studies and, if indicated by stress pulmonary function or history, echocardiography. Based on patient and family history—including double joints, joint dislocations, hyperflexibility, accelerated worsening of eyesight, and mitral valve prolapse—a screen should be considered for connective tissue disease. Associated chest pain, dyspnea on exertion, decreased exercise tolerance, exercise-induced asthma, or cardiac anomalies are possible indications for operative correction.[27,28,33–36] Patients who begin with symptoms such as dyspnea on exertion or exercise-induced chest pain show significant improvement of these symptoms postoperatively.[40,47] In addition, the need for future sternotomy, as in children with Marfan's syndrome, should be considered an indication for correction in childhood.[48]

Psychological symptoms are not uncommon in these patients and include embarrassment reactions, marked depressive reactions, social anxiety, feelings of stigmata, and others.[39] These manifestations can seriously alter the mental and physical health of a child and should be strongly considered in deciding candidacy for operative repair.

Proper timing of surgical repair is essential for adequate outcome, although this is also frequently debated and based on retrospective data. In general, good results have been reported with correction in school-aged children between the ages of 8 and 16, either before or after but not during their pubertal growth spurts.[15,42,49] The advantage of undergoing a repair before puberty is the ability of the bar to stabilize the malleable chest during this period and throughout the puberty spurt. This in turn leads to shorted recovery time and low incidence of recurrence.[48] It remains clear that Ravitch repair in patients younger than 7 years of age should be avoided because of a higher incidence of damage to the cartilaginous growth centers, with resulting acquired Jeune's syndrome.[30,50–53] A Nuss repair in patients around 8 years of age is sometimes justified when they have significant cardiopulmonary compression from their defect. In such situations, the bar should be left for up to 3 years. Additionally, the parents should appreciate that there is a higher risk of recurrent pectus excavatum when repaired at this age. The reason for higher recurrence in this age group is the removal of bar prior to pubertal growth spurt. Timing should vary with indication, as with the example of lower incidence of recurrence in children with Marfan's syndrome who underwent repair after maximal growth was obtained.[54] Success has been reported with simultaneous correction of pectus excavatum and congenital cardiac defects.[55] Age should not be a barrier to repair, as excellent long-term cosmetic results and symptomatic relief approaching 90 percent have been described in adults between the ages of 16 and 68 years.[41]

## MODIFIED RAVITCH REPAIR

Almost 60 years ago and for several decades to follow, Ravitch described subperichondrial resection of the lower costal cartilages with wedge osteotomy of the sternum as a possible repair for pectus excavatum.[6,56,57–60] This has gained wide acceptance as the gold standard operation for pectus excavatum, especially for complex or recurrent cases. Extensive experience has been reported with this procedure, and outcomes are generally excellent.[42,44,61–66] One group has reported some success with a minimally invasive endoscopic Ravitch repair.[67]

**TABLE 19-3: Summary of Operative Steps in the Modified Ravitch Repair for Pectus Excavatum**

| |
|---|
| Incision (midline or transverse) through the depth of the defect |
| Skin and muscle flaps to expose sternum and costal cartilages |
| Subperichondrial cartilage resections, usually four bilaterally |
| Sternal mobilization and transverse osteotomy |
| Sternal support; cartilage tripod and retrosternal bar |
| Wound closure with retrosternal chest tube, subcutaneous drain |

## Incision and Exposure

A modified Ravitch repair as performed at Johns Hopkins Hospital has been described (Table 19-3). A transverse inframammary skin incision is utilized at the level of the deepest portion of the sternal defect. Usually cosmetic outcomes from transverse incisions for this operation are more appealing than vertical ones. Upper and lower skin flaps are created in the subcutaneous layer, followed by creation of midline muscle flaps elevating the pectoralis muscles. This exposes the costal cartilages in their entire length bilaterally along the affected portion of the sternum. In most cases, this includes the fourth through seventh cartilages, but it can include as high as the second and third in severe cases of pectus excavatum. Exposure of the upper flap should extend to at least one normal cartilage cranial to the uppermost abnormal one, with the goal of excising at least four cartilages bilaterally.

## Subperichondrial Resection

One of the two principal goals of the operation is subperichondrial resection of all abnormal costal cartilages (Fig. 19-4A). These are resected from the lateral point of union with the rib, extending medially to the chrondrosternal junction. To keep the resection subperichondrial, the perichondrium is incised anteriorly along each cartilage, and upper and lower flaps of perichondrium are created to expose the deformed cartilage. It is imperative to keep the perichondrium entirely intact and not devascularized, as this

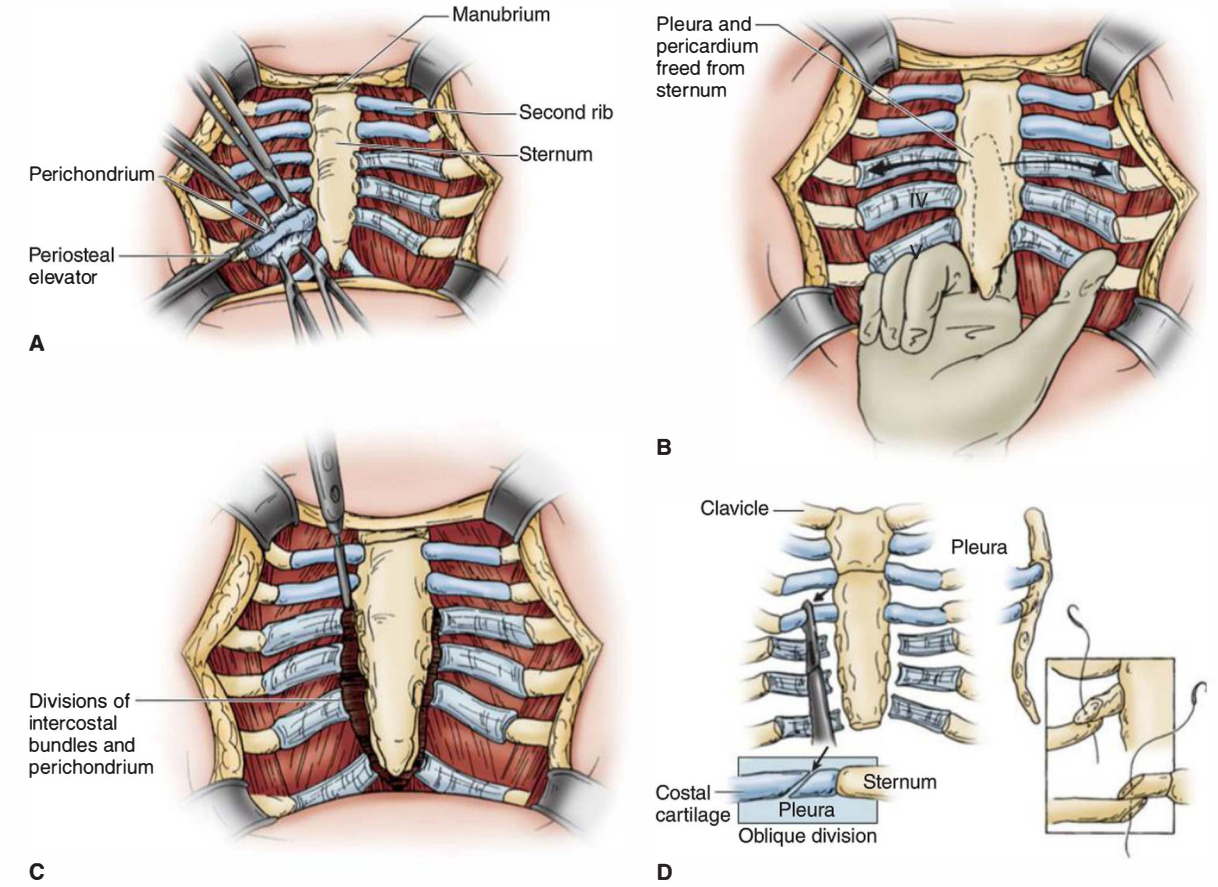

**FIGURE 19-4** Summary of the modified Ravitch procedure. **A.** Exposure of the anterior chest wall and excision of four costal cartilages bilaterally. **B.** Elevation of the sternum and its freeing from the underlying pleura (pericardium). **C.** Division of intercostal bundles. **D.** Oblique chondrotomy of three cartilages to form tripod.

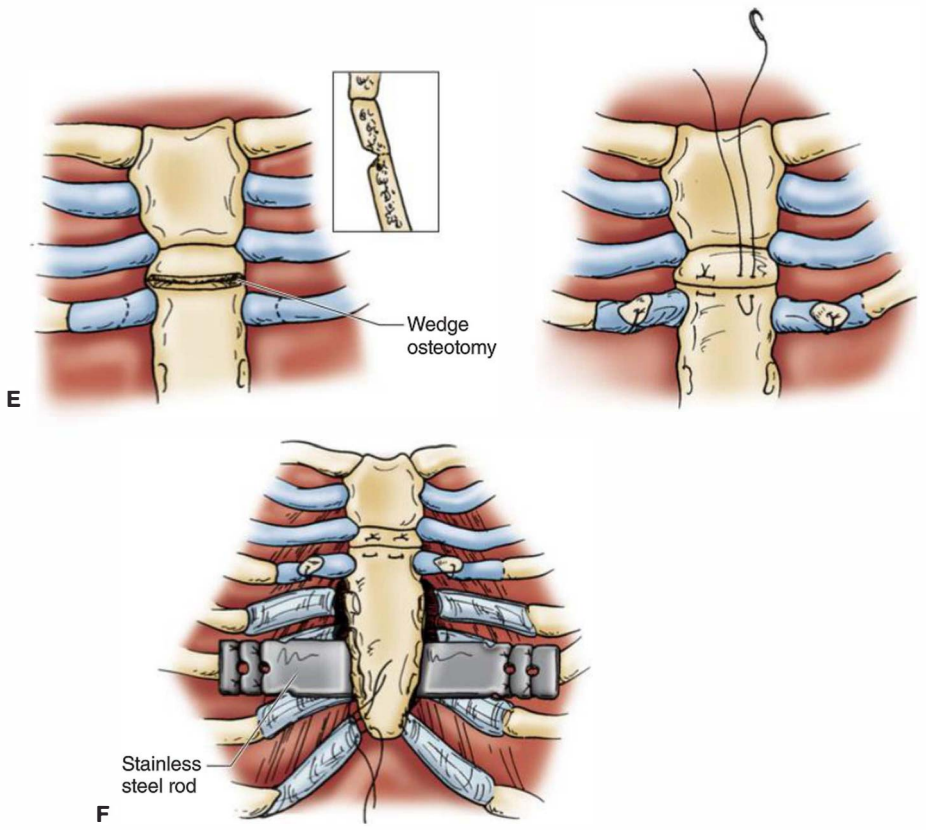

**FIGURE 19-4** (*Continued*) **E.** Transverse osteotomy. **F.** Placement of substernal strut.

provides the basis for new cartilage growth and subsequent bone. It is also suspected that devascularization of the perichondrium can contribute to the acquired Jeune's syndrome. During the dissection of the posterior perichondrium, care must be taken to avoid violating the pleural space.

## Wedge Osteotomy

The xiphoid is exposed and elevated, allowing for the creation of a substernal plane (Fig. 19-4B). This is performed mostly by blunt dissection, taking meticulous care to preserve the pleura and the pericardium as it is swept from the posterior surface of the sternum. The perichondrial bundles at the level of all of the excised cartilages are detached from the sternum, making sure that the internal mammary artery is swept laterally with the intercostals bundle and perichondrium. Just above the resected cartilages, the wedge osteotomy is performed (Fig. 19-4C). This is an anterior, triangular incision in the anterior table of the sternum performed to correct the posterior depression of the sternum by bringing it to a more anterior and neutral position. A single osteotomy is usually performed between the second and third cartilages, although at times a second osteotomy can be performed in a more caudal location (Fig. 19-4D). Tripod supports consisting of the lowest third or fourth intact costal cartilages can be used to support the sternum as well by obliquely dividing them in a medial-to-lateral trajectory and then placing the medial portion atop the lateral. Finally, for further security, the sternal periosteum is sutured in the position fashioned during the operation (Fig. 19-4E).

## Support Bar

Various modalities have been described to further support the sternum after wedge osteotomy. Autologous perichondrium has been used,[68] as have various metal struts with or without synthetic envelopes.[69] We prefer selective use of stabilizing struts for patients over the age of 10 or 12 or those with connective tissue diseases such as Marfan's or Ehlers–Danlos syndrome. A substernal stainless steel bar can be placed under the distal third of the sternum and secured in place laterally to the medial aspect of surrounding ribs (Figs. 19-4F and 5A and B). Interrupted sutures are generally sufficient to secure the bar. Alternatively, sternal fixation bars, which need to be sized and bent to configure to the contour of the sternum, can be screwed in place (Fig. 19-6A and B).

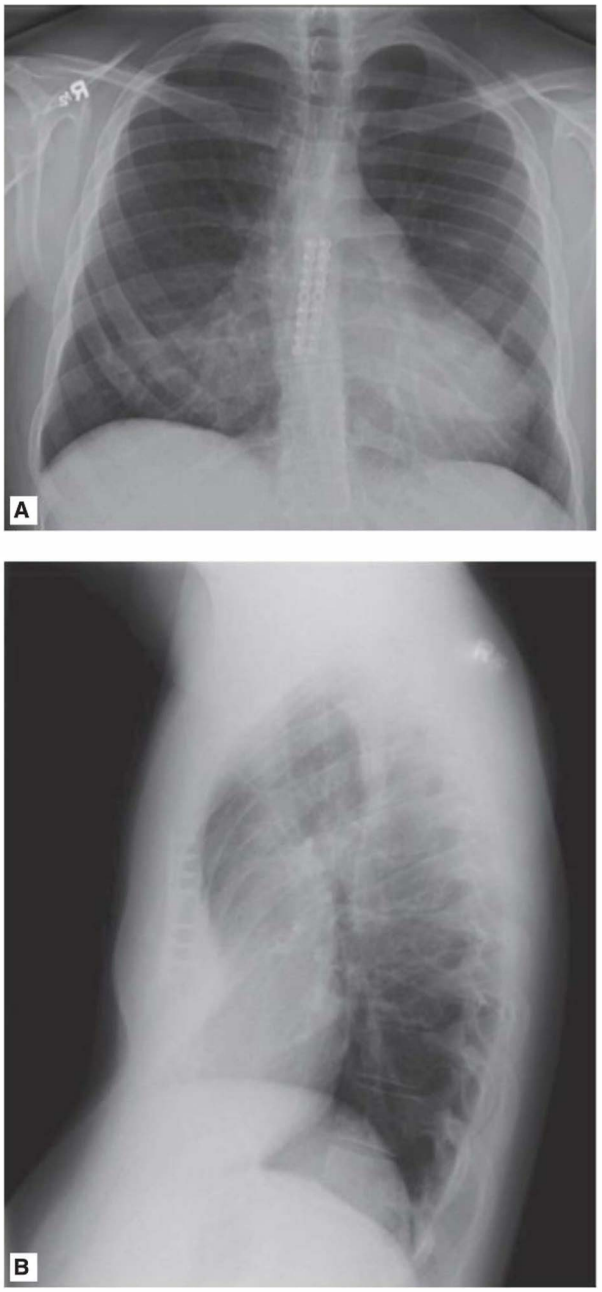

**FIGURE 19-5** PA (**A**) and lateral (**B**) chest x-ray of sternal fixation bars in place after wedge osteotomy. Screws are inserted above and below the osteotomy site (where there are no screws in the plate).

## Postoperative Management

It is not necessary to suture intercostal bundles that have been detached from the sternum back into place. If this defect is small, however, it can be closed by approximating nearby tissues. Retrosternal and subcutaneous chest drains are placed and can be removed 2 to 3 days postoperatively. After drains are removed, oral analgesia is sufficient and patients can be discharged within 3 to 4 postoperative days. A bladder catheter is recommended for the first day or two in the teenager and older patient, in whom urinary retention is not uncommon. Incentive spirometry is critical to prevent atelectasis. Contact sports for 6 to 8 weeks are usually avoided to allow cartilage regrowth and sternal fixation. A support bar, if placed, should remain for at least 6 months and can be removed in an outpatient procedure.

## Outcomes and Complications

For almost six decades, thousands of patients with pectus excavatum have been successfully treated with some modification of the Ravitch repair and followed for significantly long periods of time.[15,24,40–42,44,47,63,65,70–77] This is the gold standard operation to which all new techniques are compared.

The psychological benefits of the operation are clear.[39] The physiologic benefits of pectus repair remain controversial, with some groups demonstrating a measurable physiologic advantage[21,27–33,37] and others showing no difference before and after corrective operations.[23–28] It is possible that only selected patients with certain preoperative physiologic handicaps will benefit in this regard from surgical repair.

Hospitalization rarely exceeds 3 days, and 97 percent of patients experience a good result from the operation.[15] Although the operation is mostly performed in male patients, females with pectus deformities fare equally well after surgical repair.[70] Complications generally occur in fewer than 5 percent of patients undergoing a modified Ravitch repair; these are listed in Table 19-4. Early complications include pneumothorax, pleural effusion, pericarditis, seroma, wound infection, urinary retention, and atelectasis. Bar migration and pectus recurrence can occur as late complications. Acquired Jeune's syndrome is a terrible complication and is discussed later in this chapter. Urinary retention is usually seen in older teenagers and

adults and 1 to 2 days of bladder catheterization is required in this population. In addition, aggressive pulmonary toiled is advocated to reduce atelectasis and the risk of pneumonia. Recurrence occurs in approximately 2 percent of patients, with a higher incidence if the operation was performed at an early age (below 7 years).

In a review of 375 patients over 30 years, Fonkalsrud and associates report 12 cases of atelectasis, 13 pleural effusions, 5 recurrences, and 3 patients with pericarditis.[40] Of 777 procedures for pectus repair in a single center, 98.5 percent were successful, with an overall complication rate of 6.7 percent, a major recurrence rate of 1.5 percent, and a minor recurrence rate of 4.5 percent.[73] Shamberger and coworkers reported 704 patients seen over a period of 30 years who were repaired by a modified Ravitch technique, with 4.4 percent rate of complications including 11 cases of pneumothorax, 5 wound infections, 1 seroma, 1 hemopericardium, and 17 major recurrences (2.7 percent), of which 12 required revision.[44]

Complications may occur more commonly in adults because of the magnitude of dissection required and the anatomic difference that cartilage has developed into bone. Still, this operation is safe and successful in adults, with no statistical significance in reported complications in most studies. Of 116 patients over the age of 18 undergoing modified Ravitch repair, Fonkalsrud and colleagues report 7 pleural effusions, 2 pneumothoraces, and 2 patients with pericarditis.[47] Table 19-4 summarizes complications of the Ravitch operation.

## NUSS REPAIR

In 1998, Nuss reported a seminal 10-year series of 42 patients for whom he achieved adequate correction of pectus excavatum defects using a minimally invasive approach that does not involve excision of the costal cartilages.[7] Instead, through small bilateral incisions, a convex steel bar was surgically placed under the sternum to allow repositioning and remodeling of the deformed costal cartilages and sternum. After keeping the bar in place for 2 years to allow distraction and splinting of the costal cartilages as well as rotation of the sternum to a more neutral position, the bar was removed. Although a number of modifications have been described, experience with this procedure has become extensive, outcomes remain excellent, and the modified Nuss procedure has become the initial procedure of choice for many pediatric surgeons.[78–82] Success has even been reported for this procedure in the repair of patients failing modified Ravitch procedures.[83]

### Positioning, Incision, and Exposure

The patient is positioned supine on the operating table with arms abducted at the shoulders (Fig. 19-6A). This allows access to the lateral chest wall for bilateral 5-cm transverse incisions positioned just above the deepest portion of the sternal defect. Care should be taken to avoid hyperabduction, thus resulting in possible brachial plexus injury. Alternatively, the patient's torso can be supported by a mattress and arms can be extended posteriorly. This is particularly advantageous when using a thoracoscope. The thoracoscope can be placed superior to the incision. However, the chest can be overextended with this position, thus altering the patient's anatomic deformity. Variations exist regarding ideal placement of the incisions and support bar. In our experience, placement of the incisions at the caudalmost portion of the defect within the costosternal region, avoiding the xiphoid, allows for optimal results in almost all types of patients. In addition, the older the patient, the more medially the bar should pass the chest wall. This provides for a shorter and thus stronger arch to elevate the sternum.

On both sides, flaps of skin and subcutaneous tissues are raised, using electrocautery to expose one intercostal space above and below the chosen incisions. This mobilization provides room for the laterally placed bar stabilizers. Using the intercostal space corresponding to the deepest portion of the sternal defect, the pleural space is entered bilaterally, protecting the lung from parenchymal injury during this maneuver. Usually the anterior axillary line is chosen as an entry point, allowing for entry where the ribs transition from the anterior to the lateral chest wall.

### Retrosternal Dissection

A retrosternal tunnel is next created to allow passage of the steel bar in the retrosternal space. A Crawford clamp or similar device is carefully advanced by blunt dissection from the left hemithorax to the right side. For this maneuver, bone hook elevation of the distal sternum or video-assisted thoracoscopic surgery (VATS) may be helpful or necessary. We insist that the clamp pass from left to right, thus avoiding injury to the heart and pericardium. An umbilical tape is attached to the clamp and pulled retrogradely back through the retrosternal tunnel (Fig. 19-6B–D).

### Lorenz Bar

Using a series of bar templates, the appropriate size and approximate shape are selected for the stainless steel Lorenz bar (Walter Lorenz Surgical, Jacksonville, FL) (Fig. 19-6C). With the help of a bar-bending system, the bar is curved so that the substernal segment is as flat as possible to afford a sturdy support. One of the umbilical tapes is tied to the end of the Lorenz bar, and it is guided with the concave side up (upside down) through the retrosternal tunnel from left to right using VATS or sternal elevation (Fig. 19-6D). A steel bar turner is used to flip the bar in a craniocaudal direction and hold it in place while the correction of the pectus defect is examined (Fig. 19-6E). To remain most stable, the lateral parts of both sides of the bar arch must rest on the rib cage. Major changes to the concavity of the bar may require

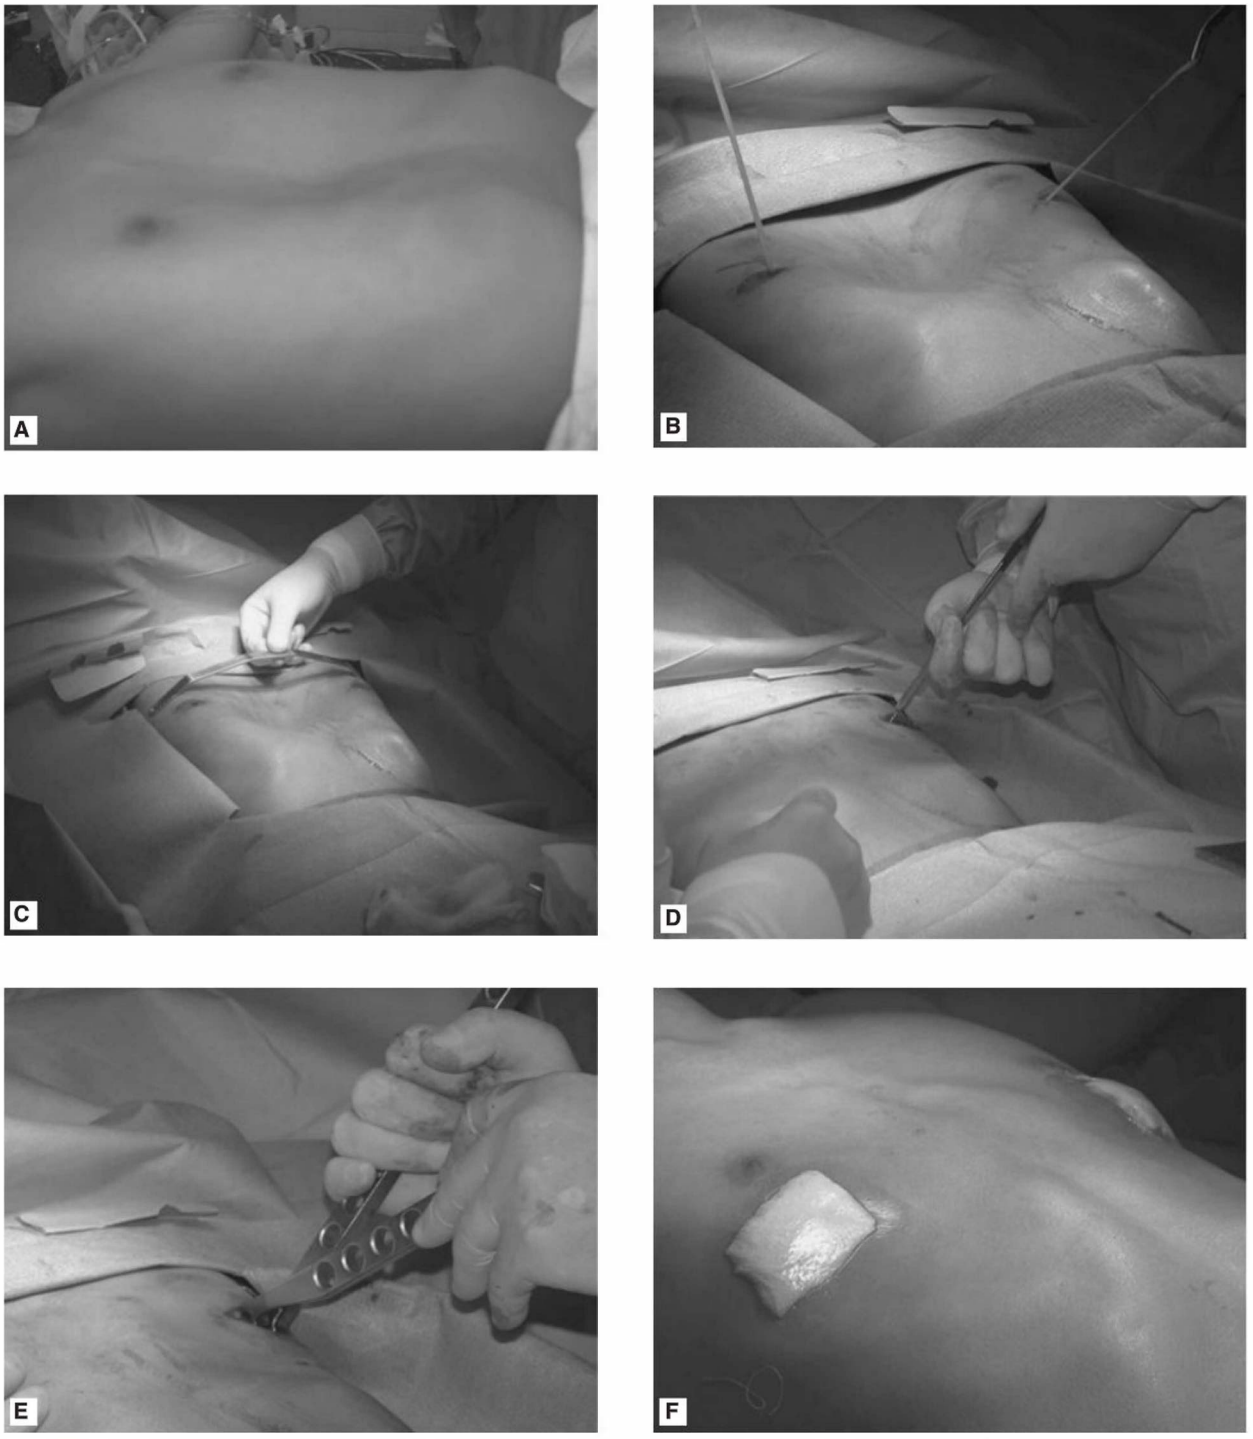

**FIGURE 19-6** Nuss repair. **A.** Patient positioned for procedure with arms outstretched. **B.** Umbilical tape is threaded through a retrosternal tunnel. **C.** Lorenz bar curved to conform to the patient's chest. **D.** After incisions are made into the pleural space bilaterally, a retrosternal tunnel is made and the bar is threaded through the tunnel, using the umbilical tape. **E.** Bar benders are used to bend the bar against the lateral chest wall. Stabilizing clips and stainless steel wires are used to further immobilize the bar. **F.** Completion of operation without chest tubes or drains.

**TABLE 19-5: Summary of Operative Steps in the Modified Nuss Repair for Pectus Excavatum**

1. Bilateral inframammary incisions at the deepest level of the sternum
2. Template measurements to determine length of bar; precurve bar to chest size
3. Development of retrostrenal plane from left to right (with or without thoracoscopy)
4. Passage of substernal clamp/umbilical tape
5. Insertion of pectus bar under sternum
6. Bar rotation and application of stabilizers
7. In situ bar bending and fixation with 5-mm or 6-mm surgical wire
8. Wound closure

unflipping the bar, with or without removal, and rebending it. Minor changes can be fixed with an in situ bar-bending system, which, in our experience, allows for optimal contour and subsequent stabilization. We place bilateral stabilizing clips and bend the end of the bar to keep the stabilizer in place. The bar is also fixed to the crossing rib using no. 5 or 6 wire sutures medial to each clip. Table 19-5 outlines these steps in the operative procedure.

## Evacuation of Pneumothorax

Usually, no chest tubes or drains are required (Fig. 19-6F). For closure, continuous fascial sutures are placed bilaterally but not tied. Then 40 cm of sustained inspiratory pressure is administered by the anesthesia team while the sutures are quickly pulled up and tied after the pleural air has escaped. Skin is reapproximated using a running subcuticular closure.

## VATS

Although VATS is not routinely used in the pediatric population, it is used at many centers performing the minimally invasive Nuss procedure. Typically right-sided VATS is used, but some surgeons employ either left-sided or occasionally bilateral approaches.[48,74] The trocar for VATS can be either inferior to the incision or through the incision site itself. The goal is to keep the introducer tip in view during VATS. If there is poor visualization from the ipsilateral side, the thoracoscope should be inserted from the contralateral side to visualize the introducer tip.

## Postoperative Management

Patients undergoing a modified Nuss procedure have a significant amount of postoperative pain; this is usually the limiting factor for discharge planning. In our experience, the analgesia requirement is even greater for this procedure than for the modified Ravitch repair. Patients should be placed on a patient-controlled analgesia (PCA) pump. Older patients are offered an epidural catheter. The PCA is discontinued within 48 to 72 h after which oral analgesics are used. Ketorolac is often added to the postoperative analgesic regimen. Patients are also prophylactically started on stool softeners to prevent constipation. Most patients are discharged on postoperative day 4 or 5. They are encouraged to return to school when they feel able to do so. This is usually 2 to 3 weeks after the operation. We restrict participation in sporting activities for up to 6 weeks. The Lorenz substernal bar is left in place for a period of at least 2 years to allow for optimal remodeling of the costal cartilages and repositioning of the sternum. Longer bar placement may be used for patients requiring reoperation and those with elastic cartilage abnormalities. Bar removal is usually an outpatient procedure and should not be scheduled during a growth spurt.

## Outcomes and Complications

The original report of 42 patients by Nuss and associates in 1998[7] has been followed by two reports from his group describing a 14-year experience of repair in 329 patients, including 14 reoperations for failed Ravitch repairs and 10 for failed Nuss repairs (2 of which were performed by the Nuss group).[78,82] Perioperative antibiotics and aggressive incentive spirometry are advocated to prevent bar infection, pneumonia, and atelectasis. Epidural anesthesia is recommended for analgesia, and both VATS and sternal elevation are described for bar insertion to minimize the risk of mediastinal injury. They report no cases of cardiac perforation, thoracic chondrodystrophy, or death using these techniques. Although 52 percent of patients developed pneumothorax, most resolved spontaneously, with only 1.2 percent requiring aspiration and 1.5 percent requiring tube thoracostomy. Pericarditis responsive to either indomethacin or pericardial fluid aspiration was reported in 2.4 percent of patients in this review, pneumonia in 0.9 percent, and wound infection in 2.6 percent, responsive mostly to antibiotics but resulting in bar removal in 3 patients. Before the routine use of bar stabilizers, bar displacement occurred in 15.7 percent of patients; this was reduced to 5.4 percent with stabilizers and even further with wire sutures. In 13 percent of these patients, double stabilizing bars were used.

Several other large series have reported similarly encouraging results, with good results in over 95 percent of patients but also with a reminder that a learning curve is associated with the introduction of this new technique.[79–81,84] Quality of life has been studied objectively and, using two quality-of-life models, was found to be improved.[85] Complications of the Nuss procedure include ileus, pleural effusions, atelectasis, flipped or displaced bar, pericarditis, chronic pain, worsening of chest wall asymmetry,[84] anterior thoracic artery pseudoaneurysm, thoracic outlet obstruction,[79] sternal erosion, and liver injury.[80]

A review of three major complications following Nuss repair was reported by Moss and colleagues.[86] One patient suffered a cardiac perforation requiring urgent sternotomy and repair on cardiopulmonary bypass. A second patient required open pleural and cardiac debridement for staphylococcal sepsis, bilateral empyema, and bacterial pericarditis. Three patients suffered thoracic outlet syndrome with persistent paresthesias. Postpericardiotomy syndrome refractory to nonsteroidal anti-inflammatory treatment has also been described and treated successfully with intravenous methylprednisolone. Table 19-6 outlines the complications reported following the modified Nuss procedure.

A recent meta-analysis that compared the Nuss and the Ravitch procedure found no significant differences in overall complications, length of hospital stay and time to ambulation. However, the rate of reoperation, postoperative hemothorax and pneumothorax after the Nuss procedure were higher when compared with the Ravitch procedure. There was also no clear difference noted in patient satisfaction from any of the studies that were part of the meta-analysis.[87] As reported in these studies, advantages of the Nuss repair include shorter operative time, smaller incisions, and less dissection at the potential expense of longer hospital stay, a high complication rate, more difficulty with success in older children and patients with connective tissue disorders, and a paucity of long-term outcome data.[87,88]

## ACQUIRED JEUNE'S SYNDROME

A dreaded complication of surgical correction for pectus excavatum is acquired thoracic chondrodystrophy, or acquired Jeune's syndrome (the congenital syndrome is described later in this chapter) (CXR, Fig. 19-7). This has been described in children referred for severe cardiopulmonary symptoms due to arrested chest wall growth following pectus operations.[51] These children underwent a modified Ravitch surgical repair at a very early age (<4 years old) that involved extensive resections of five or more costal cartilages.

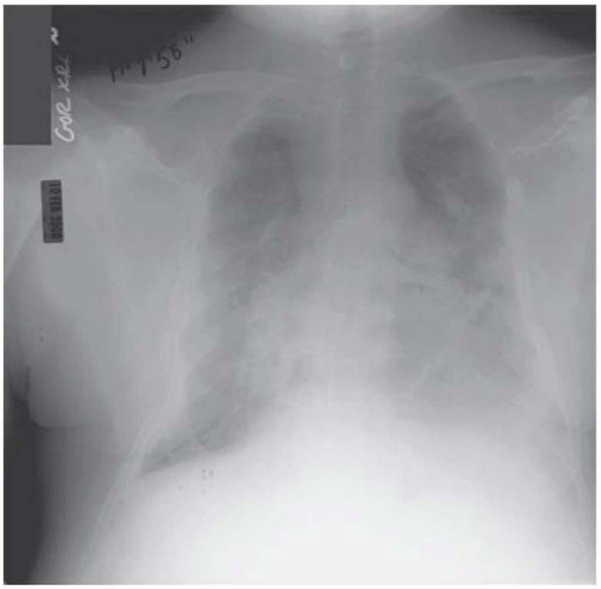

**FIGURE 19-7** Chest x-ray of a patient with acquired Jeune's syndrome. Note the small chest cavity in relation to chest wall and depressed diaphragm.

The restriction of chest wall growth resulted in FVCs of 30 to 50 percent predicted and forced expiratory volumes ($FEV_1$) of 30 to 60 percent.

Acquired Jeune's syndrome should not be mistaken for a recurrence of the pectus excavatum defect. The entire anterior chest wall is hypoplastic, as compared to the reversible depression of the sternum in the case of recurrent pectus. Acquired thoracic chondrodystrophy represents severe restriction of chest wall growth and movement; its natural history includes irreversible pulmonary hypertension.

Diagnosis is best made by clinical examination and CT scanning (Fig. 19-8A and B). Pulmonary function testing reveals very severe restrictive disease, with FEVs and FVCs <30 percent of predicted in most cases. Treatment is extensive and involves excision of all substernal cartilages, mobilization of all of the ribs to the anterior axillary line, and bar stabilization of the sternum. Rib grafts and sternal support bars may be required to stabilize the sternum after such a procedure. The use of rib grafts/compression/expansion plates and substernal support represents attempts to expand the compromised chest cavity. The best treatment for this life-threatening complication, however, is avoidance by delaying Ravitch operative repair in small children until at least the ages of 6 to 8 and minimizing chest wall resection and dissection in younger children.[51]

## RECURRENT PECTUS EXCAVATUM

Up to 5 percent of patients undergoing pectus excavatum repair will have a recurrence following initial surgical correction. The incidence of this is higher in younger patients

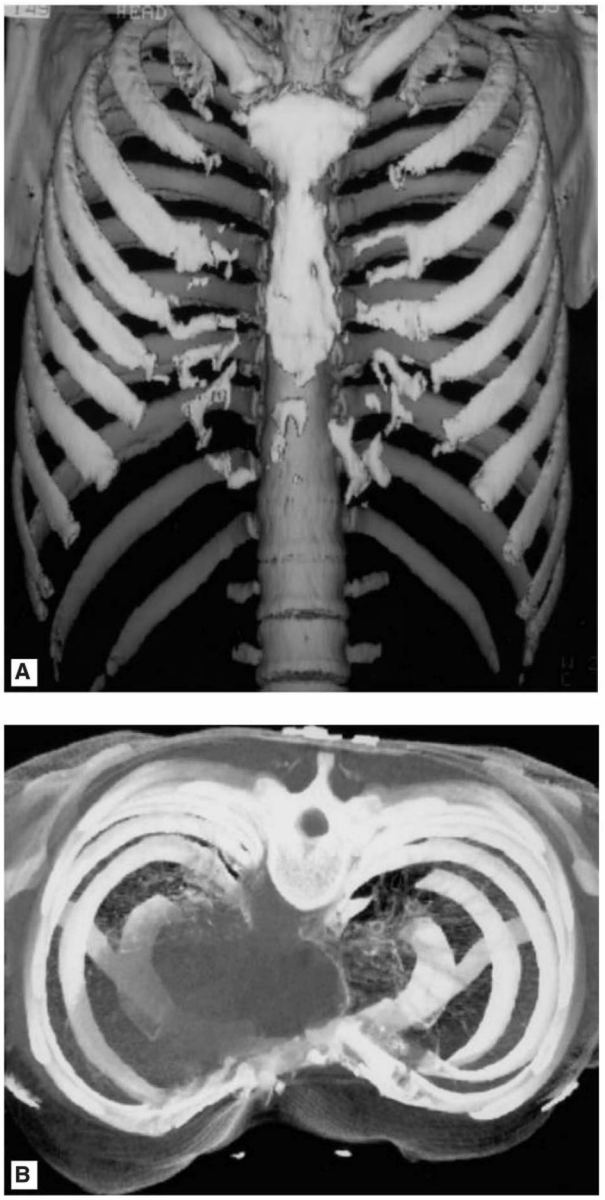

FIGURE 19-8 Recurrent pectus; three-dimensional scan reconstruction with two views (**A** and **B**) of patient with recurrent pectus excavatum.

undergoing repair prior to completion of the teenage growth spurt, in patients with connective tissue disorders such as Marfan's syndrome, and in patients undergoing redo repair.[53,54] Operative repairs using modifications of the techniques of Ravitch or Nuss have been successful.[53,66,83,89]

After a Ravitch repair or one of its modifications, the incidence of recurrence in large studies with long-term follow-up is reported at 2 to 11 percent.[53,63,77,90] One possible cause of recurrence is fibrous nonunion of the edge of the sternum to the costal margin after cartilage resection. As the child progresses through the growth spurt of the teen years, both a fibrous nonunion allowing bending of the sternum and the weight of the chest may play a pathophysiologic role in recurrences, as most are seen in patients below the age of 12 years.[61] If the rib cartilages entirely fail to reattach to the edge of the sternum, an unstable anterior chest wall is created rather than a recurrence, with an easily movable or "floating" sternum.[91]

On initial evaluation of a child with chest wall abnormalities following pectus excavatum repair, a recurrence must be distinguished from a carinatum deformity, an acquired Jeune's syndrome, or a floating sternum. These three deformities are addressed in other sections of this chapter. The severity of the recurrence should be assessed by clinical examination as well as CT scan if necessary. Pretorius and Haller studied the role of spiral CT in evaluating candidates for reoperation and found that CT could accurately define the orientation of the ribs, costal cartilages, and sternum as well as their interrelationships in both the pre- and the postoperative periods. CT findings can help plan an individualized operative repair.[45,92] Pulmonary function tests as well as cardiac output measurements or echocardiography should be performed to evaluate the extent of cardiopulmonary restriction.[28,29]

Indications for reoperative correction are the same as for primary repair and include significant pain, exercise intolerance, a Haller index greater than 3.0, sternal depression greater than 2.5 cm, or significant restriction demonstrated by pulmonary function tests or cardiac evaluation. Timing is critical, and reoperation in teenagers should be postponed until growth spurts have been completed.

The choice of operation depends on the initial operation used to correct the pectus deformity, the type of recurrence, the severity of the defect, the age of the patient, and the experience of the surgical team planning the operation. Successful repairs of pectus recurrences have recently been reported in large series using both modified Ravitch procedures[66,89] and modified Nuss repairs.[83]

Important considerations in preventing recurrence after reoperative Ravitch repairs include the use of a bar placed substernally to elevate the sternum to a neutral position, wiring of the costal cartilages to the edge of the sternum, or repeat subperichondrial resections of the costal cartilages. Wedge osteotomy is usually required, as with primary Ravitch repairs.[6,53,77]

Worldwide experience with Nuss repairs has led to considering the following modifications to primary Nuss repairs as well as reoperations using the Nuss technique. The Lorenz bar is fixated at the point where the bar exits the pleural cavity to first cross over a lateral rib. If the bar is not stable, a second wire is used at the point where the bar crosses a rib in the midaxillary line. Bilateral stabilizing clips are used much more liberally. A second bar is used above the first if the upper sternum remains depressed or below the first if the lower costal margin remains significantly depressed. Finally, in patients with recurrences or connective tissue disorders, placement of the Lorenz bar for periods in excess of the original 2-year recommendation seems

to have decreased problems in these patient populations. VATS is more valuable in reoperative patients as most of these patients do have some pleural adhesions because of their prior operation. An additional port may be necessary to lyse these adhesions. It is important to place chest tubes to help with postoperative hemopneumothoraces, which are more common in this reoperative group. About two-thirds of such patients have an excellent repair with the Nuss procedure. There is a very small (<2 percent) failure rate after the reoperative Nuss procedure.

## PECTUS CARINATUM

### Introduction

The pectus carinatum defect or keel chest mirrors the excavatum defect, with anterior protrusion deformity of the chest wall. Figure 19-9 depicts atypical patient with pectus carinatum. Incidence is about one-tenth that of pectus excavatum, with 0.06 percent of live births with a male predominance pattern like excavatum and a 25 to 30 percent reported family history.[93] Recent work has shown that milder forms of pectus carinatum do exist based on incidental findings on computer tomography.[94] Rotation and lengthening of the costal cartilages causes anterior displacement of the cartilages and resulting sternal protrusion. Carinatum can occur at any age, as early as in the toddler years, but like pectus excavatum, it becomes clinically apparent in the early teenage years. A number of unusual deformities can occur, including unilateral asymmetrical patterns, mixed carinatum/excavatum lesions, and upper chondromanubrial deformities.[94] A number of large clinical reports demonstrate successful surgical correction of carinatum deformities in both male and female patients.[41,47,70,71,93,95–99]

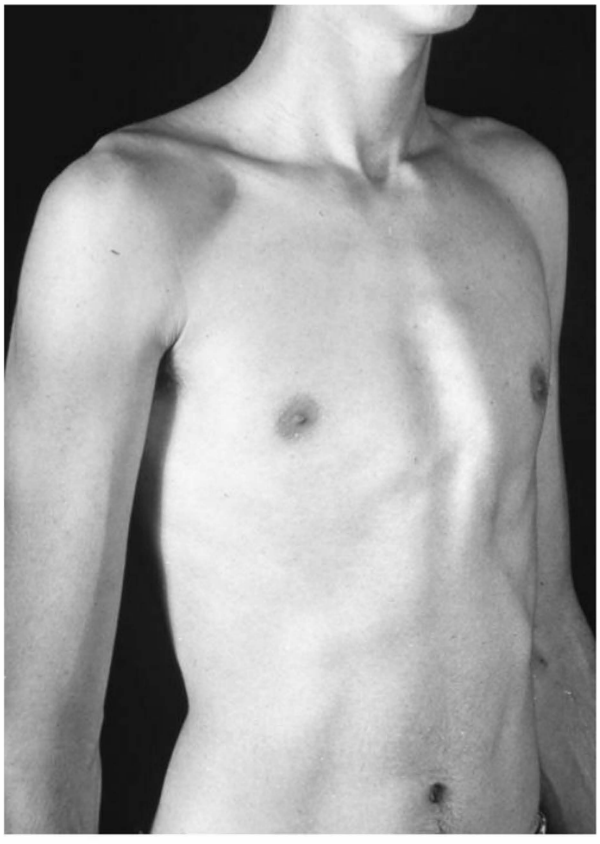

**FIGURE 19-9** Typical pectus carinatum patient with unilateral defect.

### Development and Pathophysiology

As with pectus excavatum, the etiology of pectus carinatum remains unknown. Familial proclivity has been reported,[93] and dominant mutations in the type II collagen gene *COL2A1* have been associated with pectus carinatum.[100] Scoliosis and other spinal deformities or a family history of these are associated with pectus carinatum as well.

Defective and elongated cartilage is responsible for pectus carinatum as well as excavatum. Rapid growth of the cartilages pushes the sternum forward, thus causing carinatum. If these cartilages displace the sternum posteriorly, excavatum occurs.

Since no significant cardiopulmonary abnormalities can be demonstrated with this lesion of the chest wall, carinatum remains a clinical diagnosis and no further diagnostic tests are required. Children with this anomaly do, however, complain on occasion of exertional dyspnea, limitations to exercise potential, frequent respiratory infections, and chest discomfort.[95,96] If necessary, CT scanning can clarify any question of differential diagnosis, better assess the anatomic defect, and help to plan the surgical correction.

Pectus carinatum can cause significant body disfigurement and pain and can have a profound effect on a growing teenager's body image (Fig. 19-10). Indications for surgical correction of pectus carinatum include pain, respiratory symptoms, ease of injury, and psychosocial concerns of body image. Because of a 20 to 30 percent chance of recurrence if this condition is corrected prior to the completion of pubertal growth spurts, repair must be deferred until the patient is fully grown, where the risk of recurrence is less than 1 percent. Table 19-7 outlines typical signs and symptoms of pectus carinatum.

### Operative Repair

Surgical correction for pectus carinatum utilizes the basic principles outlined earlier in this chapter for the modified open Ravitch repair (Table 19-8). Surgical goals include excision of all abnormal cartilages and return of the sternum to a neutral straight position. The same incision and flaps are created as described for patients with pectus excavatum. A meticulous search should be made for abnormal

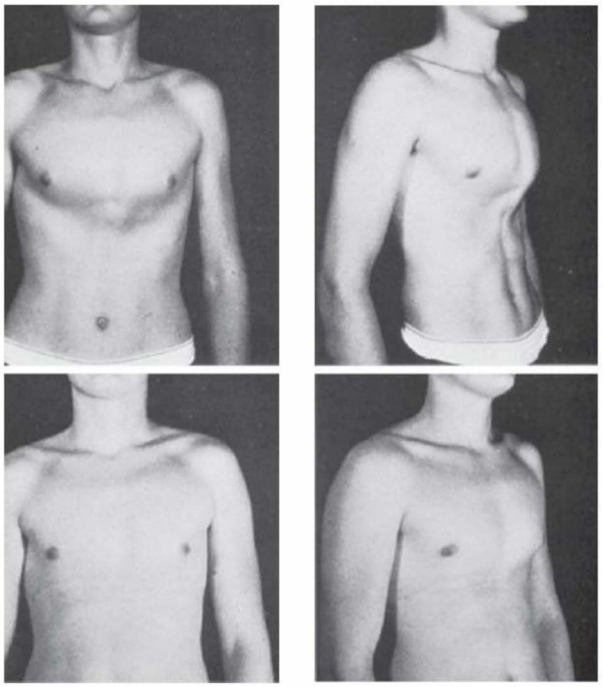

**FIGURE 19-10** Severe pectus carinatum with bilateral involvement of costal cartilages and elevation of the sternum; pre- and postoperative views.

cartilages, since they may be difficult to identify and those that go unrecognized are sources of recurrence. All abnormal cartilages, usually bilaterally, are resected using the subperichondrial technique of Ravitch. If the sternum remains anterior or rotated after subperichondrial resection, anterior sternal osteotomies can be performed to facilitate depression of the anterior table of the sternum to a neutral position. Oblique osteotomy corrects sternal rotation. In our institution, we use subpectoral and subcutaneous drains to avoid seromas. Hospital stay is usually 3 to 4 days, and neocartilage formation of 6 to 8 weeks' duration precludes contact sports or strenuous activity for this postoperative period.

**TABLE 19-7: Signs and Symptoms of Pectus Carinatum**

| |

3. Excision of all elevated cartilages
4. Contralateral cartilage resection (if unilateral)
5. Anterior sternal osteotomy to depress sternum to neutral position
6. Bone wedge to hold sternum in neutral position
7. Wound closure with closed drainage

## Outcomes and Complications

Fonkalsrud and Beanes have described their 30-year experience with 90 children who underwent surgical repair of pectus carinatum defects.[96] All of the children were symptomatic, including 84 with exertional dyspnea and exercise limitation, 52 with respiratory infections, 24 with asthma, and 38 with pain. Modified Ravitch-type repairs were used in all patients. Deaths were none and complications were minimal, with only 5 patients developing seroma, 3 with pleural effusions, and 2 with pneumothorax. Mean hospital stay was 2.6 days and follow-up was 12.8 years. The authors described one recurrence amenable to reoperation, and all children reported marked clinical improvement. Similar success, although with greater technical difficulty, has been reported with pectus carinatum repair in adults.[41,47,71]

Two other large series have reported success in the surgical correction of pectus carinatum defects. Saxena and Willital reviewed a 14-year experience of 111 patients using double bilateral chondrotomy and retrosternal mobilization and stabilization with metal struts; they reported 98 percent success, 1.8 percent major recurrences, and 2.7 percent minor recurrences.[99] Shamberger and Welch reported a 12-year experience of 152 pectus carinatum repairs utilizing bilateral resection of costal cartilages and osteotomy, with satisfactory results in all patients and only a 3.9 percent complication rate, including pneumothorax, wound infection, atelectasis, and local tissue necrosis. Experience at our own institution has been similar, with virtually no recurrence in patients corrected after maximal growth.[98]

# OTHER CHEST WALL ANOMALIES

## Poland's Syndrome

Alfred Poland, as a medical student affiliated with Guy's hospital, is credited with having described, in 1841, the congenital absence of pectoralis major and minor muscles, although this had previously been reported in the French and German literature in 1826 and 1839, respectively.[101–103] Poland's finding was attributed to his name in 1962 by Clarkson of the same hospital.[104] Poland's syndrome or

pectoral aplasia is a spectrum of deficiency or absence of components of the chest wall, including the pectoralis major, pectoralis minor, serratus anterior, ribs 2 to 5, and the breast and areolar complex.[105] Associated hand deformities include brachydactyly, syndactyly, and ectromelia.

The incidence of this disease is approximately 1 in 30,000 live births.[106,107] Shamberger and associates recently reported a 33-year 75-patient experience with Poland's syndrome.[108] Of these patients, 40 were male and 35 female; 44 were right-sided, 30 left-sided, and 1 bilateral. Absence of the pectoralis major and minor muscles or their significant hypoplasia was described in all patients. The spectrum of chest wall involvement included 41 patients with normal chest walls, 10 with hypoplasia of the ribs, 11 with major depression deformities and 5 with minor depression deformities of the ribs, and 8 with complete aplasia of the ribs.

In its most severe form, the classic presentation of Poland's syndrome involves herniation of the lung through the chest wall defect during coughing or crying in a newborn. For this flail segment, prompt repair is necessary. Without lung herniation, toddlers with this syndrome can be observed until adolescence, when the remaining muscles of the chest wall have reached a size sufficient to facilitate repair. Repair should be timed based on clinical symptoms, cosmetic abnormalities, and the age and physical build of child.

Successful surgical repair using autologous rib grafts,[108] latissimus muscle flaps,[109] synthetic mesh,[110] or a combination of these modalities has been described. CT is an acceptable means of evaluating these patients after surgical repair. Figure 19-11 shows a typical patient before and after repair. Postoperative recurrence is unlikely and can be repaired with rewiring of the original bone or cartilage grafts to the sternum and native rib cage or with autologous grafts and mesh similar to the procedure in primary repair.

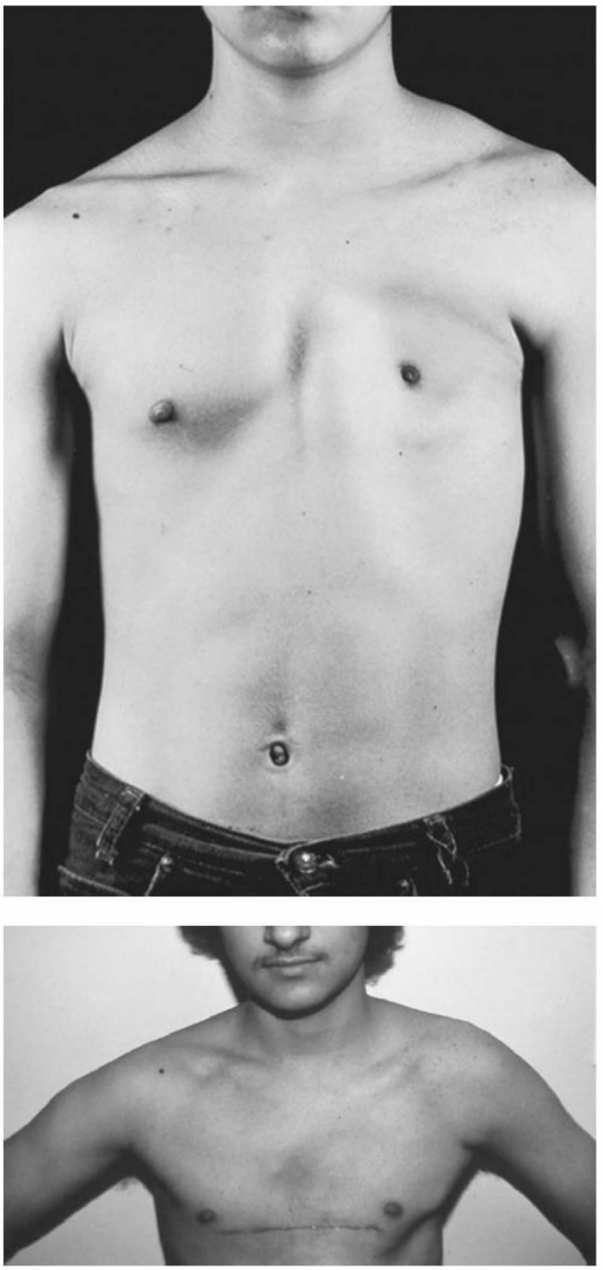

**FIGURE 19-11** Teenager with right-sided Poland's syndrome; pre- and postoperative views.

## Pentalogy of Cantrell

A syndrome of lower sternal cleft, epigastric or high omphalocele, anterior diaphragmatic defect, absent pericardium, and an intracardiac anomaly was originally described in 1958 by Cantrell.[10] The developmental etiology is unknown, but it has been suggested to relate to anomalies in defined subunits of a ventral midline developmental field.[111] As with all developmental syndromes, a spectrum of clinical manifestations can be found. The heart is usually found within the omphalocele defect and, if the omphalocele ruptures, an ectopia cordis can be created (Fig. 19-12). Regardless, immediate surgical attention is warranted in any case of pentalogy of Cantrell. Staged repair is usually required to first close the epigastric omphalocele, repair the diaphragmatic defect, and effect skin coverage of the heart. Secondary procedures to obtain bony coverage of the heart may be delayed for 2 to 3 years to allow for adequate growth. Repair of the intracardiac defect is usually deferred until after somatic closure, although in rare instances simultaneous repair can be accomplished.

## Jeune's Syndrome

Originally described by Jeune in 1954,[9] the syndrome of asphyxiating thoracic chondrodystrophy ranges from a lethal condition at birth to a survivable and surgically treatable disorder.[112] The original patient described had a narrow, rigid chest wall and multiple cartilaginous anomalies and died early in the perinatal period from respiratory insufficiency.

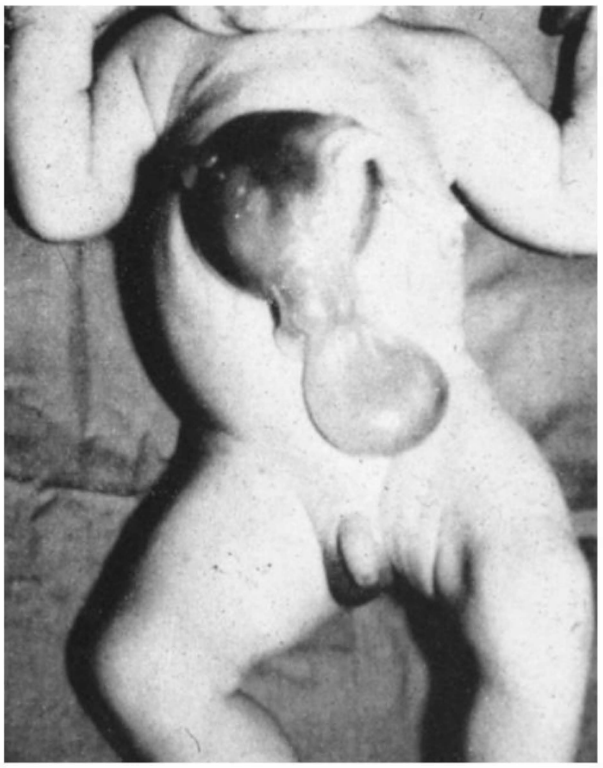

**FIGURE 19-12** Photograph of a newborn infant with pentalogy of Cantrell. Note the upper omphalocele, foreshortened sternum with defect, and pericardial defect.

An autosomal recessive pattern of inheritance has been described, but not in association with known chromosomal abnormalities.[113]

Clinical features include a narrow thorax along both the transverse and the sagittal axes, protuberant abdomen, little respiratory movement of the chest wall, short and wide ribs, costochondral junctions that are splayed and barely reach the anterior axillary line, and irregular costal cartilage. Associated findings include short extremities with relatively wide bones, fixed and elevated clavicles, and a small hypoplastic pelvis (Fig. 19-13A and B). Pulmonary development can also be abnormal; findings vary from patient to patient.[114]

Operative repair offers limited success and is usually performed when children are on oxygen and may be ventilator-dependent. Available modalities for surgical chest wall expansion include sternal splitting, anterior chest wall release, autologous grafts, artificial ribs, stainless steel support struts, and mesh and other prostheses. After axial growth, further procedures may be required to facilitate chest wall expansion. The limiting factor for survival following surgical correction is not the chest wall itself but the underlying pulmonary hypoplasia.

## Cleft Sternum

Failure of ventral fusion of the thoracic wall causing cleft sternum or sternum bifidum is extremely rare, and the largest series in the literature comprise fewer than 10 patients

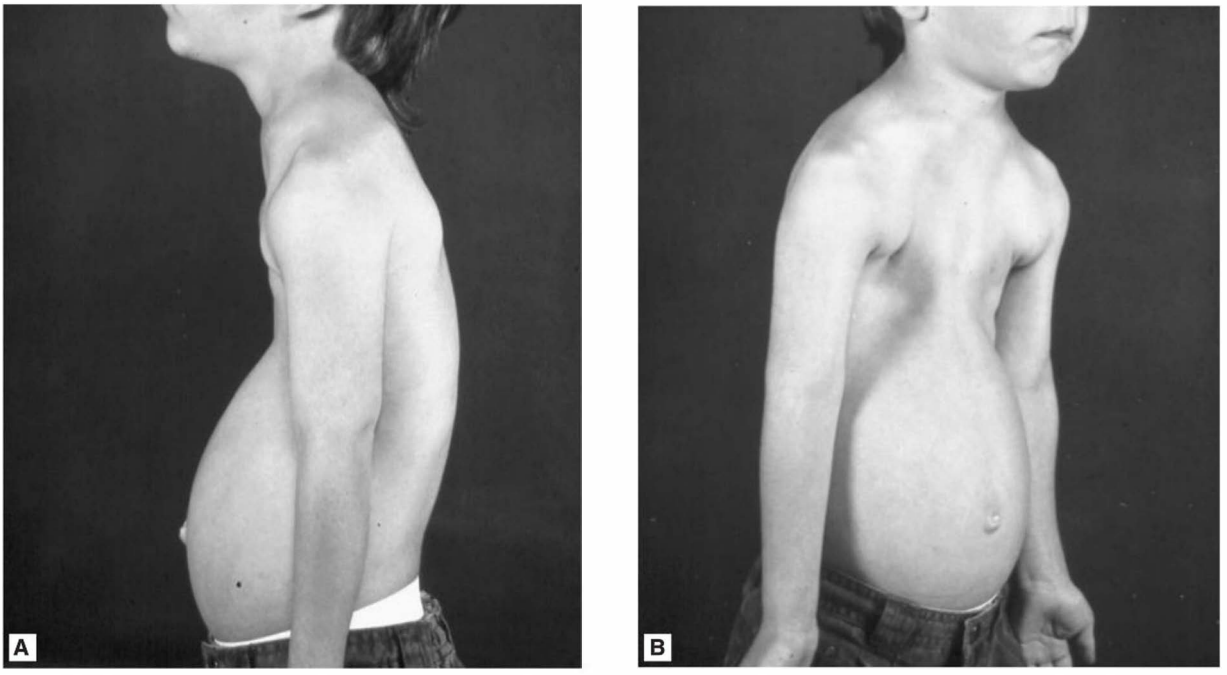

**FIGURE 19-13** Patient with congenital Jeune's syndrome. The lateral view (**A**) shows a marked decrease in the AP diameter of the chest, while the anterolateral view (**B**) shows marked undergrowth of ribs.

each.[115–117] Associated malformations include congenital cardiac abnormalities, maxillofacial hemangiomata, and omphalocele.[115,118] The goals of surgical correction of the split sternum are bony protection of the heart, great vessels, and other mediastinal structures as well as anterior thoracic stability to maintain normal physiologic pressures for the support of respiratory function and circulation.[118,119]

Cleft sternum can be classified into superior, inferior, and total. This is based on where the cleft exists on the sternum proper. Patients will notice paradoxical deepening of the sternum on inspiration and protrusion with coughing or expiration. Occasionally, the heart can be seen pulsating under the skin.

Repair of sternal clefts is best performed in the neonatal period, where primary repair is possible.[115,117,118,120,121] Isolated reports have demonstrated some success of surgical correction in adults as well, using bone grafts, muscle flaps, sliding chondrotomies, posterior sternal wall repairs, posterior periosteal flaps, sternal bars, and chondral grafts.[117, 118,121–124]

Acastello and coworkers recently reviewed their experience with 8 patients over a 14-year period, 6 (75 percent) of whom were female, who underwent surgical correction of sternal cleft with 1- to 8-year follow-up.[115] Three methods were used: (1) primary closure; (2) partial resection of the upper three costal cartilages and disruption of the sternoclavicular junction, followed by closure of the sternal bars with wire; and (3) mobilization and approximation of sternocleidomastoid muscles with costal homograft and mesh. All three groups fared relatively well, although one patient in group 3 had an unsatisfactory result and required reoperation with the technique of group 2. The patients corrected with primary repair had the best outcomes, although mild pectus excavatum developed in some in the long term.

## Minor Anomalies

A number of chest wall anomalies may occur that usually require specific diagnosis but may not require operative intervention. Rib anomalies include fusion, partial absence, and growth deformities. Similar findings may occur with the costal cartilages, particularly in the costal margin area of the lower chest. Most of these anomalies do not require surgical intervention unless there is instability of the chest wall or significant body image issues exist. Most anomalies for which operative repair is contemplated should be observed until children reach school age or complete teenage growth.

## CONGENITAL CHEST WALL ANOMALIES BOARD REVIEW QUESTIONS (CHAPTER 19)

1. Which of the following statements is incorrect regarding repair of pectus excavatum in children?
   A. Repair should be avoided during pubertal growth spurt.
   B. Repair has good outcomes before pubertal growth spurt.
   C. Repair has good outcomes after pubertal growth spurt.
   D. Puberty has predictable effects on chest wall morphology.

2. Which of the following is correct regarding pectus excavatum?
   A. Pectus excavatum is associated with trisomy 18.
   B. Pectus excavatum does not occur in patients with Ehlers–Danlos syndrome.
   C. Up to two-thirds of children with Marfan's syndrome have pectus excavatum.
   D. Patients with connective tissue disorders do not achieve the similar functional results after repair of pectus excavatum compared with the average patient.

3. Patients with Jeune's syndrome:
   A. May have an autosomal recessive pattern of inheritance
   B. Typically have chromosomal abnormalities
   C. Have normal pulmonary development
   D. Have best results from surgery when asymptomatic

4. Which is correct regarding repair of pectus excavatum with the Nuss procedure?
   A. Bilateral chest tubes should be placed at the end of the operation
   B. Retrosternal dissection should be carried out from right to left side
   C. Dissection may be performed using thoracoscopy
   D. The Nuss procedure should be reserved for children and adolescents

5. Which is true regarding the preoperative workup for repair of pectus excavatum?
   A. Psychological factors have little impact in children.
   B. Repair is indicated for a Haller index of 3 or above.
   C. Patients do not need pulmonary function studies unless they require oxygen at home.
   D. Preoperative dyspnea on exertion related to pectus excavatum is unlikely to be improved.

## ANSWERS

1. **Answer: D.** Proper timing of surgical repair is essential for adequate outcome, although this is also frequently debated and based on retrospective data. In general, good results have been reported with correction in school-aged children between the ages of 8 and 16, either before or after but not during their pubertal growth spurts. Repair during growth spurts is not recommended because of the variable change in the morphology of the child's chest during this time.[15,42,49] There is a slight advantage of undergoing a repair before puberty, which is the ability of the bar to stabilize the malleable chest during this period and throughout the puberty spurt.
2. **Answer: C.** Pectus excavatum is relatively common, occurring in approximately 1:400 live births, with a male predominance of up to 5:1.[15] No genetic abnormalities or chromosomal aberrations have been associated with pectus excavatum, although a familial tendency has been described.[15,16] Up to two-thirds of children with Marfan's syndrome and a high frequency of Ehlers–Danlos patients develop pectus excavatum deformities.[3,4] Children with connective tissue disorders can present later in life, have more progressive defects, and suffer from more complicated postoperative courses, but successful cosmetic and functional results can be achieved even in these patients.[4]
3. **Answer: A.** An autosomal recessive pattern of inheritance has been described in patients with Jeune's syndrome, but not in association with known chromosomal abnormalities.[113] Pulmonary development is typically abnormal; findings vary from patient to patient.[114] Operative repair offers limited success and is usually performed when children are on oxygen and may be ventilator-dependent. Available modalities for surgical chest wall expansion include sternal splitting, anterior chest wall release, autologous grafts, artificial ribs, stainless steel support struts, and mesh and other prostheses. After axial growth, further procedures may be required to facilitate chest wall expansion. The limiting factor for survival following surgical correction is not the chest wall itself but the underlying pulmonary hypoplasia.
4. **Answer: C.** During the Nuss procedure, a retrosternal tunnel is created to allow passage of the bar in the retrosternal space. A Crawford clamp or similar device is carefully advanced by blunt dissection from the left hemithorax to the right side. For this maneuver, bone hook elevation of the distal sternum or video-assisted thoracoscopic surgery (VATS) may be helpful. We insist that the clamp pass from left to right to minimize potential injury to the heart and great vessels. Pneumothoraces on both sides are evacuated at the end of the operation with a sustained Valsalva maneuver; routine chest tube placement is not necessary. The Nuss procedure can be performed on older adolescents and adults; there is no specific age contraindication in the adult population.
5. **Answer: B.** Factors determining candidates for repair of pectus excavatum defects include anatomic, physiologic, psychological, considerations as well as proper timing (Table 19-2). A CT scan can accurately define the anatomic defect, including the severity index of the sternal depression as well as its effects on cardiac and pulmonary anatomy. A Haller index of 3 or greater is an indication for surgery.

# 20 Benign Pleural Disorders

*Joshua T. Taylor*
*Maurice A. Smith*

## KEY CONCEPTS

The pleura are anatomically and physiologically distinct structures. The pleural cavities are formed early during embryonic development from the intraembryonic coelom. Anatomically, the pleura are divided into two structures: the visceral and the parietal pleura. The visceral pleura lines the lungs and is intimately invested with the lung parenchyma. The parietal pleura lines the chest wall, diaphragm, mediastinum, and the superior portion of the lungs.

- Pathophysiology
  - The pleura and pleural fluid production are tightly regulated anatomical and physiologic entities. The pleura function as serous membranes that line the lungs and chest wall by creating a sealed space between the lungs and atmosphere, allowing for the development of distinct intrathoracic pressures necessary for respiration and the production of pleural fluid. Pleural fluid serves as a lubricant as well as a mechanical coupler between the chest wall and the lungs during respiration. The pleural cavity is a potential space that exists until various pathologic processes interrupt the normal anatomy or physiology of the space, exposing the cavity. Air, excess pleural fluid, chyle, infections, and fibrous tissue are all potential pathologic entities that can disrupt the pleura and pleural space.
- Clinical features
  - Patients presenting with pleural disorders often complain of a myriad of symptoms; however, most commonly patients will present with one or more of the following: dyspnea, chest pain, and cough. The history and physical examination help to differentiate the etiology of these symptoms. Questions that investigate the onset and duration of these symptoms, their character, and past medical and surgical history can all be illuminating. The physical examination is indispensable in investigating pleural diseases. Dullness or hyperresonance on percussion, decreased or increased tactile fremitus, breath sounds, and visual inspection of the chest wall and respiratory pattern can further refine the diagnosis.
- Diagnostics
  - Diagnosing pleural disorders often starts with a standard posteroanterior and lateral chest x-ray. The lungs, chest wall, and mediastinum are visualized, and if a pathologic process occurs, the pleural cavity is also visualized. More advanced visualization techniques such as a computed tomography (CT) scan and ultrasound may be necessary to further define the process. In some cases, invasive techniques (i.e., thoracentesis in pleural effusions) are required to finalize a diagnosis.
- Management
  - Benign pleural disorders are a diverse group of diseases that require complex management and often a combination of both medical and surgical approaches. For example, for pneumothoraces, conservative management involves evacuating the pleural space. If conservative management fails or there is worsening of the disease or recurrence, the patient proceeds to surgical therapy. Conservative management attempts to decrease the disruption within the pleural space and treat the underlying cause. Surgery is often reserved for refractory cases or patients with contraindications to conservative management.
- Outcomes and prognosis
  - The term "benign" is misleading in describing nonmalignant pleural disorders. If left untreated or not properly treated, these diseases can lead to significant morbidity and even mortality. Some disease processes do recur and ultimately require more extensive surgical management or chronic conservative treatment. However, with prompt and appropriate treatment, patients can be managed effectively, and morbidity and mortality rates reduced significantly.

# INTRODUCTION

The pleura and lung work in concert to perform the mechanics of respiratory function. The potential space between the pleura and lung provides negative pressure, serves as a lubricant, and is a mechanical coupler between the lung and chest wall during respiration. This delicate balance can be interrupted by benign processes that alter the normal anatomy of the pleura and pleural space. With an estimated incidence of 1.5 million pleural effusions in the United States annually, an understanding of the diagnosis and treatment of this and other benign pleural diseases is valuable in one's clinical armatorium.

# PLEURAL EMBRYOLOGY

## Formation of the Pleural Cavities

The pleural cavities are formed during the fourth week of embryonic development. Initially, the septum transversum evaginates into the intraembryonic coelom separating the coelom into a primitive pericardial cavity and peritoneal cavity. The septum transversum migrates to its final position inferior to the lung buds, where it eventually forms part of the diaphragm. The primitive pericardial cavity is separated into the pleural and pericardial cavities by pleuroperitoneal folds that grow from the lateral walls of the cavity medially. The medial fusion of these projections forms three distinct cavities: the two lateral pleural cavities and the medial pericardial cavity. Inferiorly, the pleural cavities communicate with the peritoneal cavity but are eventually closed by dorsoventral growth from the pleuroperitoneal membranes (failure to close in the fetus results in congenital diaphragmatic hernia).[1,2]

## The Pleura

The lung forms from a respiratory bud that evaginates from the embryonic foregut and grows ventrally into the newly forming pleural cavities. The respiratory epithelium of the lungs is derived from the endodermal cells of the foregut; however, the supportive cartilage, muscle, and the visceral pleura are formed from the mesoderm that the respiratory bud is surrounded by as it evaginates. The mesoderm, which composes both the visceral and the parietal pleura, differentiates into a single layer of mesothelial cells and a supportive tissue forming a serous membrane that allows frictionless movement in the pleural cavity as the lungs expand and retract.[1,2]

# PLEURAL ANATOMY

## Gross Anatomy

In adults, the pleura is divided into the visceral and parietal pleura. The visceral pleura is a thin serous layer that completely invests the lungs, including the fissures. There is no separation between the visceral pleura and the lung parenchyma. The blood supply to the visceral pleura is through the bronchial arteries, and venous drainage through the pulmonary veins. Lymphatic drainage of the visceral pleura occurs primarily through deep pulmonary plexuses within the lung parenchyma at the interlobar and peribronchial spaces. The visceral pleura is not innervated by the somatic nervous system.

The parietal pleura lines the chest wall, diaphragm, portions of the pericardium and mediastinum. Thus, the parietal pleura has distinct anatomical names; the costal pleura, diaphragmatic pleura, pericardial pleura, mediastinal pleura, the cupula of the pleura, or cervical pleura, where the pleura reflects over the superior portion of the lungs. The cupula protrudes into the anterior inferior neck, posterior to the sternocleidomastoid muscle, extending approximately 2 to 3 cm cephalad from the superior border of the first rib. The parietal pleura tightly adheres to both the diaphragm and the pericardium, but is dissectible from the ribs, cupula, and mediastinum. Arterial blood is supplied to the parietal pleura through branches of arteries supplying the ribs, diaphragm, and mediastinum. Venous drainage is through the veins running parallel with the arterial supply, and direct drainage into the superior vena cava. Lymphatic drainage of the parietal pleura occurs anteriorly through the internal mammary nodes, posteriorly into the intercostal nodes, and the diaphragmatic parietal pleura drains into the retrosternal and mediastinal nodes. The parietal pleura is innervated by the somatic, sympathetic, and parasympathetic nervous system through the intercostal nerves. Similarly, the diaphragmatic parietal pleura is innervated through the phrenic nerve.

The visceral and parietal pleura are continuous with each other at the lung hilum. At the inferior lung root, the reflections of anterior and posterior pleura come together along the mediastinum and extend inferiorly to the diaphragm, forming the pulmonary ligament. The pulmonary ligament functions to anchor the inferior lung to the diaphragm.

In healthy adults, only a thin layer of serous fluid separates the parietal and visceral pleura. Normally, the pleural cavity is a potential space that exists between the visceral and parietal pleura. This cavity becomes apparent when large amount of fluid or air is present during pathologic processes. The lung fills the pleural cavity almost entirely, except for the inferior recesses of the diaphragm and the anteriomedial mediastinum posterior to the sternum. These spaces are known as the phrenicocostal sinus and costomediastinal sinus. These sinuses are the earliest sites of excess fluid accumulation during pathologic processes.

## Histology

The pleura consist of five layers: (1) an innermost mesothelial cell layer, (2) a submesothelial interstitial connective tissue layer, (3) an inner thin elastic fiber layer, (4) an outer interstitial connective tissue layer, and (5) a thick elastic fiber layer. The mesothelial cells are lined with microvilli.[3]

The microvilli function to increase surface area of the mesothelium thereby serving two functions: (1) cellular transport and metabolic activities related to pleural fluid reabsorption and (2) enmesh glycoproteins that aid in lubricating the pleura, decreasing friction during lung movement.[4] These functions are supported by the geographic distribution of the mesothelium with microvilli. In general, the visceral pleura contains more cells with microvilli than the parietal pleura, and the density of microvilli increases caudally. This is due to the role the visceral pleura plays in reabsorption of the pleural fluid, and the increased friction at the base of the lung, respectively.

## PHYSIOLOGY OF THE PLEURA

### The Pleura

The pleura serves three primary functions. First, the pleura forms a serous layer over the lung and chest wall, preventing adhesions of the lung to the chest wall and allowing for easy deformation of the lungs when in contact with other structures (i.e., the pericardium or diaphragm). Second, the pleura produces pleural fluid, whose function will be described later. Finally, the pleura acts as a barrier between the atmosphere and the alveolar space allowing for the development of distinct intrathoracic pressures necessary for normal respiration.[4–6]

### Pleural Fluid

Pleural fluid is produced primarily by the parietal pleura through the capillaries feeding the parietal pleura. The negative intrathoracic pressure produces a hydrostatic pressure that counteracts the oncotic pressure within the capillaries, thus favoring fluid movement into the pleural cavity. Pleural fluid is absorbed by the visceral pleura through passive and active uptake by the mesothelial cells as well as lymphatic stomas within the parietal pleura. Roughly 3.4 mL/kg of fluid is produced per day by the pleura; however, only 0.1 to 0.3 mL/kg of fluid is present in the pleural cavity at any given time.[5,6]

The fluid serves two important functions. The first is converting the shearing perpendicular forces generated by the chest wall and diaphragm that are exerted onto the lung into sliding forces, thereby, coupling the movement of chest wall and lung expansion.[5] Second, it provides lubrication for the lung and chest wall, which decreases friction of movement during respiration, thus decreasing the amount of work required for respiration.

## PNEUMOTHORAX

### Definition

A pneumothorax is defined as air in the pleural cavity. Air enters the pleural space by two primary methods[7]:

**TABLE 20-1: Causes of Pneumothorax**

| |
|---|
| Spontaneous |
| Primary spontaneous |
| No underlying respiratory disease, often ruptured bullae or blebs |
| Secondary spontaneous |
| Underlying respiratory disease, most commonly COPD |
| Traumatic |
| Noniatrogenic |
| Blunt or penetrating thoracic trauma |
| Iatrogenic |
| Invasive thoracic procedures |
| Tension |
| Catamenial |

1. Communication between the pleural cavity and the atmosphere.
2. Communication between alveolar air and the pleural cavity.

Clinically, pneumothoraces can be divided into four major categories: spontaneous, traumatic, tension, or catamenial. Table 20-1 lists the causes of pneumothorax.

### Clinical Features

Symptoms of a pneumothorax can be diverse and are often dependent on concomitant disease and methods of presentation. For spontaneous pneumothoraces, sudden onset of dyspnea, unilateral pleuritc chest pain, and cough are the most common symptoms. The chest pain often resolves within 24 h and the dyspnea is dependent on the size of the pneumothorax, but usually it is a minor symptom in an otherwise healthy patient.

### Diagnosis

The physical examination can be helpful if the pneumothorax is significant. Decreased breath sounds and tactile fremitus in the area of the pneumothorax as well as hyperresonance on percussion can be present. However, it is important to remember that small pneumothoraces will often have normal examinations and clinical suspicion of a pneumothorax should be investigated further.

The radiographic modality of choice is an upright posteroanterior or lateral (with the affected side superior) chest x-ray. Findings on x-ray include a thin pleural line displaced from the chest wall often accompanied by a radiolucent area devoid of lung markings. Small pneumothoraces may be difficult to evaluate on chest x-ray and computed tomography (CT) scans may be necessary. However, CT scans should not be routinely employed to diagnose a pneumothorax.

True tension pneumothorax is a rare, but clinically significant manifestation. It is important to be able to recognize physical signs of a tension pneumothorax, as delay in

diagnosis can be catastrophic. Often these patients present with symptoms mentioned earlier, but the dyspnea is out of proportion to the common presentation and is accompanied by diaphoresis, tachycardia, cyanosis, hypotension, and deviation of the trachea away from the affected side. These symptoms are a result of air trapping within the pleural cavity causing a shift of the mediastinum as well as reduced preload and stimulation of the sympathetic nervous system.[8] Prompt recognition and resolution is vital, and radiology is often deferred until treatment has been instituted.

## Spontaneous Pneumothorax

Spontaneous pneumathoraces can be subdivided into primary spontaneous pneumothorax (PSP) and secondary spontaneous pneumothorax (SSP). A PSP is a pneumothorax that develops without insult in a patient with no underlying pulmonary disease. Classically, these patients are tall, thin, young adult males, who are found to have ruptured apical subpleural pulmonary blebs. The etiology of pulmonary blebs is often unclear, but it has been postulated to be due to heredity, congenital malformations, or distal airway inflammation. PSPs have a reported incidence of 7.4 to 18 cases/100,000 per year in males and 1.2 to 6 cases/100,000 per year in females. Roughly, 20,000 new cases are reported annually in the United States. Patients are usually between the ages of 10 and 30 years, and cigarette smoking is a significant risk factor.[9]

SSP occurs without warning in patients with known pulmonary disease. The most common pulmonary disease associated with SSP is chronic obstructive pulmonary disease. Children with underlying pulmonary disease, such as cystic fibrosis, can also present with SSP. Clinically, these patients often present in severe respiratory distress due to the existing respiratory dysfunction. SSPs have a reported incidence of 6.3 cases/100,000 in males and 2 cases/100,000 in females.[9]

## Traumatic Pneumothorax

There are iatrogenic and noniatrogenic traumatic pneumothoraces. Noniatrogenic pneumothoraces are commonly encountered with patients presenting with either blunt or penetrating thoracic trauma. Pneumothorax is the second most common sign of thoracic trauma, occurring in up to 50 percent patients.[10] In these cases, the diagnosis of pneumothorax may be unclear, but in any patient requiring mechanical ventilation after thoracic trauma, a chest tube should be placed and a CT scan obtained.[8]

Iatrogenic pneumothoraces are the most common nosocomial pneumothorax. Pneumothorax occurs following transthoracic needle biopsy (24 percent), subclavian vein catheterization (22 percent), thoracentesis (20 percent), transbronchial lung biopsy (10 percent), pleural biopsy (8 percent), and positive-pressure ventilation (7 percent).[11] Iatrogenic pneumothorax is often a result of physician's inexperience with the procedure and therefore diagnosis is often delayed.

## Tension Pneumothorax

The etiology of tension pneumothorax is often multifactorial. The underlying pathophysiology is an injury that allows air to enter the pleural space without subsequent removal leading to the development of positive intrathoracic pressures, which cannot be overcome by the respiratory cycle.[12] Thoracic trauma is the most easily recognized cause of tension pneumothorax, but other etiologies exist. Spontaneous pneumothoraces can evolve into tension pneumothorax if the parenchymal lesion is not contained with the initial collapse. Iatrogenic pneumothoraces, such as barotraumas, and puncture injures can lead to tension pneumothoraces as well. Treatment of tension pneumothorax should be done promptly and judiciously. The most common primary treatment is decompression with needle thoracostomy. Needle thoracostomy allows for rapid resolution and does not require the procedural skills necessary for tube thoracostomy. However, the definitive therapy for a tension pneumothorax is tube thoracostomy, and therefore placement of a chest tube should not be delayed. Needle thoracostomy is a temporizing agent.

## Catamenial Pneumothorax

Catamenial pneumothorax is a rare form of spontaneous pneumothorax. It generally occurs in women aged 30 to 40 years. The pneumothorax most often presents between 24 and 72 h after the onset of menstruation. Several theories have been postulated as to the cause, but most commonly, the presence of pelvic or thoracic endometriosis leading to perforation of the diaphragmatic pleura and the introduction of air into the pleural space are the causes. Treatment for catamenial pneumothorax is separate from other types of pneumothoraces, as the first occurrence requires surgical management due to the high probability of recurrence. Mechanical pleurodesis along with closing any openings within the pleura that are visualized should be instituted. Hormonal therapy exists as an option as well; however, the side effects are significant and patients should be counseled on its implementation.[8]

## Management

Management of pneumothoraces is often complex and dependent on multiple variables, such as size of the pneumothorax, hemodynamic stability, associated symptoms, concomitant disease, and primary or recurrent pneumothorax. Management options are observation, aspiration, tube thoracostomy, pleurodesis, and surgery. Observation is generally reserved for small spontaneous pneumothoraces

without significant symptoms. Inhaled supplemental oxygen can be instituted in these patients. These patients should be observed in the hospital, as enlargement of the pneumothorax is possible.

Aspiration can be used in patients with a mild-to-moderate pneumothorax. Aspiration allows for evacuation of the pleural cavity and complete lung expansion. Studies have demonstrated that needle thoracostomy carries a risk of minimal complications and patient discomfort as well as success rates comparable with tube thoracostomy.[7] When performing an aspiration, the needle can be placed in either the second intercostal space in the midclavicular line or the fifth intercostal space in the midaxillary line, similar to tube thoracostomy. The needle is generally attached to either a stopcock, allowing for manual aspiration, or a one-way valve. Follow-up chest x-ray should be obtained to confirm resolution of the pneumothorax. If the pneumothorax does not resolve, tube thoracostomy should be employed.

Larger pneumothoraces or those causing significant symptoms should be treated with a chest tube. The chest tube should be placed in the fifth intercostal space in the midaxillary line. Creating a subcutaneous track can help prevent air leaks and aid in positioning of the chest tube. The tube should be directed posterior and superior. At our institution, we add additional holes to the chest tube to aid in drainage of pleural effusions at the inferior portion of the pleural cavity (it must be kept in mind to place the final hole through the radiopaque line so that proper placement can be visualized on chest x-ray). On initial placement, the chest tube is placed on suction. Once re-expansion has been demonstrated for 24 h, the chest tube can be placed on water seal.

Tube thoracostomy is 90 percent successful in resolving a first occurrence of a PSP, 50 percent for a first recurrence, and 15 percent for second recurrence. PSPs have been reported to recur in 33 percent of patients, 62 percent of those patients will recur a second time, and 83 percent of those a third time.[8,9] Prophylactic treatment to prevent recurrence of PSPs is generally not recommended after the initial pneumothorax, but patients who report recurrence are recommended for treatment.

Pneumothorax recurrence can be treated through two options, chemical pleurodesis or operative management. Chemical pleurodesis is employed in patients who are not good operative candidates or those who refuse surgery. The agents most commonly used are one of the tetracycline antibiotics and sterile talc. The agent is infused through the chest tube and the patient rotated side to side to distribute the chemical. Recurrence rates are high with chemical pleurodesis.

Surgical indications include recurrence as well as bilateral spontaneous pneumothoraces, persistent air leaks, and incomplete lung re-expansion. Patients at high risk of reoccurrence (i.e., aviation personnel, scuba divers) are often treated operatively after a primary occurrence. Operative management consists of irritation of the pleura with or without parenchymal removal. Thorough pleurodesis is the primary goal of the procedure. This is generally accomplished by both mechanical pleurodesis as well as the use of a chemical sclerosant. Visualization of bulla or blebs is a relative indication for removal. Removal without pleurodesis results in high recurrence rates.[7] The most common surgical approach is video-assisted thoracoscopic surgery (VATS) but thoracotomy may be necessary depending on the clinical situation.

## PLEURAL EFFUSIONS

### Definition

A pleural effusion is defined as an excess of pleural fluid within the pleural cavity. This is generally considered to be an accumulation of 500 mL or more in the pleural space. As mentioned previously, the pleural fluid serves an important function in coupling the movement of the chest wall with movement of the lungs. This coupling depends immensely on the volume of pleural fluid present, as an increase in volume will decrease the amount of force that is transmitted from the movement of the chest wall to the lung. Excess fluid accumulates through three possible mechanisms[5]:

1. Change in pleural pressure balance
2. Impaired lymphatic drainage
3. Increased mesothelial and capillary permeability.

As mentioned in the physiology section, normal pleural fluid is primarily a result of plasma from capillaries in the parietal pleura being drawn into the pleural cavity. As a result, those pleural effusions that are related to changes in pleural pressure balance bear similar characteristics to the plasma, also known as a transudative effusion. In contrast, those effusions related to impaired lymphatic drainage and increased permeability result in fluid that has increased protein and other cellular components. These effusions are called exudative pleural effusions. Laboratory differentiation of transudative and exudative effusions is described later.

### Clinical Features

Patients with a pleural effusion are often dyspneic upon presentation and may or may not complain of pleuritic chest pain. The dyspnea is relative to the size of the effusion as well as underlying respiratory disease. Other symptoms may accompany the dyspnea, but are often related to causes of the effusion (i.e., fever, weight loss, or weight gain).

### Diagnosis

Physical examination in a pleural effusion can often aid in diagnosis. Patients demonstrate decreased breath sounds in the areas of the effusion, with crackles heard at the border of the effusion and the lung. Dullness to percussion as well as decreased tactile fremitus is present.

The primary mode for definitively diagnosing a pleural effusion is chest x-ray. Fluid can best be demonstrated on chest x-ray in the lateral decubitus position. On lateral films, the fluid can be seen to be freely mobile or loculated. Ultrasound and CT of the chest can demonstrate effusions as well, but are not routinely employed for diagnosis. Ultrasound and CT are useful adjuncts in precisely locating loculated pleural effusions and guiding thoracentesis.

Once a pleural effusion has been diagnosed on radiography, a diagnostic thoracentesis is indicated. Thoracentesis is used as a diagnostic modality as a well as a therapeutic option. Thoracentesis will help to differentiate the likely etiology of a pleural effusion. Light et al. described diagnostic criteria that divided pleural effusions into two categories: transudative and exudative. The diagnosis of exudative effusions requires one of the following[13,14]:

1. Pleural fluid protein to serum protein greater than 0.5
2. Pleural fluid lactate dehydrogenase (LDH) to serum LDH greater than 0.6
3. Pleural fluid LDH greater than two-thirds of the upper limits of normal for serum LDH.

If a patient meets none of these criteria, they are diagnosed with a transudative effusion.

Visual examination of pleural fluid can assist in diagnosis. Normal pleural fluid is straw colored and clear. If the effusion is milky it may suggest a chylous effusion, parapneumonic effusion, or pseudochyle.

## Etiology

The etiology of pleural effusions are extensive, but as has been illustrated, is best divided into transudative and exudative etiologies. Table 20-2 lists common causes of pleural effusions.

**TABLE 20-2: Causes of Pleural Effusions**

| |
|---|
| Transudative |
| Congestive heart failure |
| Cirrhosis |
| Nephrotic syndrome |
| Pulmonary embolism |
| Exudative |
| Malignancy |
| Infection of lungs and surrounding tissue |
| Bacterial |
| Viral |
| Tuberculoid |
| Fungal |
| Chylous effusion |
| Hemothorax |
| Asbestosis |
| Sarcoidosis |

## Management

### TRANSUDATIVE EFFUSIONS

Transudative effusions are often caused by systemic disease that result in fluid overload, most commonly seen in congestive heart failure, cirrhosis, and nephrotic syndrome. However, pulmonary embolisms can also result in transudative effusions and high suspicion should be kept for those patients at risk for developing deep vein thromboses. For patients in fluid overload states, it causes a decrease in capillary oncotic pressure leading to increased pleural fluid production and overwhelmed ability to reabsorb the fluid. Pulmonary emboli cause increased venous pressure within the lungs and decrease the ability of the visceral pleura to absorb the fluid.

Conservative management consists of treating the underlying disease, along with diuretic therapy in fluid overload states, and often thoracentesis. Diuresis decreases the hypervolemic state that contributes to the increased pleural fluid production, and in most cases, rapidly resolves the effusion. Thoracentesis is reserved in patients with new onset effusions, unilateral or loculated effusions, febrile patients, and those with severe symptoms. For patients who fail conservative management, or are at end stage, pleurodesis can be employed. Often these patients are not good operative candidates and chemical pleurodesis is the treatment of choice.

### EXUDATIVE EFFUSIONS

Exudative effusions are often a result of a systemic process causing inflammation of the pleura. The primary goal in managing exudative effusions should be treating the underlying cause. Initial treatment of the effusion is accomplished through thoracentesis. Thoracentesis is used as a tool both for diagnosis as well as a therapeutic option. Often exudative effusions do reaccumulate and repeated thoracentesis is not recommended because it can result in pleural adhesions causing loculations as well as a risk of bacterial contamination. These patients should be managed with a tube thoracostomy in the short term. Long-term management for chronic effusions can be through chronic drainage with an indwelling chest tube, or through surgical management often with mechanical pleurodesis.

# PARAPNEUMONIC EFFUSIONS AND EMPYEMA THORACIS

## Definition

An empyema thoracis is a purulent pleural effusion. Infection can enter the pleural space through two primary ways[15]:

1. Direct inoculation from the surrounding viscera, most commonly the lung
2. Through the chest wall, seen in trauma or iatrogenic inoculation (commonly postsurgical).

Empyema thoracis is the final stage in the progression of stages of parapneumonic effusions. Parapneumonic effusions develop when a patient has an underlying pneumonia. These can be divided into uncomplicated and complicated. Generally, uncomplicated effusions are mild, contain no bacteria, and resolve with antibiotic treatment and resolution of the pneumonia. Complicated effusions can become loculated or infected progressing into an empyema requiring drainage. Parapneumonic effusions occur in 20 to 60 percent of hospitalized patients with bacterial pneumonias. Approximately 5 to 10 percent of these patients will progress to an empyema.[16]

Parapneumonic effusions progress through three stages. The first stage is called the exudative stage. The exudative stage consists of swelling of the pleural membrane with discharge of a pleural fluid that has a low LDH, normal glucose, and normal pH. This stage is reversible through appropriate antibiotic treatment of the pneumonia. If the pneumonia is untreated or incompletely treated, the effusion progresses into stage two or the fibrinopurulent stage. In this stage, bacteria invade the effusion, white blood cells enter the pleural space causing frank purulence on visual examination, and fibrin is diffusely deposited throughout the pleural cavity creating loculations. If appropriate antibiotics and drainage are not instituted, patients progress to the final stage, known as the organization stage. During this stage, fibroblasts grow into the fibrin sheets that have formed within the pleural space creating a thick collagen membrane known as a "peel." The peel entraps the pus within the pleural cavity and also compresses and entraps the lung.[15,16]

Several complications can arise as a result of an empyema. The fibrous tissue that forms the peel around the empyema can lead to a condition known as fibrothorax, which is discussed later. The extensive fibrosis can also invade the lungs and lead to significant pulmonary fibrosis as well. Also, the infection can track either laterally through the chest wall forming a fistula through the skin, known as an empyema necessitatis, or through the lung parenchyma into the bronchi, known as a bronchopleural fistula.[15]

## Clinical Features

Empyemas often present with a history of pleuritic pain, high fever, cough, dyspnea, and localized tenderness of the chest wall. These symptoms can develop acutely or can be present for weeks, depending on the stage of development of the parapneumonic effusion.

## Diagnosis

Pleural fluid obtained through thoracentesis will meet the criteria for an exudative effusion. Furthermore, a pleural fluid pH of 7.21 to 7.29 is the most sensitive criteria for diagnosis of an empyema. A low glucose, less than 50 mg/dL, and a high LDH, greater than 1000 IU/L, indicate an empyema.[16] Measuring the white blood cells within the fluid is of limited value because other noninfectious causes of exudative effusions can create an increased cell count such as pancreatitis. Culture of the pleural fluid is recommended; however, an organism is not isolated approximately 80 percent of the time.[15]

Determination of the stage of development at which parapneumonic effusion exists is difficult to assess clinically. Incorporation of ultrasound and CT has greatly increased the ability to identify patients who can be managed conservatively and those who will need drainage and possible decortication. Ultrasound can distinguish between pleural fluid, as well as definition of the acoustic makeup of a gathering effusion, pleural thickening, and parenchymal consolidation. CT scans are effective in determining if loculations exist within the effusion, if the lung is entrapped or involved with the effusion, and contrast CT scans will illuminate a fibrous peel.

## Conservative Management

Management of parapneumonic effusions and empyemas reflect the management of other pleural effusions. Initially, a thoracentesis is employed. For patients whose laboratory data are not indicative of a complicated pleural effusion, thoracentesis with appropriate antibiotics is often enough. However, patients with complicated effusions or with frank empyema require drainage. Simple tube thoracostomy is often ineffective and is no longer the standard of care. Placement of a pigtail catheter using image guidance is a common first approach. Patients who are considered candidates for catheter drainage are those without evidence of lung entrapment or obvious peel as evidenced by contrast enhanced CT. Once the catheter is in place, fibrinolytics are employed through the catheter to break up the fibrous capsule and aid in adequate drainage. Examples of fibrinolytics include streptokinase and tissue plasminogen activator. This approach can yield success rates of up to 70 to 80 percent for parapneumonic effusions and early-stage three patients.[16]

## Surgical Management

Failure of conservative management is defined as patients without improving symptoms and radiographic features after drainage and three doses of fibrinolytics.[16] If a patient

fails conservative management VATS can be employed to break up the fibrous adhesions, drain the pleural space, and assist in placement of chest tubes. Some authors argue for early thoracoscopy as a primary treatment. Studies have shown that early thoracoscopy has improved outcomes versus conservative management. For patients that are determined to be in the late portion of stage three, multiple areas of loculation, symptoms longer than 10 days, or parenchymal involvement decortication is indicated.

# CHYLOTHORAX

## Definition

Chylothorax is an accumulation of chyle in the pleural space caused by the disruption of the thoracic duct or one of its main divisions.

## Clinical Features

Patients often experience shortness of breath related to the effusion. These symptoms can be mild to severe depending on the acuity in onset and size of the effusion. Chylothorax can present as right, left, or bilateral effusions. The presentation is a result of the site of the lesion, and the anatomy of the thoracic duct as it ascends superiorly through the thorax.

The classic anatomical construction of the thoracic duct is present in only 65 percent of patients.[17] In the classic configuration, the thoracic duct forms in the midline from the cisterna chyli at the level of L1–L2. The cisterna chyli is a saccular confluence of lymphatic ducts from the lower body, hepatic lymphatics, and intestinal lymphatics. At the superior apex of the cisterna chyli, the thoracic duct is formed and begins its ascension. The thoracic duct enters the thorax through the aortic hiatus between T10 and T12, just to the right of the midline, alongside the right border of the aorta. At the level of T5–T6, it crosses the midline posterior to the aorta through the mediastinum and transcends superiorly along the left border of the esophagus. As the thoracic duct enters the neck, it arches 2 to 3 cm above the clavicle and travels laterally and anteriorly until it anastomoses with the venous system at the junction of the left internal jugular and subclavian veins. This anatomy can be important in determining the location of the leakage from the thoracic duct.[18]

## Physiology of Chyle

The primary function of the thoracic duct is to deliver chyle to the venous system. Chyle is composed primarily of lymph, but also contains electrolytes, proteins, enzymes, red blood cells, and a predominance of T lymphocytes. The lymph is primarily from the intestines and liver, and as a result is high in triglycerides (TGs), which gives chyle its characteristic milky appearance. Approximately 60 to 70 percent of fat that is absorbed in the intestines is transported in chyle and enters the bloodstream through the thoracic duct.[18] Up to 2.5 L of fluid can pass through the thoracic duct daily. Given that the primary component is nutritional fat, this amount varies—increasing after ingestion of fat and decreasing with starvation or diet low in long chain fatty acids. Given the high content of nutrients in chyle and substantial volume, which can be lost, a sustained chylothorax without nutrient replacement can lead to severe malnutrition. Of note, chyle is high in T lymphocytes and various immunoglobulins; therefore, the fluid that accumulates in the pleural space is generally sterile. However, this can render the patient immunocompromised due to decrease in circulating lymphocytes, which can further lead to morbidity.

## Causes of Chylothorax

There are congenital, traumatic, neoplastic, and miscellaneous causes of chylothoraces. Congenital chylothorax is rare; however, it is the leading cause of pleural effusions in the newborn. Congenital causes include anatomical defects in the thoracic duct and its tributaries. Birth trauma has also been identified as an etiology. Traumatic chylothorax can occur after most types of blunt or penetrating trauma. Operative trauma is a common cause of traumatic chylothorax. Almost every thoracic surgical procedure has been reported as a cause of chylothorax. With traumatic chylothorax, the insult to the thoracic duct can be minor. Simple abrupt hyperextension of the spine can cause a rupture of the thoracic duct. Importantly, in 1971, Beesone et al.[19] argued that chylothorax caused by nonsurgical trauma should cause concern for underlying malignancy and warrants investigation. Neoplastic causes of chylothorax include lymphoma, lymphosarcoma, or primary lung cancer. The most commonly reported mechanisms of chylothorax from a neoplasm are direct invasion of the thoracic duct causing distension and rupture of tributaries, or compression and subsequent erosion of the duct. Miscellaneous causes include lymphangioleiomyomatosis, which is seen in women of reproductive age, infections, filariasis, cirrhosis of the liver, and tuberculosis.

## Diagnosis

The majority of the time chyle is a milky odorless fluid, and visual inspection of the fluid is often considered helpful in diagnosis. However, it is important to remember that chylous effusions can lose their milky appearance if the patient has been fasting, and further confusion can arise if the thoracic duct leak was caused by trauma, leading to bloody effusions. Furthermore, it is important to keep in mind mimics of chylothorax. Pseudochylothorax often has a similar milky appearance and should be distinguished from chylothorax. Pseudochyle is associated with chronic pleural effusions, commonly seen in malignant tumors and infection, and it

is milky because of the presence of cholesterol in the fluid. Laboratory studies are commonly used to differentiate chylous effusions from other etiologies. The most common laboratory diagnosis is based on TG levels.[18] An effusion with a TG level greater than 110 mg/dL has been shown to have a less than 1 percent chance to be a nonchylous effusion. An effusion with a TG level of less than 50 mg/dL is chylous less than 5 percent of the time.[20] Further confirmation can be obtained by examining the cholesterol to TG ratio. Chylous effusions generally have a ratio of less than 1, whereas nonchylous effusions have a ratio of greater than 1. If the diagnosis is unclear after these laboratory studies, the gold standard for diagnosing a chylothorax is the demonstration of chylomicrons in the effusion. This is accomplished by lipoprotein analysis. A lipoprotein analysis is used to demonstrate chylomicrons in the effusion, which are considered pathognomonic for chylothorax.

## Medical Management

Unfortunately, there is no clear pathway for patients who should be treated conservatively versus those who will require surgery. Often this is due to the diverse presentations and etiologies of chylothorax. However, it should be stressed that treatment of a chylothorax is necessary, given the severity of nutritional deficiencies that can develop with a sustained leak. Therapeutic options include treating the underlying cause, conservative medical management, and surgical management. Treating the underlying cause, as with neoplastic etiologies, can help to alleviate the chylothorax, but often requires additional therapy.

The pillars of medical management involve drainage of the effusion, nutritional supplementation, and attempts to reduce/stop the flow of chyle. Drainage is accomplished by tube thoracostomy. Careful attention should be paid to the amount of drainage, as it is used as an indication for surgery, which is detailed later. Furthermore, chronic chest tube drainage of chyle can become obstructed due to the fatty nature of chyle, requiring multiple thoracostamies. Nutritional supplementation, historically, consisted of either oral supplementation with medium chain TGs (given their preponderance for absorption in the portal circulation) or nothing by mouth (NPO) with total parental nutrition (TPN). Studies have indicated that any oral intake increases chyle flow, regardless of its composition, and the NPO/TPN therapy has shown improved closure rates. With either therapeutic option, it is important to monitor the patient's nutritional status and adequately replete nutritional deficiencies because malnutrition can lead to increased morbidity and mortality. Finally, to stop chylous flow, various attempts at ensuring complete expansion of the lung, leading to compression of the lesion, were instituted in the past. Chemical pleurodesis was the most common option, but positive-pressure ventilation and inhaled nitrous have also been reported. Excitingly, beginning with the first case report in 1990, a new therapy has been reported in the literature.[21] The use of somatostatin, or its synthetic analogue octreotide, has increasingly been described as a conservative option. The mechanism of action is unclear, but it has been hypothesized that the peptide decreases the flow of chyle through the thoracic duct due to its inhibitory effects on intestinal absorption. Currently, there have been no randomized trials evaluating its efficacy, but the reported data are encouraging and should be considered as an option. Imaging via invasive lymphangiography can be diagnostic to determine not only the site of the chylous leak, but also if anatomic anomalies are present. This could help in operative planning. Therapeutically, the contrast used has been known to help seal the chyle leak in up to 50 percent of cases.

A trial of medical management should be no longer than 7 days, but surgery may be indicated prior to this timeline, as is indicated later. If the patient responds to therapy, objectively measured by low chest tube output (<250 mL/24 h), evacuation of the pleural space as evidenced by radiographic findings, and the patient has improved symptomatically, a trial of regular diet can be instituted. If the chest tube output remains low and no evidence of reaccumulation of a chylous effusion is present, the chest tube can be pulled.

## Surgical Management

In 1973, Selle et al.[22] reported a pathway that has served as a general guideline for surgical indications for chylothorax. They are the following:

1. Idiopathic cases in the neonate usually respond well to thoracentesis.
2. Nontraumatic chylothorax, exclusive of the neonatal group, usually suggests a widespread fatal illness, and operative intervention is usually ineffective and should, therefore, be avoided.
3. In cases resulting from trauma, an initial trial of nonoperative management is indicated. Transthoracic ligation of the duct is indicated when
   a. The average daily chyle loss has exceeded 1500 mL/day in adults or 100 mL per year of age in children for a 5-day period.
   b. The chyle flow has not diminished while approaching 7-day duration.
   c. Nutritional complications appear imminent.

If patients do require surgical management, the current approach to chylothorax is thoracic duct ligation, introduced by Lampson in 1948.[18] Ligation of the thoracic duct should occur just above the diaphragm, in the right chest, as the thoracic duct enters the thorax. Approximately 75 percent of patients have a single thoracic duct that enters the right chest, and this has been proven to be the most effective therapy.[17,22] There are several approaches to ligate the thoracic duct. These include direct ligation of the thoracic duct, mass ligation of the thoracic duct, thoracoscopic ligation, application of fibrin glue, pleuroperitoneal shunt, and pleurectomy.

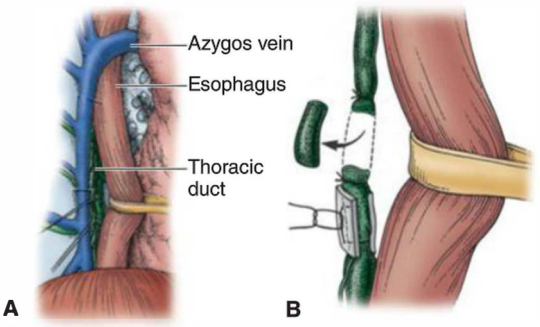

**FIGURE 20-1** **A.** Surgical anatomy of the thoracic duct and **B.** mass ligation of the thoracic duct with Teflon Pledgets. (Reproduced with permission from Miller JI. Anatomy of the thoracic duct and chylothorax. In: Shields TW, LoCicero J, Ponn RB (eds). *General Thoracic Surgery*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2000;747–756. Copyright Lippincott Williams & Wilkins.)

Direct visualization of the chyle leak intraoperatively can be attempted by giving the patient a fatty oral substance, such as olive oil, through the nasogastric tube 2 to 3 h prior to the operation. This will create a milky white flow through the thoracic duct that can aide in visualizing the lesion. Another option includes administering 1 percent aqueous solution of Evans blue dye in the patient's leg. The dye will appear in about 5 min and can last up to 12 min.[18]

There are two postsurgical chylothoraces that require special mention. Chylothorax after esophagectomy has been reported as a complication between 2 and 4 percent. This is generally thought to be related to the close anatomical proximity that the thoracic duct shares with the esophagus. For these patients, medical management has not proven effective and surgical management is the optimal treatment. Conversely, pulmonary resections have a significantly lower reported rate of chylothorax and often respond well to medical management. Finally, it should be emphasized that any thoracic duct lesion that is directly visualized intraoperatively should be repaired prior to closure.[18]

Figure 20-1 depicts surgical anatomy of the thoracic duct as seen via thoracotomy.

# FIBROTHORAX

## Definition

Fibrothorax is the development of a fibrous adhesion between the pleura. Fibrothorax can have multiple etiologies, but the underlying pathophysiology is similar.

## Clinical Features

Chronic pleural effusions, transudative or exudative, result in inflammatory responses by the mesothelium of the pleura. This response results in the deposition of a fibrinous layer of collagen matrix around the effusion. The matrix encapsulates the effusion forming a membrane that separates the effusion from the rest of the pleural space. This membrane can be thin, as seen in transudative effusions, or a thick peel as seen in empyemas. The membrane adheres to the pleura; however, the pleura itself is usually not invested in the matrix, resulting in a discrete extrapulmonary mass. The pleura can become invested if the initial effusion was an extension from a parenchymal process. As the fibrinous membrane evolves, it becomes adherent to the pleura lining the chest wall and diaphragm and can impair their movement, as well as create a mass effect against the lung, preventing it from expanding properly. Consequently, patients often present with dyspnea on exertion that worsens over time. Cough and fatigue are often present, and worsen with the increased involvement of the chest wall and diaphragm.[23,24]

## Diagnosis

Physical examination demonstrates decreased breath sounds over the affected area as well as dullness to percussion. The intercostal spaces surrounding the fibrothorax are often decreased, leading to decreased ability to fully expand the chest wall during inspiration. Pulmonary function tests demonstrate a restrictive ventilatory defect due to chest wall involvement and decreased lung expansion.[24]

CT is the diagnostic modality that best visualizes fibrothorax. The scans confirm the extrapulmonary location of the fibrothorax and can efficiently demonstrate the size and characteristics of the mass. Furthermore, the lungs can be visualized to determine if there is parenchymal involvement as well as inspection for the underlying etiology. Chest x-ray demonstrates radioapaque densities generally present in the diaphragmatic region with blunting of the costodiaphragmatic angle. The hemithorax is often reduced in size and the mediastinum shifted toward the affected side.

## Management

Intervention for fibrothorax is indicated in patients with symptomatic disease, ventilatory defects, or those with significant pleural involvement. Conservative management primarily consists of attempts at draining the pleural effusion either through thoracentesis or tube thoracostomy. The efficacy of these techniques depends on the maturation of the fibrinous peel. The patient should be assessed to determine if their symptoms have improved, and if the effusion has decreased on radiography. If not, surgical management should be considered.

The classic management for fibrothorax is decortication. Decortication is indicated if a patient has failed conservative management, the lung is determined to be more than 50 percent collapsed, or the apex is collapsed. Decortication consists of dissecting the peel off the underlying pleura and

suction evacuation of the pleural cavity. Timing of decortication depends on the underlying etiology; for example, fibrothorax secondary to hemothorax should be performed at least 6 weeks following the insult to allow for maturation of the peel.[23,24]

## BENIGN PLEURAL DISORDERS BOARD REVIEW QUESTIONS (CHAPTER 20)

1. Which of the following is true regarding pleural anatomy?
   A. The visceral pleura does not invest the fissures.
   B. Venous drainage from the visceral pleura is through bronchial veins.
   C. The visceral pleural is not innervated by the somatic nervous system.
   D. Venous drainage from the parietal pleura is through the pulmonary veins.
   E. Lymph drainage from the parietal pleura is through the thoracic duct.

2. Which is true for pneumothorax?
   A. Cigarette smoking is not a risk factor for PSP.
   B. The most common pulmonary disease associated with SSP is cystic fibrosis.
   C. The incidence of secondary pneumothorax is higher than primary pneumothorax in males.
   D. Pneumothorax occurs in up to 50 percent of thoracic trauma patients.
   E. In-hospital pneumothorax occurs most commonly from positive-pressure ventilation.

3. Which of the following is not an indication for surgical treatment of pneumothorax?
   A. Incomplete lung expansion
   B. Bilateral spontaneous pneumothorax
   C. Persistent air leak
   D. Recurrent pneumothorax
   E. Large air leak

4. Which is correct regarding empyema?
   A. 5 to 10 percent of patients with a parapneumonic effusion will develop empyema.
   B. The fibrinopurulent stage is reversible with appropriate antibiotic therapy.
   C. Pleural fluid has a high LDH and low glucose in the exudative stage.
   D. The presence of white blood cells in the pleural fluid is pathognomonic of empyema.
   E. Over 90 percent of patients with have a positive pleural fluid culture.

5. Which is true for the treatment of chylothorax?
   A. Neonates should have prompt placement of a chest tube to prevent fibrothorax.
   B. Long-term TPN is the preferred strategy for chylothorax after esophagectomy.
   C. Surgery is indicated when chyle losses exceed 1500 mL/day.
   D. Ligation of the thoracic duct is best performed via left thoracotomy at the level of the diaphragm.
   E. Chylothorax after pulmonary resection requires prompt reoperation.

## ANSWERS

1. **Answer: C.** The visceral pleura is not innervated by the somatic nervous system. It does invest the fissures and venous drainage is through the pulmonary veins. Venous drainage of the parietal pleura occurs through companion veins to the arterial supply, and lymphatic drainage is through the local and regional lymph node systems.
2. **Answer: D.** Up to 50 percent of patients with thoracic trauma will have an associated pneumothorax. Cigarette smoking is an important risk factor for pneumothorax. The most common underlying pulmonary disease is emphysema. Primary pneumothorax is more common than secondary pneumothorax in males. In-hospital pneumothorax is most commonly due to percutaneous lung biopsy.
3. **Answer: E.** If the lung is well-expanded and the patient is otherwise stable, the presence of a large air leak is not an indication for surgical treatment.
4. **Answer: A.** Up to 10 percent of patients with a parapneumonic effusion will go on to develop empyema. The exudative phase is reversible with appropriate antibiotics. High LDH and low glucose is characteristic of the chronic phase. The presence of white blood cells is not pathognomonic of empyema. Up to 80 percent of patients will have a negative pleural fluid culture in the setting of empyema.
5. **Answer: C.** When chyle losses exceed 1500 mL/day, conservative therapy is unlikely to resolve the chylothorax and surgery is indicated. Neonatal chylothorax is treated with repetitive thoracentesis. Chylothorax after esophagectomy requires surgery, whereas chylothorax after pulmonary resection should be initially treated with medical management. About 75 percent of patients have a single thoracic duct entering the right chest at the diaphragm; therefore, ligation is best performed via right thoracotomy.

# Benign and Malignant Pleural Tumors

*Siva Raja*
*Carol F. Farver*
*Sudish C. Murthy*
*David Mason*

**KEY CONCEPTS**

- Epidemiology
  - Pleural tumors are a small but significant subset of thoracic malignancies. The majority of pleural tumors tend to be malignant and mesothelioma is the most common diagnosis. Most patients have had environmental exposure to asbestos.
- Pathophysiology
  - Pleural tumors are generally characterized as benign or malignant. Benign tumors are usually slow growing and do not cause symptoms until they exert mass effect, or in the case of MPM, when they cause pain by tumor invasion or dyspnea secondary to pleural effusion.
- Diagnosis/clinical features
  - Many pleural-based tumors are diagnosed incidentally on imaging performed for unrelated reasons. The primary radiographic evaluation consists of CXR and CT scan. Once the pleural-based lesions have been identified, tissue diagnosis is obtained via image-guided core-needle biopsy or through thoracoscopic biopsy. When symptoms are present, they are most commonly chest wall pain from tumor invasion or dyspnea from restriction or cough.
- Treatment
  - Benign tumors of the pleura are followed with serial imaging or resected. Treatment options for MPM are varied and range from palliation of symptoms to radical surgery within a multimodality regimen.
- Prognosis
  - The prognosis for benign lesions of the pleura is excellent and recurrences are rare after complete resection. MPM, however, is often advanced at presentation and prognosis is poor. However, early-stage patients with epithelioid histology and negative resection margins have promising long-term survival.

## INTRODUCTION

The diagnosis and treatment of pleural diseases was a formidable task for practitioners of ancient and medieval medicine as most maladies of the thoracic cavity proved to be rapidly and universally fatal. The development of general anesthesia, thoracic imaging, and closed suction drains has greatly facilitated the diagnosis and treatment of pleural disease, including primary tumors of the pleura.

## PLEURAL ANATOMY

The pleura refers to a continuous mesothelial tissue layer of mesenchymal origin that lines the chest cavity and blankets thoracic structures.[1,2] Standard nomenclature differentiates the parietal pleura, which covers the chest wall, mediastinum, and diaphragm, from the visceral pleura, which invests the lung parenchyma. The hilum of the lung and the inferior pulmonary ligament serve as the anatomic interfaces

between these two layers. Blood supply and lymphatic drainage follow that of structures—parietal pleura supplied by intercostal, internal mammary, superior phrenic, and anterior mediastinal arcades. Lymphatics drain to intercostal, mediastinal, and phrenic lymph nodes. Communications across the diaphragm and chest apex link the thorax to the peritoneal cavity and ipsilateral axillary lymph nodes respectively. The visceral pleura contain both a pulmonary and a bronchial blood supply but drains solely into the pulmonary venous circulation. Visceral pleural lymphatics drain to mediastinal lymph nodes. Autonomic and somatic fibers innervate the pleura. The visceral pleura carry autonomic fibers only. Pain, carried through somatic routes, is generated from parietal pleural inflammation, such as by direct tumor invasion or local irritation.

## EVALUATION OF PLEURAL-BASED ABNORMALITY

The evaluation of a patient with pleural pathology begins with a thorough history and physical examination (Fig. 21-1). Identification of environmental exposures, particularly asbestos, can provide important insight to the etiology. Other risk factors for pleural disease such as a known prior malignancy or a history of tuberculosis should be identified. A history of cough or fever suggests infectious etiology, whereas a history of weight loss and chest pain portends a malignant diagnosis. Surprisingly, many pleural tumors are diagnosed incidentally on radiographic examinations performed for screening of unrelated diseases.

Dyspnea and chest pain are the most common presenting symptoms in patients with pleural tumors. For symptomatic patients, the plain chest radiograph (CXR) is typically the first diagnostic test performed, although this is neither sensitive nor specific. Common CXR findings are pleural plaques and effusions. Most CXR findings lead to computed tomography (CT), or possibly, magnetic resonance imaging (MRI). Chest CT scans are relatively inexpensive and provide excellent high-resolution anatomic information. Due to this, chest CT scan is the most commonly used noninvasive modality to differentiate pleural from parenchymal disease. MRI is more expensive, relatively difficult to obtain at most centers, and confounded by motion artifact, but it can add information regarding mediastinal, vascular, chest wall, or diaphragmatic invasion.

Once the presence of a suspicious pleural lesion is confirmed, tissue diagnosis is typically obtained for definitive diagnosis. This can be accomplished by cytologic examination of fluid obtained via thoracentesis of a pleural effusion or image-guided core-needle aspiration of a pleural-based mass. Should these tests prove nondiagnostic, a single-port video-assisted thoracic surgery (VATS) pleural biopsy is indicated. In addition to clarifying the diagnosis, VATS can both confirm the lesion as pleural-based and facilitate pleurodesis should this be appropriate. Care should be taken to plan the biopsy incision within the line of a possible future thoracotomy so that the site can be excised at the time of definitive surgery and limit potential port site implants (especially for mesothelioma).

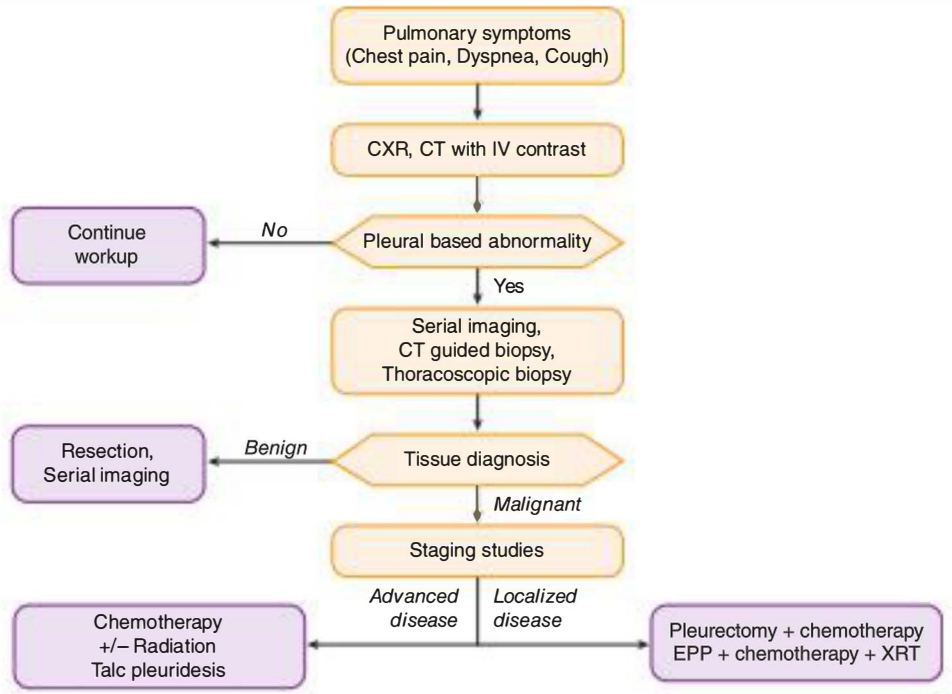

**FIGURE 21-1** Decision algorithm for evaluating pleural tumors.

## BENIGN TUMORS OF THE PLEURA

Benign lesions of the pleura are relatively common and usually detected incidentally. These include lipomas, plaques, and pleural thickening. Rounded atelectasis is often misdiagnosed as a pleural lesion. The most common presenting symptom, if any are present at all, is dyspnea secondary to parenchymal compression. Chest pain is unusual for benign tumors.

### Pleural Lipomas

Pleural lipomas are benign, slow-growing tumors that arise from fat cells present in the pleural lining. They are well circumscribed, small tumors but can grow to large sizes leading to compressive symptoms. They have a characteristic low density, homogenous appearance on CT imaging.[3] Malignant transformation of lipomas is extremely rare. Pleural lipomas can typically be differentiated from their malignant counterpart, liposarcoma, which tends to have a heterogeneous appearance on imaging.

When the adipose tissue of a suspected lipoma consists of fetal brown fat, it is referred to as a hibernoma.[4] These lesions are distinguished on pathology by increased vascularity and immature fat cells with multiloculated c ytoplasm. Some reports have also suggested that the skin over these lesions is warm due to the heat generated via an uncoupling of the mitochondrial electron transport. Small lipomas can be followed with serial imaging, whereas larger lipomas are typically excised for cure.

### Pleural Plaques and Diffuse Pleural Thickening

Although not technically tumors, pleural plaques and pleural thickening represent a reaction to environmental irritants and can mimic malignancy.[5] Plaques are reactive fibrosis, which are typically located on the chest wall or diaphragm and incited by asbestos exposure. Calcification of these plaques is pathognomonic for asbestosis (Fig. 21-2). Diffuse pleural thickening is a more extensive process that can involve circumferential encasement of lung parenchyma with accompanying pleural symphysis.[6] Etiology includes diffuse inflammatory conditions, radiation exposure, infection (empyema), and idiosyncratic medication response (bromocriptine and methysergide).

### Rounded Atelectasis

Rounded atelectasis can be seen in the setting of asbestos exposure as well as in association with other inflammatory conditions. It is thought to be initiated in the setting of an exudative pleural effusion that ultimately leads to thickening, contraction, and fusion to an adjacent fold of pleura.[7] This process creates atelectasis of the dependent lung parenchyma to produce a rounded peripheral nodule. It is a silent condition whose diagnosis is usually made incidentally during the workup of a solitary pulmonary nodule or a pleural-based mass. Clues on radiographic imaging can help differentiate rounded atelectasis from other lesions. CXR characteristics include volume loss of the ipsilateral lung, peripheral location, presence of pleural thickening adjacent to the lesion, and the pathognomonic "comet tail" finding, a convergence of the pulmonary vasculature as it enters the hilar side of atelectatic lung. The "comet tail" is best seen on CT scan. As rounded atelectasis is usually metabolically inactive, positron emission tomography (PET) scan is sometimes helpful in ruling out a malignant diagnosis.[7]

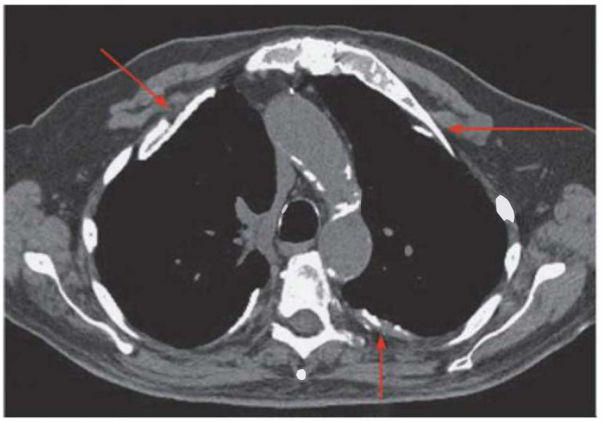

**FIGURE 21-2** CT scan of pleural plaque with calcification (arrow).

## MALIGNANT TUMORS OF THE PLEURA

### Solitary Fibrous Tumors of the Pleura

Although most solitary tumors of the pleura (SFTP) are composed of benign-appearing cells, they can nonetheless undergo malignant transformation and cannot simply be classified as "benign" lesions.[8] SFTP are most commonly discovered as incidental radiographic findings. They can grow very large and cause chest pain, cough, and dyspnea from mass effect. Although unusual, malignant transformation is evidenced by rapid growth or even distant metastasis. Occasionally, SFTP are secretory and the liberation of factors such as insulin-like growth factor 2 (IGF2) can create hypoglycemia.[9] SFTP are also associated with pulmonary osteoarthropathy.

Chest CT scan is typically adequate for diagnosis of SFTP although occasionally MRI or PET scanning can provide useful diagnostic and anatomic information. SFTP has pathologic correlates in the kidney, cervix, meninges, thigh, pelvic fossa, retroperitoneal, and serosal surfaces. In earlier literature, this entity was referred to as "localized mesothelioma" or "fibrous mesothelioma." However, it has now

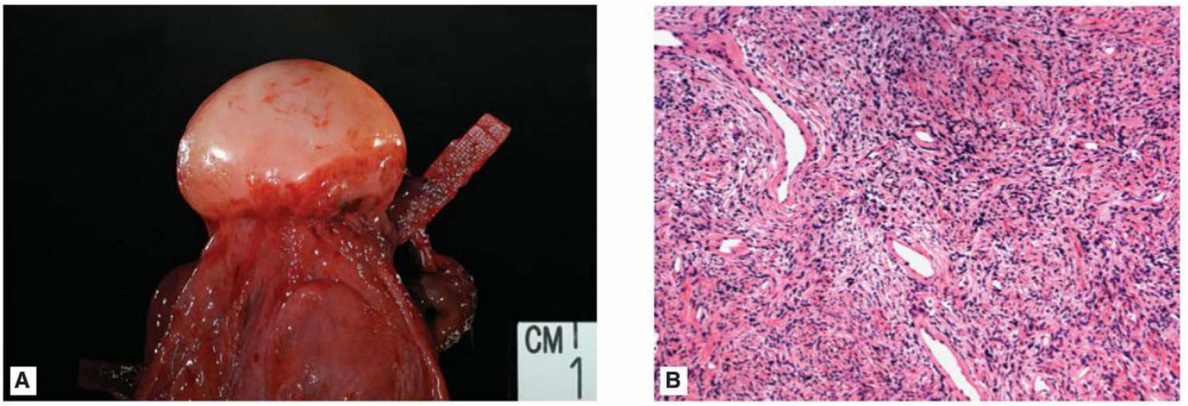

**FIGURE 21-3** Solitary fibrous tumor of the pleura: Gross image (**A**), H&E stained section (**B**).

become clear that these tumors arise from pleural mesenchymal cells most closely resembling pericytes (a dendritic-like smooth muscle cell) rather than mesothelium. The majority of SFTP arise from the visceral pleural layer, presenting as pedunculated lesions (Fig. 21-3A).

The histologic features include bipolar spindle cells with varying areas of cellularity, often with small vessels and perivascular hyalinization (Fig. 21-3B). These tumors stain for CD34 (a vascular marker) and are distinguished from sarcomatoid mesotheliomas by absence of staining for cytokeratin and calretinin.[10,11] There are no definitive histologic features that discriminate benign from malignant SFTP. However, tumors with a mitotic rate greater than 4 mitoses per 10 high-power fields and greater than 10 cm in size are more likely to recur locally. The treatment of SFTP is surgical resection (Fig. 21-3A). Adjuvant therapy is not typically warranted, particularly if the lesion is completely resected.

## Malignant Mesothelioma

### EPIDEMIOLOGY

Malignant pleural mesothelioma (MPM) is a rare thoracic malignancy, directly linked to asbestos exposure. The incidence of MPM remains low at about 2000 to 3000 new cases[12] per year compared with lung cancer that has over 160,000 new cases per year, but has gradually increased over the past 5 decades. Although the use of asbestos dates back to thousands of years, it became widespread with increased industrialization as it was used as a form of insulation in many industries. These include construction, shipbuilding, pipefitting, and car brake assembly, due to its properties of light weight, low cost, and high heat resistance. Asbestos is a natural silicate mineral that can be categorized as serpentine and amphibole. Serpentine asbestos is composed of spiral fibers compared with amphibole asbestos whose fibers are linear and needle-like. This shape of amphibole is believed to cause chronic irritation that may lead to malignant transformation of the pleura.

The link between asbestos and MPM was first noted in asbestos mine workers dating back to the 1940s.[13,14] The vast majority of patients diagnosed with MPM have a documented link to asbestos exposure. Other less common etiologies include high-dose radiation exposure as well as simian virus infection.[12] However, asbestos remains the most clearly established causative agent. The development of mesothelioma typically trails exposure by 2 to 3 decades.

### PATHOLOGY

MPM arises from the mesothelial lining of the pleura and is often radiographically characterized by diffuse pleural thickening (Figs. 21-4 and 21-5). They are typically found as two major histologic variants: epithelioid type and sarcomatoid types (Figs. 21-6A and 21-6B). Some tumors have characteristics of both and are considered biphasic or mixed. In the workup, MPM must be differentiated from pleural dissemination of non–small cell lung cancer (especially adenocarcinoma). Although it is difficult to distinguish between the two with routine histologic examination, antibodies specific to mesothelioma have greatly increased diagnostic accuracy. Specially, antibodies to calretinin, Wilms tumor-1 (WT-1), and cytokeratin 5/6[15] are strongly positive in malignant epithelioid mesothelioma but are negative in adenocarcinoma.

Recent advances in cancer genetics have identified several pathways that appear to be in MPM. Numerous tumor suppressor genes including p16, p14, and p53 are affected, and aberrant expression of growth factors/receptors such as transforming growth factor-α (TGF-α), platelet-derived growth factor (PDGF), insulin-like growth factor (IGF), and hepatocyte growth factor (HGF) are identified.[16] However, the molecular mechanism by which asbestos induces MPM has not been determined.

### CLINICAL PRESENTATION

The most common presenting symptom of MPM is dyspnea, and it is typically caused by pleural effusion. On physical examination, dullness to percussion is found on the affected

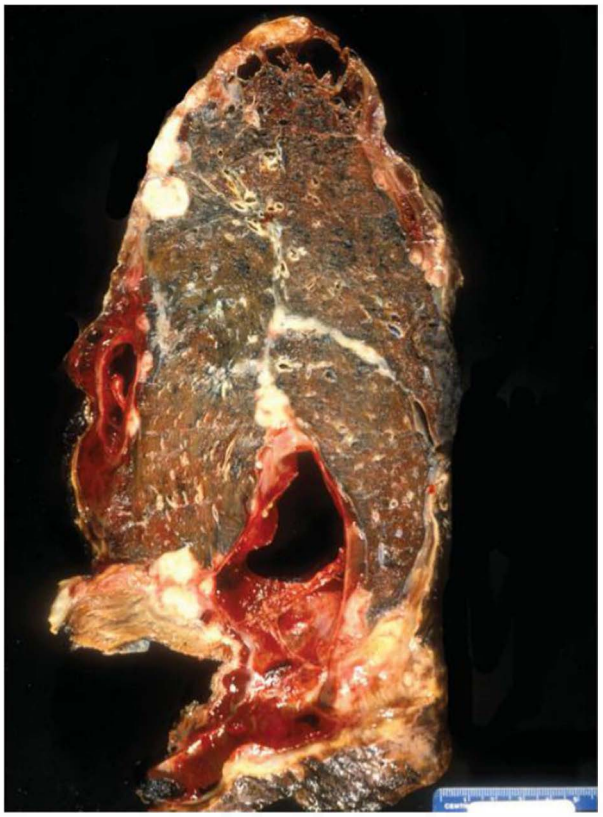

FIGURE 21-4 Sagittal plane image of malignant pleural mesothelioma from an extrapleural pneumonectomy specimen.

hemithorax. Chest pain is also common due to tumor involvement of the parietal pleura or chest wall. Weight loss is an ominous and late sign of disease along with generalized malaise and failure to thrive. No specific laboratory studies are diagnostic of MPM although thrombocytosis can be present.[17]

## RADIOGRAPHIC EVALUATION AND CLINICAL STAGING

Chest CT is the most commonly used modality for the evaluation of MPM. Early-stage tumors present with focal areas of pleural thickening and may be accompanied by pleural effusions. (Fig. 21-5). In later stages, MPM presents as large masses or circumferential tumors that completely encase the lung and invade mediastinal structures. PET scanning is used to screen for metastatic disease that is common,[18] although it is not as helpful for detecting locoregional and lymph node involvement.[19] MRI can be used to evaluate transdiaphragmatic invasion if radical surgery is being considered.

## CLINICAL-PATHOLOGIC STAGING

Clinical staging occurs after definitive tissue diagnosis. This can be obtained by cytology obtained from a pleural effusion or via a single-port thoracoscopy. Again, this port should be placed in line of a potential future thoracotomy if the patient appears to be a multimodality therapy candidate. The staging system for MPM has been defined in the 7th edition of the American Joint Commission on Cancer (AJCC) staging manual using standardized T, N, and M designations. PET scanning is useful in clinical staging although its sensitivity for T and N staging has been questioned. As mediastinal lymph node disease portends poor prognosis, cervical mediastinoscopy is recommended for patients who are candidates for aggressive multimodality therapy. Brain imaging should be performed to rule out metastatic disease. Although some centers recommend peritoneal lavage to rule out transdiaphragmatic spread, this is not routine for most centers. Due to the inherent inaccuracy of T and N staging based on CT and PET imaging, clinical staging of mesothelioma is imperfect. Definitive staging can only be obtained after radical surgical resection and evaluation of the entire pathologic specimen. Transdiaphragmatic and extensive chest wall invasion are usually contraindications to radical surgery.

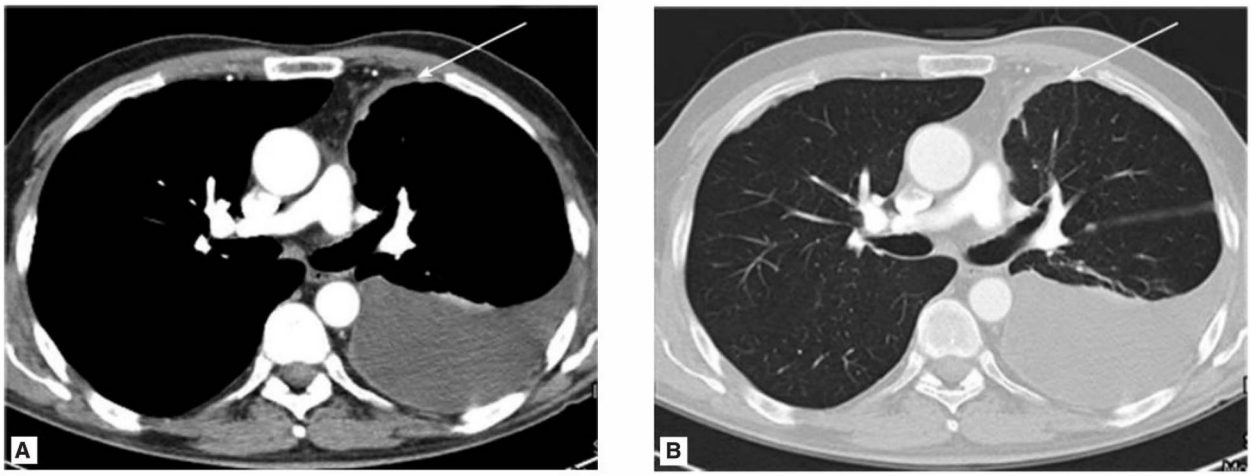

FIGURE 21-5 Malignant pleural effusion is seen posteriorly. Arrow shows pleural thickening.

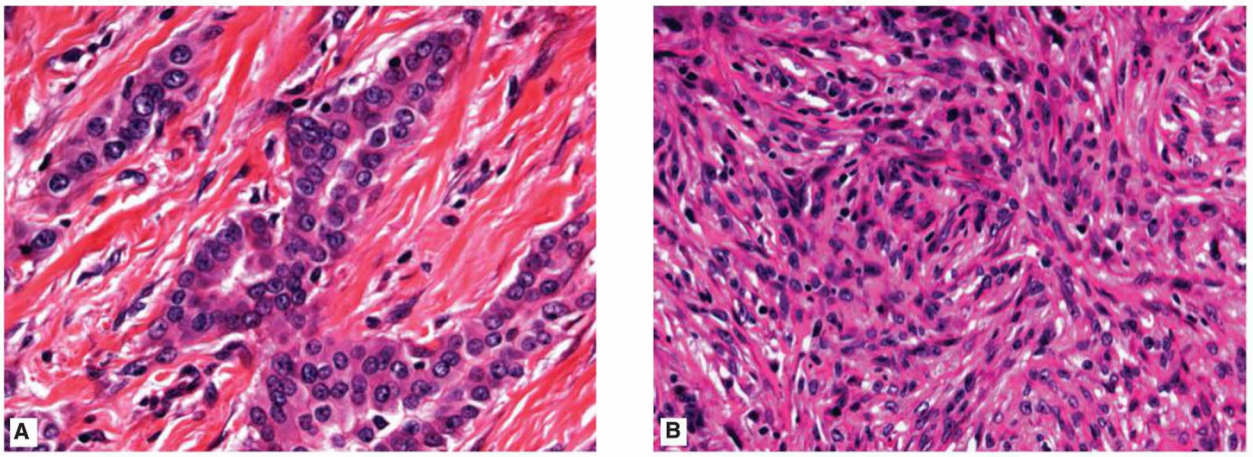

FIGURE 21-6 Malignant pleural mesothelioma. **A.** Epithelioid type. **B.** Sarcomatoid type.

### TREATMENT

***Medical.*** Treatment modalities depend on the patient's age, performance status, and disease stage at presentation. As most patients present with advanced disease, the mainstay of therapy for most is chemotherapy. Life expectancy in advanced disease is short and prolongation of life with chemotherapy is limited. The 5-year overall survival for this group of patients is about 15 percent. Traditional chemotherapy had included monotherapy with a wide variety of agents. Recently, a phase III trial testing a doublet using pemetrexed and cisplatin has shown efficacy. There was an overall 23 percent risk reduction for this cocktail compared with cisplatin monotherapy and the median survival was increased from 9.3 to 12.1 months.[20] Thus, the current recommendations for chemotherapy for mesothelioma include cisplatin and an antifolate agent such as pemetrexed or raltitrexed.

Radiation therapy is not indicated as primary therapy given the large treatment field required and associated toxicities. Instead, radiotherapy is used as an adjunct after radical surgery (extrapleural pneumonectomy, EPP) in multimodality therapy treatment protocols, or for palliation of pain.

Intraoperative photodynamic therapy (PDT) is a less common therapy. PDT uses laser light to activate a photosensitizer loaded into tumor cells to cause cytotoxicity and apoptosis. This treatment also stimulates a vigorous antitumor immune response.[21] It has been argued that because the cytotoxic effect penetrates several millimeters in depth on surfaces such as the visceral pleura and the diaphragm, radical resection is unnecessary.[22] Although there have been no studies that have clearly shown a benefit, future studies in early-stage patients may yet validate this treatment modality.

***Surgical.*** Although still debated, surgical therapy appears to offer improved survival in highly selected patients with MPM. Unfortunately, only a small fraction of patients who present with MPM are candidates for surgical resection. Due to the nature of MPM, "complete" resection is improbable and the goal of surgery is as a cytoreductant. Adjuvant therapies are aimed at eradicating residual microscopic disease postoperatively.

The main surgical options include EPP or pleurectomy/decortication (P/D). P/D is preferred for patients with disease primarily limited to the parietal pleura, where the removal of the parietal pleura provides significant tumor cytoreduction. When more extensive disease is present, EPP may yield maximal cytoreduction. The outcomes from both surgeries are comparable when adjusted for stage.[23] The results of that study also suggested that P/D might be preferred for stage I disease and EPP for stage II disease.

Most studies have focused on surgery with adjuvant therapy rather than surgery as monotherapy. A report of 183 patients who underwent EPP followed by chemotherapy (carboplatin and paclitaxel) and radiation (30 Gy) demonstrated a 2- and 5-year survival of 38 and 15 percent, respectively, as well as a 3.8-percent per-operative mortality.[24] Nodal metastasis, sarcomatoid subtype, and positive resection margins were risks for poor survival. In the absence of these risk factors, a 5-year survival of 45 percent and a median survival of 51 months were observed. Another recent study examining induction chemotherapy followed by EPP and hemithoracic radiation (>50 Gy) also showed similar survival.[25,26] Specifically, a 75-percent survival in ypT1-2NO patients and an overall 5-year survival for node negative patients of 53 percent were demonstrated. Intracavitary hyperthermic chemotherapy (ICHC) has been tested but has not shown a clear benefit.

## OTHER PLEURAL MALIGNANCIES

### Lymphoma

Pleural involvement of systemic lymphoma is common. However, there have been reports of a lymphoma limited to the pleura (primary pleural lymphomas). In a recent

single-institution study, just 6 of 34 patients with pleural involvement of lymphoma were found to be primary.[27] Diagnosis was predominantly made with pleural needle biopsy and the most common subtypes were diffuse large B-cell lymphoma followed by follicular lymphoma.

## Pleuropulmonary Synovial Sarcoma

Synovial sarcoma occurs predominantly on para-articular surfaces. Primary presentation in the lung, pleura, and chest wall is exceedingly rare.[28] The diagnosis of pleuropulmonary synovial sarcoma (PPSS) initially requires the exclusion of an extrathoracic primary. On chest CT scan, these lesions are large with well-circumscribed borders and heterogeneous enhancement due to central necrosis and hemorrhage. Similar findings are seen on MRI. Unfortunately, radiographic imaging does not help differentiate this lesion from other fast-growing lesions of the pleura and lung. Most synovial sarcomas have a translocation and fusion of the SYT gene on chromosome 18 with that of the SSX1/2 genes on the X chromosome. This alteration is present in almost 90 percent of these tumors. Treatment involves resection, followed by chemotherapy and radiation. Given the low prevalence of this tumor, therapeutic recommendations are derived from extremity synovial sarcomas.

## Pleural Epithelioid Hemangioendothelioma

Pleural epithelioid hemangioendothelioma is another rare malignant tumor, which arises from vascular tissue within the pleura. Epithelioid hemangioendothelioma can be found in many other locations in the body such as lung, liver, heart, spleen, and thyroid.[29,30] Pleural epithelioid hemangioendothelioma behaves more aggressively than when encountered in other anatomic locations. Widespread pleural seeding is common. Reactivity with antibodies directed against vimentin, factor VIII, BNH9, and CD31 confirm the diagnosis and a lack of cytokeratin staining helps differentiate this from pleural carcinomatosis. Treatment is relegated to chemotherapy and radiotherapy, which have variable efficacy.

# CONCLUSIONS

Primary pleural tumors are rare but familiarity with diagnosis and treatment is critical for thoracic surgeons. Benign tumors are treated surgically with excellent results. The most common malignant lesion is MPM, which carries a poor prognosis. However, the prospect of long-term survival exists with aggressive multimodality therapy for highly selected patients with early-stage disease, and significant life extension can still be achieved with less extensive therapies for more advanced disease.

## BENIGN AND MALIGNANT PLEURAL TUMORS BOARD REVIEW QUESTIONS (CHAPTER 21)

1. Which is correct regarding primary pleural tumors?
   A. Solitary fibrous tumors of the pleura are benign lesions.
   B. Malignant transformation of a lipoma is extremely rare.
   C. Malignant mesothelioma occurs at an incidence of 5000 to 10,000 new cases per year.
   D. Synovial sarcomas are small, poorly circumscribed lesions.
   E. Pleural plaques are not associated with asbestos exposure.

2. Which is the most useful imaging modality to further evaluate a pleural abnormality seen on chest x-ray?
   A. Chest ultrasound
   B. CT scan
   C. PET scan
   D. MRI
   E. Thoracoscopy

3. Which of the following would be considered unresectable disease for a patient with malignant mesothelioma?
   A. Involvement of visceral pleura
   B. Involvement of the diaphragm
   C. Involvement of the pericardium
   D. Focus of tumor involving the soft tissue of the chest wall
   E. Invasion of a rib

4. Which of the following interventions, in addition to chemotherapy, would be most appropriate for a patient with malignant mesothelioma involving only the parietal pleura and moderately reduced pulmonary function?
   A. Talc pleurodesis
   B. Pleurectomy and decortication
   C. Chest wall resection
   D. Extrapleural pneumonectomy
   E. No surgery

5. Which of the following interventions, in addition to chemotherapy, would be most appropriate for a patient with bulky malignant mesothelioma that invades the fissures of the lung?
   A. Talc pleurodesis
   B. Pleurectomy and decortication
   C. Chest wall resection
   D. Extrapleural pneumonectomy
   E. No surgery

## ANSWERS

1. **Answer: B.** Malignant transformation of a lipoma is extremely rare. Solitary fibrous tumors can undergo malignant transformation. Malignant mesothelioma occurs at an incidence of 2000 to 3000 new cases per year. Synovial sarcomas are large, well-circumscribed lesions. Pleural plaques are incited by asbestos exposure.
2. **Answer: B.** CT is less expensive and provides high resolution of anatomy. MRI can add detail on vascular or other organ invasion, but is more expensive. Thoracoscopy is used to obtain tissue for diagnosis. Ultrasound and PET are not first-line imaging modalities for an x-ray abnormality.
3. **Answer: E.** Rib invasion is considered a T4 lesion and unresectable. Involvement of the visceral pleura is a T1b lesion. Diaphragm involvement is a T2 lesion. Involvement of the pericardium and focus of tumor involving the soft tissue of the chest wall are both considered T3 lesions.
4. **Answer: B.** For stage I disease, such as tumor involving only the parietal pleura, pleurectomy and decortication is the preferred therapy. Talc pleurodesis offers no chance for cure. Chest wall resection is not indicated, as the tumor does not involve the chest wall. Extrapleural pneumonectomy is reserved for stage II disease. Surgery should be offered to the patient, as moderately reduced pulmonary function is not a contraindication to operation.
5. **Answer: D.** For stage II disease, such as tumor extending into the lung parenchyma, extrapleural pneumonectomy is the preferred therapy. Talc pleurodesis offers no chance for cure. Pleurectomy and decortication is ineffective therapy for a tumor that has extended beyond the pleura. Chest wall resection is not indicated, as the tumor does not involve the chest wall. Surgery should be offered to the patient to obtain maximal survival benefit.

# 22 Diaphragmatic Disorders

*Sunil Singhal*

## KEY CONCEPTS

- Epidemiology
  - Bochdalek hernias are usually diagnosed in neonates whereas Morgagni hernias tend to be found in adults. Bochdalek diaphragmatic hernias occur in approximately 1:2000 children. Morgagni hernias occur much less frequently than Bochdalek hernias, and account for only 5 percent of all congenital diaphragmatic hernias. Acquired sliding (type I) hiatal hernias may be found in up to 15 percent of the population, and account for 95 percent of acquired diaphragmatic defects. The remaining 5 percent of acquired diaphragmatic hernias are composed primarily of paraesophageal (type II) hernias. Acquired diaphragmatic hernias are often diagnosed in patients with risk factors for increased intra-abdominal pressures. Diaphragmatic paralysis most commonly occurs following cardiac surgery procedures, with incidences ranging from less than 1 percent to approximately 10 percent. Most diaphragmatic tumors are metastatic in nature, and primary tumors of the diaphragm are quite rare.
- Pathophysiology
  - In neonates, Bochdalek hernias result in abdominal viscera assuming an intrathoracic position, typically into the left hemithorax. This displacement often impairs growth of the ipsilateral lung, causes mediastinal deviation to the contralateral chest, pulmonary compromise, and pulmonary hypertension. Morgagni hernias also result in abdominal viscera herniation into the chest; however, presenting symptoms more often are related to bowel obstruction. Sliding hiatal (type I) hernias are defined as a supradiaphragmatic displacement of the gastroesophageal (GE) junction. The abnormal anatomy impairs lower esophageal sphincter (LES) function and results in reflux symptoms. Paraesophageal (type II) hernias occur when the gastric fundus assumes a supradiaphragmatic position, whereas the GE junctions remain in its normal anatomical location. Diaphragmatic paralysis may result from any abnormality along the neuromuscular axis. Diaphragmatic tumors are most commonly the result of metastatic tumors originating in surrounding organs.
- Clinical features
  - In extreme circumstances, Bochdalek hernia may result in early respiratory compromise requiring prompt surgical interventions or extracorporeal membrane oxygenation (ECMO). Those diagnosed with Morgagni hernia often present with abdominal symptoms and discomfort. The abnormal anatomy associated with sliding (type I) hiatal hernias impair LES function, thus producing reflux symptoms such as "heartburn" and abdominal discomfort. Reflux may predispose patients to develop esophagitis and esophageal cancer. Gastric strangulation is the primary concern for those diagnosed with paraesophageal (type II) hiatal hernias. Both unilateral and bilateral diaphragmatic paralysis may be observed and, in a well-compensated patient, are compatible with normal activity. Diaphragmatic tumors are normally asymptomatic and found incidentally.
- Diagnostics
  - Plain chest radiograph is diagnostic for diaphragmatic hernias, whereas computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound may play adjunctive roles. Congenital defects may be found on prenatal ultrasound. Contrast studies may also reveal important anatomy of acquired hiatal hernias. Diaphragmatic paralysis can be suggested by plain chest radiography as indicated by elevated diaphragmatic boarders. Fluoroscopic evaluation ("sniff test") may also aid in the diagnosis of diaphragmatic paralysis. Recently, ultrasound evaluation of the diaphragm has become more common. Diaphragmatic tumors may be incidentally found with a number of modalities, and should be further evaluated using CT and MRI techniques.
- Treatment
  - Operative repair for Bochdalek and Morgagni hernias require reducing herniated abdominal contents,

resecting the hernia sac, and closing the diaphragmatic defect primarily or with a synthetic patch. Sliding (type I) hiatal hernias should first be addressed with medical management. Surgery is indicated for patients with recalcitrant symptoms, reflux complications, and signs of high-grade dysplasia in Barrett's esophagus. Surgery aims to restore the GE junction to the abdomen and uses fundoplication to minimize reflux. Paraesophageal (type II) hiatal hernia requires surgical reduction of the proximal stomach, resection of the hernia sac, and diaphragmatic defect closure. Diaphragmatic paralysis is often transient, requiring no intervention. In the case of treatment, diaphragmatic placation may be required. Surgical resection of all diaphragmatic tumors is advocated and should include en bloc resection of surrounding pleural and peritoneal layers followed by defect closure.

- Outcomes/prognosis
  - Repair of congenital diaphragmatic hernia is safe and usually successful. The morbidity and mortality associated with Bochdalek hernia are due to inadequate pulmonary development and pulmonary hypertension. Prompt repair in neonates with careful cardiopulmonary management has dramatically improved outcomes of the last 15 years. Surgical correction of acquired hiatal hernias is also associated with marked improvements and excellent long-term prognosis. Diaphragmatic paralysis usually resolves spontaneously within 1 year of injury. In the case of persistent paralysis, diaphragmatic plication is a well-tolerated procedure that produces both clinical and functional improvements. Surgical resection of benign diaphragmatic lesions is well tolerated; however, malignant lesions are associated with poor outcomes as recurrent disease is common.

## INTRODUCTION

The term "diaphragm" originates from the Greek words dia (in between) and phragma (fence). This reflects the diaphragm's anatomical role in separating the torso into the thoracic and abdominal cavities. Functionally, the diaphragm is the principal muscle of respiration.

To review, embryologic development of the diaphragm is a process that occurs between the fourth and eighth week of gestation.[1] The organ is formed by the fusion of tissues from four different sources. First, the septum transversum, a mass of mesodermal tissue located between the primitive heart tube and liver, gives rise to the central tendon of the diaphragm. This process produces two spaces (pleuroperitoneal canals) for the development of the lungs. As the lungs develop, they form bilateral folds, which fuse with the septum transversum to form bilateral pleuroperitoneal membranes.[1] Myoblasts penetrate the pleuroperitoneal membranes to form the muscular part of the diaphragm. Also, the dorsal mesentery of the esophagus becomes invaded by myoblasts and ultimately forms the crura of the adult diaphragm. Finally, the body wall contributes portions to the peripheral diaphragm. During the fourth week of fetal development, the primitive diaphragm becomes innervated by the phrenic nerves (C3, C4, and C5). By week 8, the diaphragm descends as a result of displacement by the rapidly growing neural tube. A delay or alteration in the embryologic structuring can result in a diaphragmatic hernia or congenital eventration.

Anatomically, the diaphragm is skeletal muscle composed of two distinct parts—the costal and crural aspects.[1] The costal muscle, located peripherally, is thin and causes downward displacement of the diaphragm. The costal part of the diaphragm allows the diaphragm to flatten and the lower ribs to lift, resulting in inspiration. The crural aspect of the diaphragm is thicker, supports the heart, and plays a lesser role in respiration. Both groups are innervated by the phrenic nerve. The pericardiacophrenic artery, musculophrenic artery, and superior phrenic arteries extend to the superior side of the diaphragm while the caudal area is supplied by the inferior phrenic arteries. The inferior phrenic arteries branch off the aortal hiatus directly from the aorta or from the celiac trunk. Direct branches of the aorta also vascularize the dorsal part of the diaphragm.

In the adult, the diaphragm is the primary muscle of inspiration and is responsible for 75 to 80 percent of the air brought into the lungs during quiet breathing.[2] During light inspiration, the 2 domes of the diaphragm flatten to some extent, whereas the central tendon remains almost stationary. The diaphragm typically descends 1 to 2 cm during quiet breathing but may lower as much as 6 to 7 cm with forced inspiration. The peripheral parts of the diaphragm unwrap from the lateral walls of the chest by contraction during deep breathing. Both movements widen the costodiaphragmatic recesses, which the lungs subsequently expand to partially fill.

## DIAPHRAGMATIC HERNIAS

There are four hernias we will consider (Fig. 22-1): two congenital hernias (Bochdalek and Morgagni) and two acquired defects (sliding and paraesophageal).

### Congenital Diaphragmatic Hernias

#### BOCHDALEK (POSTEROLATERAL) HERNIA

Despite major advances in prenatal diagnosis and management, infants with Bochdalek diaphragmatic hernias diagnosed at birth (1/4000 live births) have a poor prognosis.[3] Bochdalek hernia is a posterolateral hiatal defect in the diaphragm caused by a failure of the pleuroperitoneal canal fusion during fetal development. More than 80 percent occur

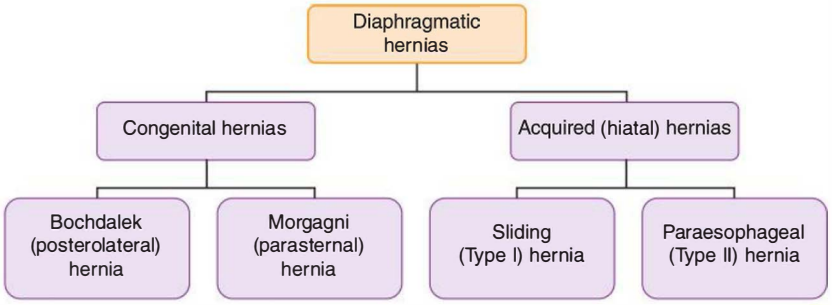

**FIGURE 22-1** Classification of diaphragmatic hernias.

in the left hemithorax, and typically are through a small circular defect (Fig. 22-2). Only 10 percent have a true hernia sac. When the intestines return to the abdomen from the yolk sac at 10 weeks gestation, the abdominal organs may herniate into the thorax through this defect. The pressure of abdominal viscera in the thoracic cavity results in a decrease in the number of bronchial branches, total number of acini, and number of vessels. Typically this results in impaired growth of the ipsilateral lung. However, in extreme cases, when the mediastinum is forced to the contralateral

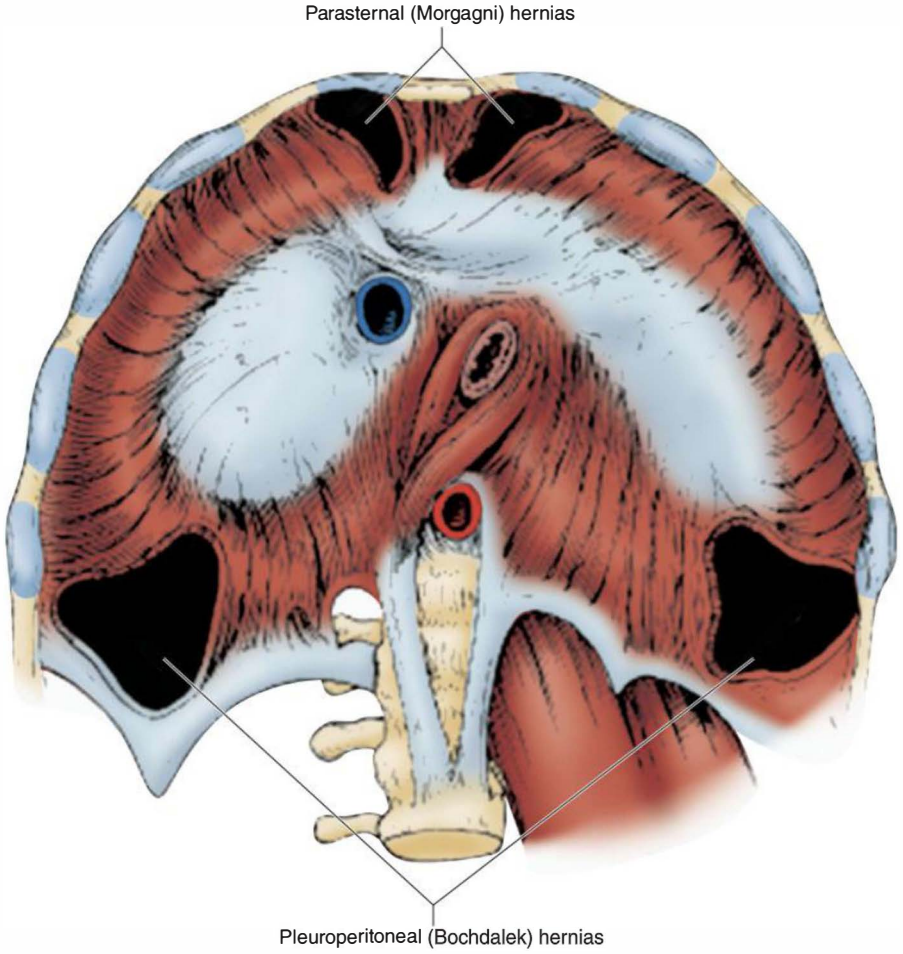

**FIGURE 22-2** Pictorial representation describing location of common congenital diaphragmatic hernias (Bochdalek and Morgagni). (Reproduced with permission from Doherty GM (ed.) *Current Diagnosis & Treatment: Surgery*, 13th ed. McGraw-Hill, Inc, 2010. Fig. 20-17.)

side of the chest, the contralateral lung may also be affected. Herniation of the viscera through the defect usually occurs during the pseudoglandular stage of lung development.

They are commonly associated with additional anomalies including congenital heart defects, hydronephrosis, renal agenesis, intestinal atresia, extralobular sequestration, hydrocephalus, anencephaly, and spina bifida.

Bochdalek hernias may result in life-threatening respiratory compromise as early as the first hours or days of life.[3] The timing of presentation is dependent on the degree of pulmonary hypoplasia, which is the main cause of morbidity and mortality associated with this disorder. Occasionally, the defect may result in respiratory distress or feeding intolerance in later infancy or childhood or may be identified on a radiograph obtained for unrelated reasons. The other element that contributes to the pathophysiology of this disease is pulmonary hypertension—this condition mimics normal fetal circulation and is termed persistent fetal circulation. This condition may result in hypoxemia and acidosis (Fig. 22-3). Severe pulmonary hypertension forces right-to-left shunting through the persistent foramen ovale and the patent ductus arteriosus.

Almost 50 percent of these congenital diaphragmatic hernias are identified during prenatal ultrasound examination.[4] The diagnosis can later be confirmed by a chest radiograph that characteristically demonstrates abdominal contents in the chest with mediastinal deviation away from the affected side (Fig. 22-4). The differential diagnosis includes congenital cystic adenomatoid malformation, other cystic diseases of the lung, and eventration of the diaphragm. Visualization of the naso- or oralgastric tube above the diaphragm also supports the diagnosis. The prenatal diagnosis of right-sided defects is extremely difficult because of the similar echogenicity of the liver and lung.

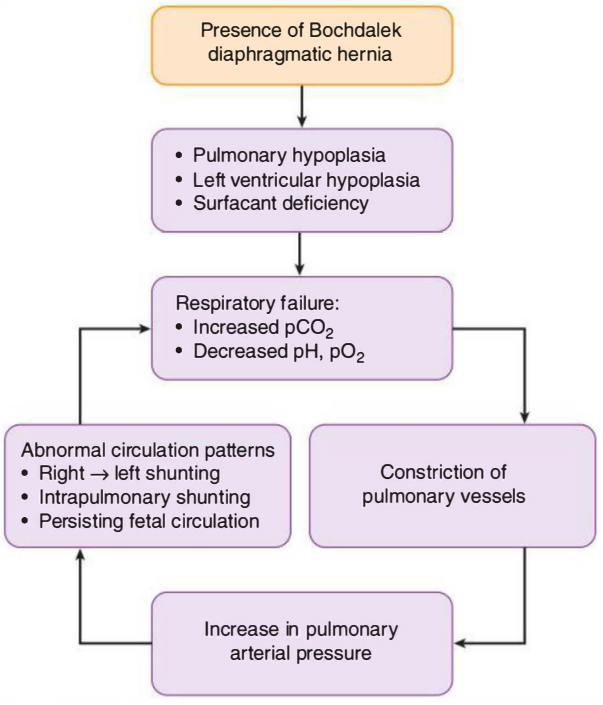

**FIGURE 22-3** Flow-diagram describing pathophysiology of acute respiratory failure associated with congenital diaphragmatic hernia in neonates. (Adapted from Ashcraft KW (ed.) *Pediatric Surgery*, 3rd ed. Philadelphia: WB Saunders, 2000:302.)

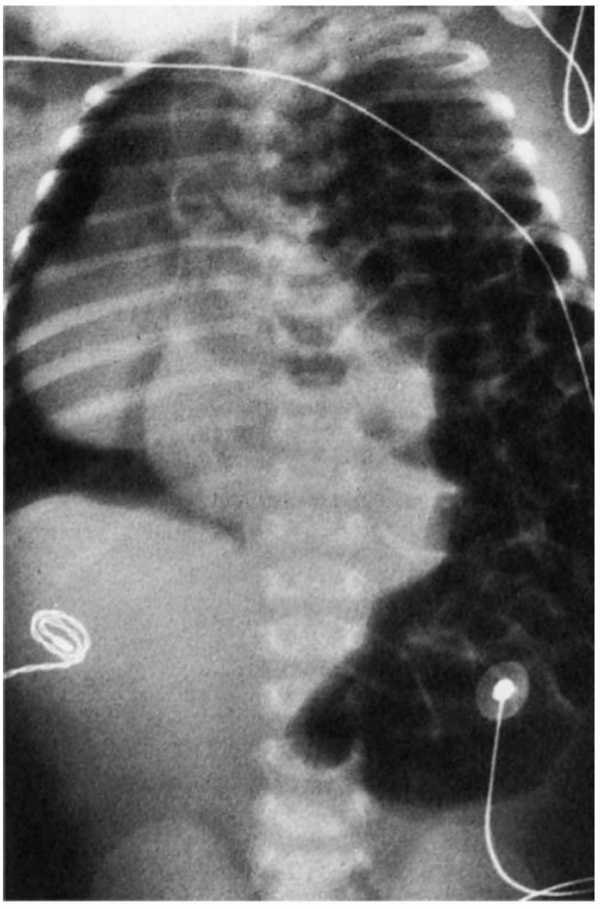

**FIGURE 22-4** Chest x-ray of a neonate with a Bochdalek hernia. Chest radiograph demonstrate abdominal organs within the left hemithorax and mediastinal shift to the right. (Reproduced with permission from Kaplan JA, Slinger PD. *Thoracic Anesthesia*, 3rd ed. Philadelphia: Churchill Livingstone, 2003:355. Copyright Elsevier.)

If a patient presents with respiratory distress at birth, the child should be promptly intubated and nasogastric decompression initiated to minimize visceral distention. Mechanical ventilation with 100 percent $F_iO_2$ and low airway pressures (<25 mm Hg and 5 of positive end-expiratory pressure (PEEP)) should be used. The patient should then be transported to a facility capable of extracorporeal membrane oxygenation (ECMO). Indication to place a baby on ECMO includes an alveolar–arterial oxygen gradient greater than 600 for 8 h, oxygen index greater than 40, pH <7.15, $P_aO_2$ <55, and progressive barotrauma. ECMO is contraindicated if the patient has preexisting weights less than 2 kg,

intraventricular hemorrhage, or has other abnormalities incompatible with life.

Repair of a Bocadaleck hernia has previously been considered a surgical emergency; however, the scheme of emergency operative repair immediately after birth has resulted in mortality rates greater than 50 percent. Recent trends include alternative forms of management, such as delayed operation, ECMO, inhaled nitric oxide, and partial liquid ventilation, all with improved results. Recent studies have demonstrated preoperative stabilization results in improvement of pulmonary compliance prior to repair.[4] Once stable, the repair can be performed through a paramedian incision or subcostal incision. A transthoracic approach has also been advocated by some for right-sided hernias. From the abdominal approach, the viscera can be returned from the chest and the hernia sac may need to be excised if present. The lung tissue should be examined; however, attempts to expand the hypoplastic lung should be avoided. Extralobar pulmonary sequestrations are resected at the time of hernia repair.

A small diaphragmatic defect is closed with permanent suture and Teflon pledgets. Larger defects, or defects whose edges may be under tension, can be closed with synthetic sheet material. Typically, bilateral chest tubes are left in place and connected to water-seal. Intra-abdominal anomalies may be corrected at the time of hernia repair if the patient's condition is stable, although there remain center-to-center preferences regarding this step. In some cases, abdominal wall fascia may not be closed primarily and these circumstances should be managed as large abdominal wall defects.

Postoperative management should aim to reduce pulmonary vascular resistance, improve oxygenation, and treat persistent fetal circulation. Frequent arterial blood gas determinations coupled with continuous pulse oximetry or transcutaneous partial pressure of oxygen and carbon dioxide monitoring provide a reliable mechanism of ventilatory status. A variety of vasodilators have been used to prevent and reverse pulmonary hypertension. It is important to realize that minor changes in ventilation can precipitate intense pulmonary vasoconstriction. Finally, one should consider that the lungs are at risk of barotrauma. As a last resort, ECMO may need to be initiated to reverse pulmonary hypertension if conventional methods fail.

In the absence of additional lethal anomalies, mortality is directly related to the degree of pulmonary hypoplasia. Other prognostic indications associated with poor outcome include additional anomalies, polyhydramnios, presence of an intrathoracic stomach bubble, and underdevelopment of the left heart region. Although the majority of these patients present within the first few days of life, patients may present later in life. This cohort of patients often presents with a variety of respiratory symptoms or sometimes bowel obstruction.

### MORGAGNI (RETROSTERNAL) HERNIA

Morgagni hernia was initially described by Morgagni in 1769. Morgagni hernias are rare and account for less than 5 percent of all diaphragmatic hernias. Unlike Bochdalek hernias, patients with Morgagni hernias typically present later in life.[3] Morgagni hernias are hypothesized to arise from the incomplete fusion of the transverse septum to fuse with the sternum and resulting abnormalities of the foramen of Morgagni (Fig. 22-2). These hernias typically are true hernias and possess a hernia sac. Commonly, the defect contains a piece of omentum that enlarges as the person grows and produces the mass within the hernia sac. However, colon and small intestine are capable of passing through larger defects. A right-sided defect occurs in 90 percent of the cases because the left side is protected by the pericardium.

Small Morgagni hernias typically remain unrecognized and asymptomatic in young children, and are diagnosed in adults. Larger ones, however, can produce severe respiratory symptoms in children. Women tend to be more commonly affected than men. Surprisingly, dyspnea is only occasionally observed in patients' past early childhood. Plain chest radiographs demonstrate a density, either solid or containing air, adjacent to the right or left side of the heart. A CT or contrast study is occasionally indicated to confirm the diagnosis. A contrast study can identify whether the stomach, small bowel, or colon is above the diaphragm in the parasternal position.

An abdominal approach for surgical repair is preferred for this hernia, and a subcostal or right epigastric paramedian incision is advocated. At the time of surgery, the contents of the hernia should be reduced into the peritoneal cavity by gentle retraction and the margins of the hernia sac should be identified. When possible, the sac should also be excised. The repair of small muscular defects is made with interrupted mattress sutures. Larger defects should be repaired using synthetic patch material. Occasionally, it may be necessary to manipulate the diaphragm to the posterior aspects of the sternum and to the posterior rectus sheath for full closure of the defect.

## Acquired Hiatal Hernias

Acquired hiatal hernias are classified according to their anatomic characteristics. Sliding hernias (type I) are characterized by a dome-shaped upward migration of the gastroesophageal (GE) junction into the posterior mediastinum. Paraesophageal hernias (type II) are characterized by an upward dislocation of the gastric fundus alongside a normally positioned GE junction. Sliding hernias are much more common than paraesophageal hernias.

### SLIDING (TYPE I) HIATAL HERNIA

Most sliding hernias are acquired defects. In this type of hernia, the GE junction moves through the esophageal hiatus into the visceral mediastinum (Fig. 22-5). The esophageal hiatus is formed by muscle fibers of the right crus of the diaphragm with little or no contribution from the left crus. These fibers overlap inferiorly where they attach over and along the right side of the median arcuate ligament. Sliding hernia occurs as a result of a weakening or attenuation of

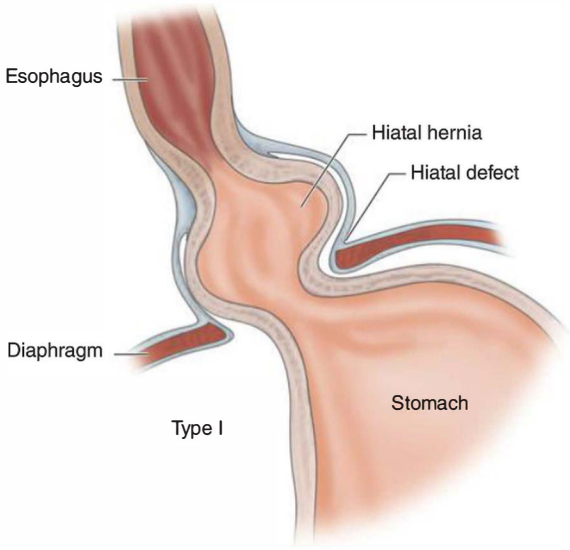

**FIGURE 22-5** Schematic demonstrating anatomy of sliding (type I) hiatal hernia. (Reproduced with permission from Sugarbaker DJ, Bueno R, Krasna MJ, Mentzer SJ, Zellos L (eds.) *Adult Chest Surgery*. McGraw-Hill, Inc, 2009. Fig. 29-3.)

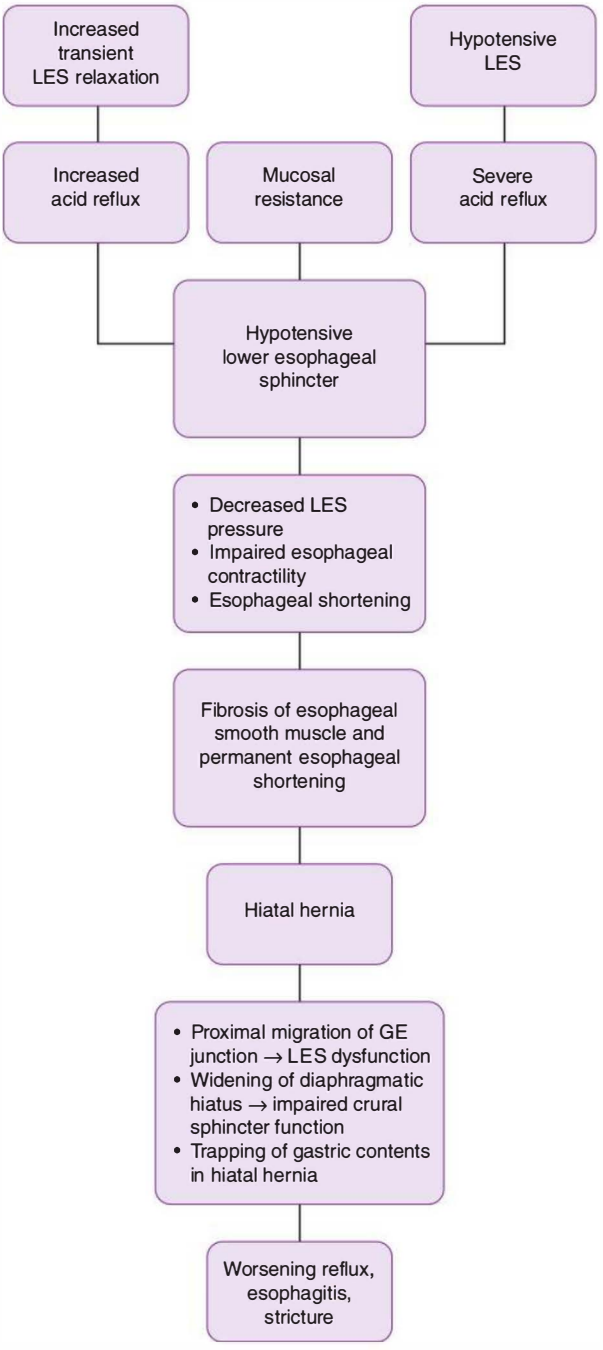
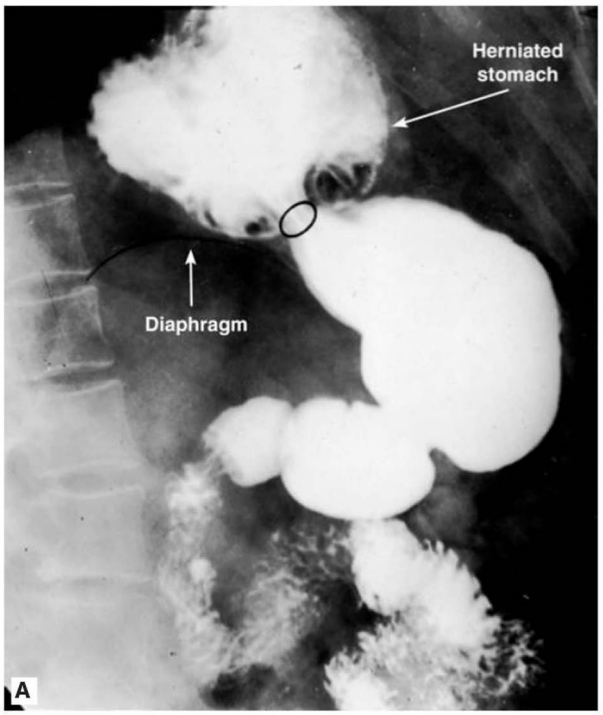
the phrenoesophageal ligament. Enlargement of the hiatus occurs by separation of the crura, posteriorly and laterally, in proportion to the amount of stomach protruding through it. Early in the process, the GE junction may be located below the diaphragm, but with straining, coughing, or recumbency may transiently migrate above it. As the hernia enlarges, this "sliding" component no longer occurs and a GE junction assumes a permanent supradiaphragmatic position.

Over time the intrinsic sphincteric component of the diaphragm diminishes. The presence of the sliding hiatal hernia is in itself of little consequence and is a common finding that occurs in over 10 to 15 percent of the population.[5] Morbidity associated with sliding hernias is dependent on the reflux of gastric contents into the lower third of the esophagus (Fig. 22-6). Whether or not esophagitis develops is determined by multiple factors and, even with significant reflux, symptoms may not be apparent. As the reflux process continues, loss of surface epithelium in the esophagus leads to superficial ulcerations. These ulcerations can cause scarring during periods of healing and contracture may lead to strictures (Fig. 22-6).

Sliding hernias are caused by multiple factors that result in increased intra-abdominal pressure: pregnancy, obesity, vomiting, and vigorous esophageal contractions. Typical presenting symptoms often include retrosternal or epigastric heartburn, postural regurgitation (especially when lying on the right side), and intermittent dysphagia. These symptoms are generally secondary to (1) reflux of gastric contents due to incompetence of the lower esophageal sphincter (LES) and (2) varying degrees of esophagitis. Symptoms are typically worse after meals and aggravated by position such as





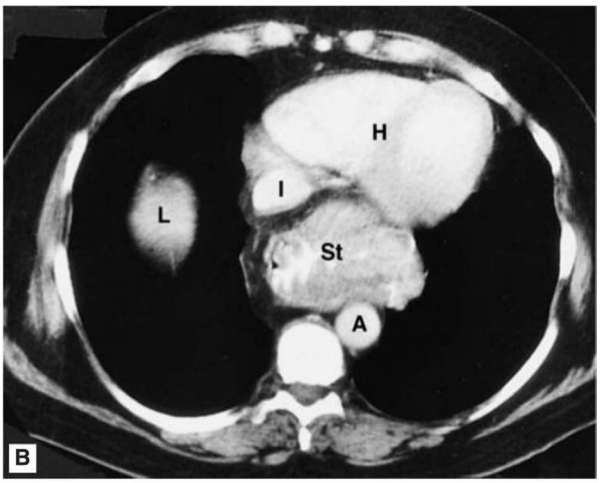


**FIGURE 22-6** Schematic describing mechanism of gastroesophageal reflux disease (GERD). Increased transient lower esophageal sphincter (LES) relaxation is the predominant mechanism of GERD. A subset of patients with GERD have hypotensive LES and usually have severe reflux disease. (Redrawn from Buttar NS, Falk GW. Pathogenesis of gastroesophageal reflux and Barrett esophagus. *Mayo Clin Proc* 2001; 76:226–234.)

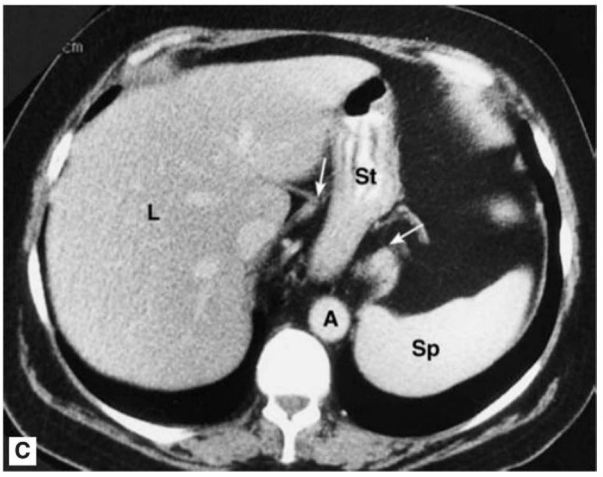

**FIGURE 22-7** Hiatal hernia. **A.** Upper GI demonstrating sliding hiatal hernia. (Reproduced with permission from Doherty GM (ed.) *Current Diagnosis & Treatment: Surgery*, 13th ed. McGraw-Hill, Inc, 2010. Fig. 20-10.) **B.** CT scan through the lower chest revealing herniation of the proximal stomach (St) through the esophageal hiatus into the inferior mediastinum. **C.** Image obtained several centimeters inferior demonstrates widening of the esophageal hiatus (arrows) and proximal stomach herniation. New York: Churchill Livingstone, 2002:1520. Copyright Elsevier.)

lying down, stooping, bending over, or straining. Relief may come with sitting or standing.

The diagnosis of a hiatal hernia can be made using chest radiography, which may suggest a lower posterial mediastinal, retrocardiac mass, often with an air–fluid level. Barium esophagogram may confirm the diagnosis (Fig. 22-7A), but is seldom required. CT scan is often required to confirm the presence of a hiatal hernia (Figs. 22-7B and 22-7C).

Medical treatment is advocated for patients with mild or transient symptoms in whom esophagitis is absent or mild. The goal of medical treatment is to minimize reflux and the irritative effects of gastric secretions. An ideal regimen entails behavior modification and medication. A patient should attempt to ingest smaller meals and avoid going to bed within 3 h of a large meal. Alcohol, caffeine, and chocolate should be eliminated from the diet. A patient should also avoid tight fitting clothing, lose weight, and elevate the head of the bed. Pharmacologically, antacids can be prescribed for before meals and bedtime to minimize the acidity of fluid in the esophagus. $H_2$-receptor antagonists and proton-pump inhibitors (PPIs) can minimize acid secretions in the stomach. The introduction of PPIs has significantly advanced the medical management of gastroesophageal reflux disease (GERD). These drugs block the $H^+$-$K^+$-adenosine triphosphate (ATPase) pump. PPIs can decrease acid secretion by 75 to 90 percent of basal and postprandial status. In the absence of symptoms, no treatment is indicated for an uncomplicated sliding esophageal hernia.

Esophagoscopy should also be carried out on all patients with symptoms of GE reflux to assess esophagitis and intestinal metaplasia. Esophagoscopy also allows for assessment of pliability of the esophageal wall, location esophagogastric junction with relation to the diaphragm, and the presence of a comorbid paraesophageal hernia. A biopsy of the mucosa should be obtained to evaluate for Barrett's esophagus. Esophagogastroscopy should be used to rule out specialized intestinal columnar epithelium within 3 cm of the GE junction.

Indications for surgery include scenarios when severe symptoms persist despite optimal nonoperative management.[6] Patients who also develop complications from reflux esophagitis such as recurrent aspiration pneumonitis or peptic strictures are also candidates.[6] Signs of high-grade dysplasia in Barrett's esophagus should warrant repair of the hernia as ongoing damage of the distal esophagus due to GERD and development of Barrett's esophagus can have serious consequences. The mere presence of a sliding hiatal hernia is *not* an indication for an operation.

Surgical goals are twofold: prevent reflux and treat the esophagitis. The ultimate goal of the surgical intervention is to reproduce the valve-like mechanism of the distal esophagus by wrapping the fundus of the stomach and the GE junction.[6] The wrap must not interfere with passage of food into the stomach; however, it must prevent reflux of gastric contents into the esophagus. The most commonly employed procedure is the Nissen fundoplication, which in short is a 360-degree wrap performed via either laparotomy or laparoscopy.

The operation of choice depends on the individual needs of the patient and expertise of the surgeon. Factors that influence the choice include whether a thoracic or abdominal approach is advantageous, whether the patient has already had a previous antireflux repair, whether a resection or esophagomyotomy is necessary, and patient's body habitus. The principle of these procedures (Nissen, Belsey, Dor Toupe) is the same. The surgeon restores the GE junction to the abdomen and reduces the hiatal hernia while also approximating the diaphragmatic crurae by wrapping the gastric fundus around the distal esophagus (fundoplication). Restoration of the distal esophagus to the positive-pressure environment of the abdomen also plays a role in preventing reflux. These procedures may require a lengthening procedure of the esophagus ("Collis procedure").

As previously mentioned, antireflux procedures for sliding hiatal hernias can be performed a number of ways. Laparoscopic Nissen fundoplication and open laparotomy accomplish the same operation, although the laparoscopic approach has less perioperative discomfort. Long-term outcome is the ultimate motivation and depends on the success of the primary operation; therefore, the patient should obtain best operation at the disposal of the surgeon.

## PARAESOPHAGEAL (TYPE II) HIATAL HERNIA

Paraesophageal hiatal hernias are much less common than sliding hernias. The hernia is a result of focal phrenoesophageal membrane weakening, typically located anteriorly and laterally to the esophagus (Fig. 22-8). The gastric cardia and lower esophagus remain below the diaphragm in the normal anatomic location; however, gastric fundus and abdominal viscera protrude through the defect into the mediastinum. The protruding organs are circumferentially covered by a layer of peritoneum that forms a true hernia sac, unlike the sliding hernia in which the stomach forms the posterior wall of the hernia sac. As the superior stomach ascends into the chest, obstruction can result at the diaphragm.

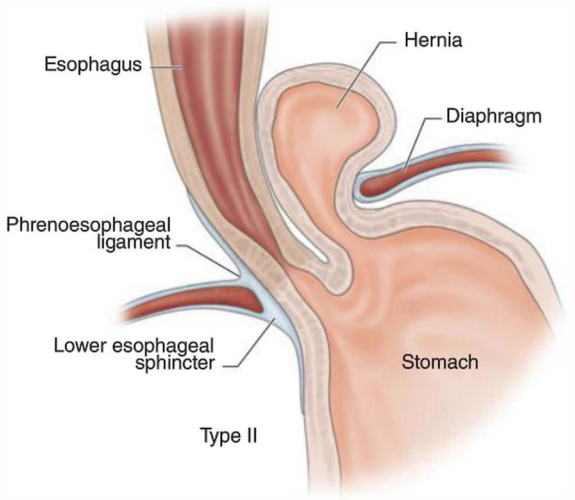

**FIGURE 22-8** Schematic demonstrating anatomy of paraesophageal (type II) hiatal hernia. (Reproduced with permission from Sugarbaker DJ, Bueno R, Krasna MJ, Mentzer SJ, Zellos L (eds.) *Adult Chest Surgery*. McGraw-Hill, Inc, 2009. Fig. 29-3.)

Patients most commonly describe postprandial retrosternal fullness, which may be relieved by regurgitation or belching. Reflux symptoms may or may not be present, and dysphagia is rare. Possible complications include bleeding, incarceration, volvulus, obstruction, strangulation, and perforation. Gastritis and ulceration have been visualized in as many as one-third of patients with paraesophageal hernias. It is suspected that these ulcerations are the result of inadequate gastric emptying and torsion of the gastric wall, particularly after repeat incarcerations, which subsequently impair the blood supply. Chronic bleeding from gastritis or ulceration leads to iron deficiency anemia with resultant fatigue and exertional dyspnea. Respiratory complications may be associated with a paraesophageal hernia and consist of dyspnea from mechanical compression and recurrent pneumonia from aspiration. In the event of gastric volvulous or obstruction, patients may describe severe nausea, abdominal pain, and an inability to regurgitate.

The diagnosis of paraesophageal hiatal hernia is typically first suspected because of an abnormal radiograph of the chest. The most common finding is a retrocardiac air bubble with or without an air-fluid level. The hernia sac and its contents occasionally protrude into the right thoracic cavity. A barium study of the upper gastrointestinal tract is the diagnostic study of choice. Once the diagnosis is established, the functional effect on the competence of the LES should be determined by endoscopy or esophageal function testing.

There is no medical treatment regimen for patients with paraesophageal hiatal hernia. Because of the potentially serious and life-threatening complications associated with this disorder (namely, specifically gastric strangulation), the mere presence of the defect has been considered an indication for

operation.[7] When a patient presents with gastric volvulus and obstruction, decompression with a nasogastric tube must be promptly performed. When unable to decompress a gastric volvulus, patients should undergo immediate operative intervention, whether or not signs of toxicity exist.

The surgical approach for paraesophageal hernia remains controversial. A thoracic approach allows for superior hernia dissection, whereas an abdominal approach is technically less demanding and allows for simultaneous placement of a gastrostomy tube. When the patient has overt signs of significant reflux esophagitis preoperatively, an antireflux procedure should be performed, thus securing the stomach within the peritoneal cavity and repairing the crural defect. In these scenarios, the procedure may be accomplished using laparoscopic techniques. Completion of a concomitant fundoplication has no proven role.

## PARALYSIS OF THE DIAPHRAGM

Paralysis of the diaphragm may be a manifestation of abnormalities located at any point along the neuromuscular axis (Fig. 22-9). In adults, however, the most common cause of hemidiaphragm paralysis is iatrogenic phrenic nerve injury, particularly from cardiac operations where topical cold solutions are used. Internal mammary artery takedown is also associated with phrenic nerve injury. The left nerve is more frequently involved. With new trends of limited opening of the pleural space, phrenic nerve injury has become a less common problem. Other techniques to minimize this injury include lung inflation to protect the nerve from contact with ice slush. Furthermore, when injury does occur, it is usually temporary and fully resolves within 6 to 12 months. Other less common etiologies of phrenic nerve paralysis include trauma, mediastinal surgery infection, neoplasm, neuromuscular disease, and lead poisoning. Occasionally, idiopathic diaphragmatic paralysis is also seen in adults but is thought to be caused by subclinical viral infections. Again, these usually manifest unilateral paralysis, though bilateral injury has been reported.

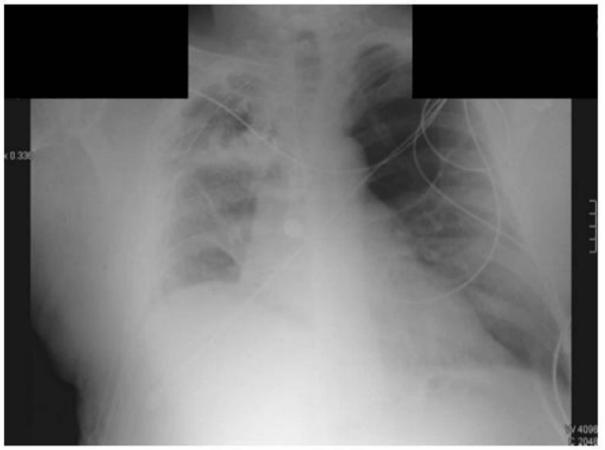

**FIGURE 22-9** Postoperative PA chest radiography demonstrating an elevated right hemidiaphragm. The etiology of this finding was a right paramediastinal mass, involving the phrenic nerve, which required surgical resection. (Image courtesy of Vincent Lotano, MD at the University of Pennsylvania Health System.)

Like adults, the most common cause of unilateral diaphragmatic paralysis in children is injury to one of the phrenic nerves during a cardiac surgery procedure. Redo operations have almost twice the incidence of phrenic nerve injury. Birth trauma and removal of a mediastinal tumor are occasional causes of nerve injury in children.

Previous reports have suggested that a reduction of 20 to 30 percent in the vital capacity and the total lung capacity can be observed with isolated hemidiaphragm paralysis. Perfusion is also diminished, however, typically to a lesser extent. Despite these findings, adults with unilateral diaphragm paralysis typically survive without significant respiratory compromise. Bilateral diaphragmatic paralysis is also often compatible with life in adults; however, it is associated with excessive compensatory movement of the accessory muscles of respiration. In infants and young adults, however, these diagnoses can be life threatening.

Pulmonary function tests often reveal decreased vital capacity in the erect position, which may be further decreased by 50 percent while supine. Lung compliance is also reduced, likely as a result of widespread atelectasis that can be visualized on chest roentogram. On inspiration, the intercostal-accessory muscles contract by expanding the rib cage and producing negative pleural pressure that draws the diaphragm and the abdominal viscera upward into the thoracic cavity. In the case of unilateral paralysis, the affected hemidiaphragm paradoxically moves upward on inspiration as a result of generated negative intrathoracic pressure. When both hemidiaphragm are paralyzed, both will move upward on inspiration.

Paralysis of the diaphragm can be suggested by basilar atelectasis on a plain chest radiograph. Ultrasound studies showing paradoxic diaphragmatic motion with a sniff test have largely replaced fluoroscopy as the gold standard. Unilateral diaphragmatic paralysis can be distinguished by the upward movement of the hemidiaphragm with sniffing. The paradoxical movements may not be observed with normal, deep inspiration as the contralateral diaphragm stretches the thoracic cavity causing a slight descent paralyzed diaphragm. Percutaneous electrical stimulation of a suspected phrenic nerve can also yield information regarding the nerve and the diaphragm function.

Conservative therapy is the treatment of choice for adults, as symptoms are often transient and phrenic nerve regeneration capacity. In the case of a completely severed nerve, direct nerve repair is rarely successful. Diaphragmatic plication works well for the patient with prolonged, severe symptoms, but should only be implemented after 1 year of the initial diagnosis (to allow for adequate time for phrenic nerve regeneration). In infants, mechanical ventilation should be the initial treatment of choice. These children are

typically placed with the involved side down and treated with continuous positive airway pressure. If resolution does not occur within 2 weeks, operative intervention is undertaken by plication of the paralyzed diaphragm. Interestingly, plication does not preclude the return of diaphragmatic function.

The objective of diaphragm placation is to reduce the muscle into a more natural (flat) position and to minimize paradoxical motion and associated shifts of the mediastinum on inspiration. Ultimately, this will allow for more efficient ventilation mechanics as the contralateral diaphragm and other accessory muscles are used. We tend to use a thoracic approach, although both open and laparoscopic approaches may be used. The lateral and posterior aspects of the diaphragm are plicated with pledgeted sutures and in a horizontal mattress pattern. These stitches should be placed approximately 1.0 cm apart, and careful consideration should be given to avoid incorporating branches of the phrenic nerve. The goal should be to ultimately make the diaphragm moderately taught. Another approach involves resection of muscle followed by primary closure.

## DIAPHRAGMATIC TUMORS

Primary tumors of the diaphragm are uncommon. Most are mesothelial in origin, although neurogenic tumors do occur. The majority of diaphragmatic tumors are discovered in the fifth to seventh decade of life, with most being benign. Simple cysts have been most commonly found, although lipomas, fibromas, and benign neurogenic tumors are possibilities. Malignant primary lesions are far less common than benign lesions, and are most frequently sarcomas of muscle or connective tissue origin.[8] Tumors are typically asymptomatic and usually noted on routine radiographs of the chest or found incidentally at time of surgery. Symptoms, when present, include lower chest pain, cough, dyspnea, and abdominal fullness. More commonly than primary diaphragmatic tumor, the diaphragm is invaded secondarily by malignant neoplasms originating from surrounding structures. The diaphragm may also be a site of distant metastasis.

Computed axial tomography and magnetic resonance imaging are usually necessary for full visualization of diaphragmatic tumors. Angiography may serve a supplemental role when liver involvement is likely. The differential for a suspected diaphragmatic mass includes an infectious collection (including *mycobacterium tuberculosis*), hematoma, congenital abnormality, and hernia. On CT scans, lipomas typically appear large, sharp-bordered, and smooth.

Resection and reconstruction of the diaphragm usually does not represent a technical challenge, and is indicated for all tumors of the diaphragm.[8] During tumor resection, the pleural and peritoneal layers should be excised en bloc with the diaphragm. The remaining defect is either closed primarily using nonabsorbable mattress sutures or with a prosthetic soft tissue patch of GORE-TEX or polypropylene mesh. There is minimal morbidity and mortality from diaphragmatic resections, and fulminant respiratory compromise is quite rare. The overall prognosis is quite good for benign lesions. Unfortunately, for malignant tumors, recurrence is common and patients tend to have poor long-term outcomes.

## DIAPHRAGMATIC DISORDERS BOARD REVIEW QUESTIONS (CHAPTER 22)

1. Which is correct regarding congenital diaphragmatic hernias?
   A. These hernias are not commonly associated with other congenital anomalies.
   B. A neonate with a Bochdalek hernia and a pH <7.25 should be placed on ECMO.
   C. A Morgagni hernia usually presents with respiratory compromise.
   D. Most congenital diaphragmatic hernias can now be diagnosed on prenatal ultrasound.
   E. Mortality is unrelated to pulmonary hypoplasia.

2. Which is correct regarding diaphragmatic paralysis?
   A. It is often associated with significant morbidity
   B. Is most commonly idiopathic
   C. Usually requires either diaphragmatic plication or pacing
   D. Is frequently bilateral
   E. Symptoms usually resolve within a year

3. Which of the following is *not* an indication for surgical intervention in a patient with a type I hiatal hernia?
   A. Recalcitrant severe symptoms despite maximal medical therapy
   B. Development of an esophageal stricture
   C. Migration of more that 50% of the stomach into the chest
   D. Recurrent aspiration pneumonitis
   E. High-grade dysplasia in the distal esophagus

4. Which of the following is correct regarding diaphragmatic tumors?
   A. They usually originate from the diaphragmatic muscle.
   B. The majority are discovered in the fifth to seventh decade of life.
   C. Most primary diaphragmatic tumors are malignant.
   D. Surgical resection of malignant tumors offers the best chance at favorable outcomes.
   E. Synthetic materials should be avoided in repairs to reduce the risk of empyema.

5. Which is the correct treatment for symptomatic paraesophageal hernia?
   A. Antacid therapy
   B. Iron supplements for anemia
   C. Antibiotic therapy for reflux pneumonitis
   D. Antiemetics for gastric bloat
   E. Surgical reduction

## ANSWERS

1. **Answer: D.** Most congenital diaphragmatic hernias can now be diagnosed on prenatal ultrasound and confirmed with chest x-ray or CT. These hernias are commonly associated with other congenital anomalies. A pH <7.15 is an indication for ECMO in a neonate with a Bochdalek hernia. Most patients with Morgagni hernias present with gastrointestinal distress in early adulthood. Mortality is directly related to the degree of pulmonary hypoplasia.
2. **Answer: E.** The most common scenario is a patient that sustains unilateral diaphragmatic paralysis from an iatrogenic injury. In this setting, there is no substantial morbidity and symptoms usually resolve within a year. Surgery is rarely required.
3. **Answer: C.** Anatomic findings, such as a large portion of the stomach in the chest, are not absolute indications for surgery. Failure of medical therapy and the development of reflux-associated complications such as aspiration pneumonitis, strictures, and Barrett's esophagus are all indications for surgery.
4. **Answer: B.** The majority of these tumors are discovered in the fifth to seventh decade of life. Most primary tumors are benign; however, the majority of diaphragmatic tumors are metastatic in origin and do not originate primarily from the diaphragmatic muscle. As a result, surgical resection is not usually indicated and is associated with poor outcomes. Synthetic materials are not associated with an increased risk of empyema.
5. **Answer: E.** A symptomatic paraesophageal hernia is an indication for surgical repair. Medical therapy has no role in the treatment of this condition.

**KEY CONCEPTS**

- Membrane potentials are created by energy-dependent ion pumps that segregate charged ions on either side of hydrophobic cell membrane.
- Cell depolarization is possible because channels open within the hydrophobic membrane to allow charged ions, driven by concentration gradients, to cross the membrane.
- Trigger for the opening of transmembrane ion channel is typically a change in the membrane potential. Different channels are triggered to open at different membrane potentials.
- The sarcomere is the contractile element of the myocyte. Each sarcomere is composed of a series of parallel myofilaments. Coaxial movement of these myofilaments, some of which are tethered to the ends of the sarcomere, result in sarcomere shortening.
- The strength of contraction is influenced by resting length of the myocyte, sudden stretch of the myocyte, or rapidly repeated contraction of the myocyte. Speed of shortening is influenced by afterload.
- A ventricle exposed chronically to high afterload will adapt by concentric hypertrophy because this reduces wall stress according to Laplace's law.
- Myocardium receiving insufficient energy supply will die (infarction), become dysfunctional (ischemia), or reduce its energy needs (hibernate). Reperfused tissue is termed "stunned" if it does not contract up to its potential in spite of adequate energy supply.
- Diastole is more energy demanding than systole, and diastolic dysfunction can be more difficult to treat than systolic dysfunction.
- Dysfunctional endothelium leads to vascular occlusion by (1) exposing underlying tissue factor to circulating factor VII, initiating thrombosis, (2) not allowing for the interaction of thrombin with thrombomodulin and the subsequent activation of protein C to its anticoagulant form, (3) not producing nitric oxide, which is important to help decrease platelet activation, decrease vasospasm, and decrease vascular inflammation.

## BASIC MYOCYTE PHYSIOLOGY

### Physiology of the Myocyte Cell Membrane

The human body is composed predominantly of salts and water. This pool of salts and water is segregated into functional units (cells and their intracellular components) that locally alter the concentration of the salts they contain. Hydrophobic phospholipid membranes surrounding the cells (and intracellular compartments) regulate the exit/entrance of water-soluble salts and allow the cells to maintain this individualized environment (Fig. 23-1).[1] Units within these phospholipid membranes actively adjust the ion content within the cell (or intracellular compartment). For example, an energy-dependent sodium ($Na^+$), potassium ($K^+$) pump extrudes $Na^+$ ions from the cell and takes $K^+$ ions into the cell at an exchange of three $Na^+$ ions extruded per two $K^+$ ions taken in. This allows cells to raise intracellular $K^+$ concentrations and lower intracellular $Na^+$. Another pump extrudes calcium ($Ca^{2+}$) in exchange for $Na^+$. This decreases $Ca^{2+}$ concentrations in the intracellular (compared with the extracellular) fluid, but allows $Na^+$ to reenter the cell. This pump is driven by the $Na^+$ gradient created by the energy-dependent $Na^+$, $K^+$ pump. Other channels within the membrane act as passages that intermittently open to allow transit of a specific ion through the cell membrane. Regulation of pump activation and channel opening is vital for the proper functioning of the cell. Similarly, intracellular compartments called the sarcoplasmic reticulum (SR) contain energy-dependent ion pumps

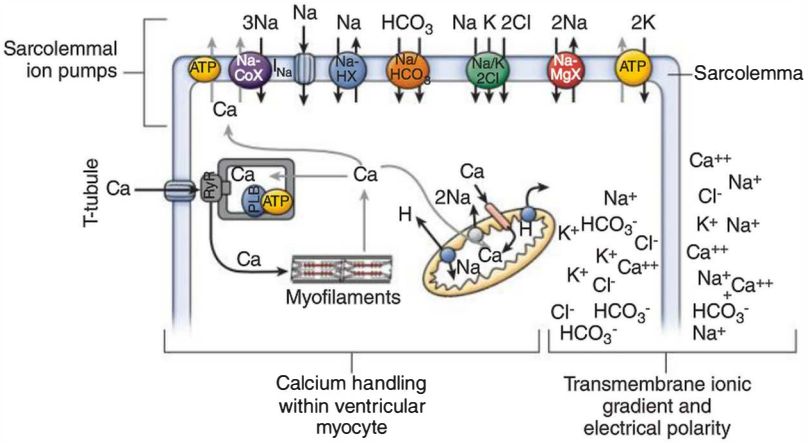

**FIGURE 23-1** Sarcolemmal ion pumps, the transmembrane concentration gradient, and electrical polarity they create, as well as calcium transport in ventricular myocyte. PLB, phospholambam; RyR, Ryanodine receptor; X, Exchanger. (Modified with permission from figure 1b, p 898, Bers DM et al., *Cardiovascular Research* 2003;57:897–912. Copyright Oxford University Press.)

in their surrounding membranes that allow them to collect the majority of the intracellular $Ca^{2+}$. Moving ions against their concentration gradient to create a relative intracellular deficit or abundance requires energy. In the cell, this energy is supplied in the form of adenosine triphosphate (ATP).

## Myocyte Depolarization

Relative to the extracellular fluid, the intracellular fluid in the resting state has a lower ratio of positively to negatively charged ions (i.e., the myocyte membrane is polarized). These electrical and ionic gradients across the myocyte membrane when at rest create the potential for rapid ionic shifts if restrictions to ion movement across the membrane are relaxed. Transmembrane ion movement is facilitated by a series of events precipitated by a small decrease in the magnitude of the electrical polarity across one point of the myocyte membrane. The resultant ion shifts increase calcium concentrations at critical intracellular sites, allowing myocyte contraction.[2]

When the transmembrane electrical potential, –90 mV, at rest, becomes less negative (i.e., depolarizes), sodium channels on the cell membrane are triggered to open (Fig. 23-2). Some of these sodium channels are also triggered at the time of membrane depolarization to close, although the onset of closure is (of course) delayed until after the channel has been opened. Other channels, like L-type calcium channels, also open when the cell membrane depolarizes. The initiation of ion passage through calcium channels is delayed until after the $Na^+$ channels have begun to close. The opening of these $Na^+$ and $Ca^{2+}$ channels results in the entrance of cations into the cell, decreasing the magnitude of the membrane potential. As the membrane potential reaches a nadir, $K^+$ channels are triggered to open. Their opening increases the rate of exit of $K^+$ from the intracellular space into which it had been concentrated. The loss of cations from the intracellular space helps return the transmembrane potential back to the resting state. This $K^+$ channel is inwardly rectified (i.e., turned off when cell is depolarized) and is responsible for maintaining the resting membrane potential. This basic sequence is somewhat modified by channels for $Cl^-$ and transiently open channels for $K^+$ (activated after depolarization to allow $Cl^-$ entrance into cell and $K^+$ efflux from cell, beginning to reverse to return the transmembrane potential toward –90 mV).

As a new transmembrane electrical gradient develops at one point on the sarcolemma (i.e., membrane of a muscle fiber), ion channels traversing the adjacent sarcolemma, closed to the passage of ions under resting transmembrane potentials, become exposed to the new transmembrane potential of the adjacent sarcolemma. This exposure increases the open probability of the nearby channels. The passage of ions through these newly open channels changes the membrane potential surrounding the channel, exposing an additional section of the cell membrane to a different transmembrane potential. In this way, the new transmembrane potential propagates along the surface of the myocytes.

The trigger to opening the sarcolemmal ion channels is often the potential or ionic concentration gradient of the surrounding milieu. Thus, transmembrane channels are frequently described as being either voltage-gated (opening probability is increased if the transmembrane potential of the surrounding membrane is within certain parameters) or ion-gated (opening probability is increased if there is a sudden change in the concentration of an ion in the surrounding fluid). Some channels, described as rectified channels, alter the resistance imposed by the channel-to-ion flow through the channel as the surrounding electrical or ion potential is changing. Speaking of $K^+$ channels, an ion whose exit from the depolarized cell tends to restore the resting membrane potential (by increasing the relative concentration of negatively charged ions intracellularly), outward rectified channels increase the

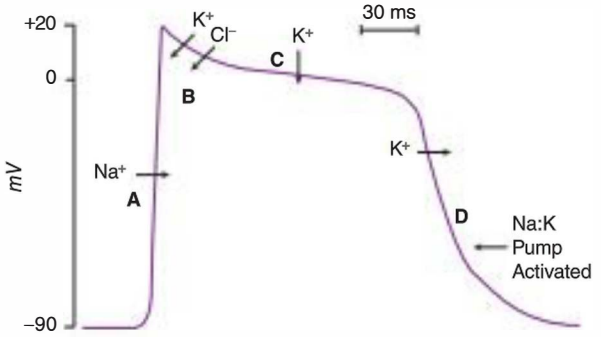

**FIGURE 23-2** Correlation between the changes in ion conductance and the resultant changes in transmembrane potential during the various phases of the cardiac myocyte action potential. A, depolarization; B, rapid repolarization; C, plateau phase; D, late repolarization. (Modified from Rubart M, Zipes DP. Mechanisms of sudden cardiac death. *J Clin Invest* 2005;115(9):2305–2315. With permission.)

resistance to $K^+$ passage as the membrane potential returns to resting state. This type of channel tends to promote restoration of the repolarized state. By contrast, inward rectifying $K^+$ channels are relatively more resistant to ion passage as the membrane is depolarized. This type of channel tends to promote the maintenance of the depolarized state (Fig. 23-2).

## T Tubules and Sarcoplasmic Reticulum

T tubules are invaginations in the cell membrane that penetrate into the cell to lie in close proximity to the myocyte contractile proteins. These T tubules act as extensions of the surface membrane and allow changes in the cell surface to effect changes deep within the myocyte.

Compared with the membrane on the surface of the cell, the membrane of T tubules has a relatively high concentration of L-type calcium channels. These T tubules extend to close approximation with the myofibrils—the contractile apparatus of the myocyte. Also located intracellularly near the junction of the myofibrils and the T tubules are compartments known as SR. The membrane of the SR contains ion pumps that both concentrate calcium within the SR and channels that, when open, allow the sequestered calcium to exit the SR. The stimulus for opening of the calcium channels on the SR is a rise in calcium in the cytoplasm surrounding the SR. Thus, as membrane depolarization propagates from the cell surface down the invaginations known as the T tubules, it stimulates L-type calcium channels in the T tubules to open. This allows calcium to enter the cell at a site near the SR, raising cytosolic calcium concentrations near the SR. These high calcium concentrations near the SR stimulate calcium release from the SR, a phenomenon known as calcium-induced calcium release. The rise in calcium concentrations near the myofibrils reorients the troponin in the thin filaments, moving the tropomyosin (attached to the troponin) and making it sterically possible for the actin of the thin filament to bind to myosin. Contraction follows. Contraction is terminated (and relaxation initiated) by the closing of calcium channels in the SR and the reuptake of calcium by the SR as a result of pumps activated on the SR. This reduces calcium concentrations surrounding the thin/thick filaments, so tropomyosin filaments return to a position preventing the interaction of actin and myosin filaments.

## Regional Differences in Cardiac Myocyte Depolarization

The ion channel(s) predominating in cardiac myocytes differ by the myocyte's location in the heart (atria/ventricles vs sinus node/AV node) (Fig 23-3).[3] This difference in predominating ion channel(s) helps explain the special features of different sites of the heart. Fast-conducting sodium channels predominate in the atria and ventricles, allowing for rapid depolarization and expediting conduction. These channels are less prominent in the SA node and AV node, reducing rate of conduction through these sites.

Additional features of the SA and AV node are responsible for the automaticity (i.e., spontaneous depolarization) that is characteristic of these cells. The resting membrane potential of contracting atrial and ventricular myocytes is maintained by an inward rectifying (i.e., shuts off when cell is depolarized) potassium channel that maintains resting membrane potential of around –90 mV. In the nodal tissues, additional channels (voltage-dependent slow Na channel that allows Na to slowly enter cell as depolarization reaches –70 to –90 mV and, possibly an outward rectifying K channel that reduces K flow as repolarization progresses) result in an unstable "resting" membrane potential. Thus, the resting membrane potential of nodal cells will spontaneously diminish from about –70 to –50 mV, at which time voltage-dependent $Ca^{2+}$ channels will open and allow complete depolarization.

Finally, nodal tissue (predominantly AV node) contains a $K^+$ channel that is central to pharmacologic interventions commonly used to treat dysrhythmias. This channel, activated by adenosine and acetylcholine ($I_{Kach,Ado}$), allows $K^+$ to exit the cell upon stimulation by either adenosine or acetylcholine. The exit of $K^+$ makes the membrane potential more negative, hyperpolarizing the cell and making depolarization more difficult. Thus, acetylcholine reduces sinus node spontaneous depolarization and adenosine blocks transmission through the AV node.

## Excitation: Contraction Coupling

The cascade of events linking myocyte membrane depolarization to myocte contraction is termed excitation:contraction coupling. It can be summarized as follows (Figs. 23-2 and 23-3):

Phase 1 depolarization, mediated by opening of voltage-gated fast Na channels, depolarizes the membrane to a point at which L-type $Ca^{2+}$ channels can open (Fig. 23-3). The influx of calcium through these (dihydropyridine-sensitive)

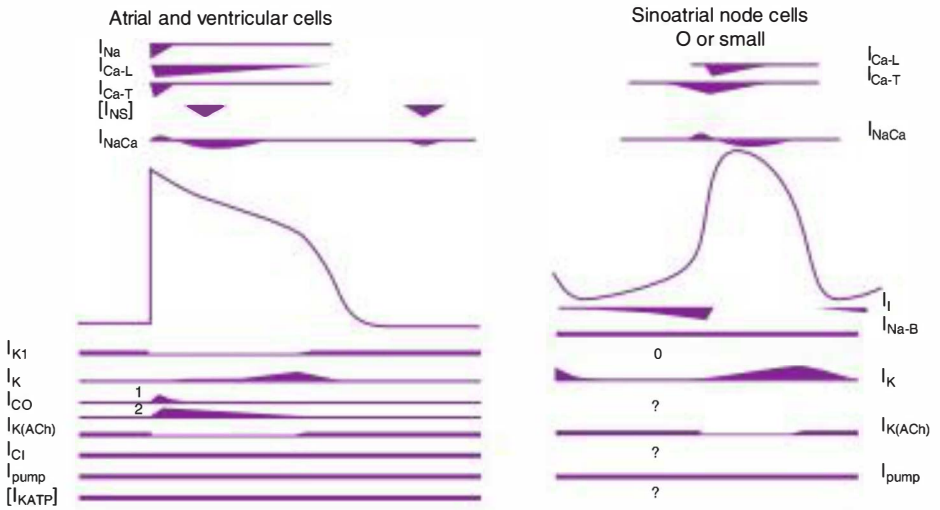

**FIGURE 23-3** A comparison of the stylized action potential of atrial and ventricular cells (left) vs sinoatrial node cells (right) as well as the ionic currents whose contribution to each action potential is confirmed. Other ion channels may exist. Ion current bar deflections depict only the approximate time course (not the magnitude) of the current. Brackets around channel names indicate the current is active only under pathologic conditions. Question mark indicates the uncertain presence of this channel in the sinoatrial node. $I_{NS}$, calcium-gated channel, sodium inward current; $I_{NaCa}$, electrogenic $Na^+$–$Ca^{2+}$ exchange current; $I_{K(ACh)}$, acetylcholine-dependent potassium current; $I_{NS} = I_{Cl}$, chloride current; $I_{pump}$, electrogenic pump; $I_f$, sodium-dependent inward current; $I_{Na-B}$, inward background sodium current. (Reproduced with permission from Sicilian Gambit: A report of the Task Force of the Working Group on Arrythmia of the European Society of Cardiology. *Circulation* 1991;84:1831–1851, P1835, Figure 2. Copyright Wolters Kluwer Health.)

voltage-gated channels, especially through those located along the T tubules, increases intracellular calcium concentration in the vicinity of the SR. (The calcium channels on the SR are termed ryanodine-sensitive calcium channels because the compound ryanodine induces their opening.) This triggers the opening of calcium channels in the SR membrane, releasing calcium stored in the SR. The result of calcium entrance into the cell via L-type calcium channel opening, combined with release of calcium from SR stores, is a dramatic increase in calcium concentration surrounding the contractile myofilaments. High concentrations of calcium allows binding of calcium to troponin C of the thin filament, modulating the troponin such that tropomyosin (attached to troponin) gets moved from its position of preventing interaction between actin (of the thin filament) and myosin. The strength of bond between actin and myosin is decreased by acidosis, high concentrations of $Mg^{2+}$, or high concentrations of phosphate. This bond is enhanced by caffeine and β-adrenergic stimulation. β-Adrenergic stimulation increases actin–myosin bonding through a cascade that results in the activation of myosin-binding protein C.

## Regulation of Myocyte Function by the Myocyte Cell-Surface Receptor

### BETA RECEPTORS

The beta receptor is a protein that is incorporated within the cell membrane. It spans the entire depth of the membrane. It has both components that extend into the cytoplasm and components exposed on the surface of the cell.[4] When an extracellular agonist stimulates the portion of the receptor exposed on the cell surface, a conformational change in the beta receptor allows the portion of the receptor protruding into the cytoplasm to bind to a G protein (i.e., it is a G protein-coupled receptor). G proteins have multiple components, and stimulation of the G protein causes dissociation of the subunits so that each subunit is free to regulate its particular effector. One such effector is adenylatecyclase, which is activated to increase intracellular concentrations of cyclic adenosine monophosphate (cAMP) and thereby activate protein kinase A (PKA). Activated PKA is then capable of phosphorylating multiple intermediaries of excitation:contraction. For example, it increases intracellular calcium concentrations by facilitating calcium entrance into the cell (via L-type calcium channels) as well as calcium release from compartments within the cell (i.e., the SR).

β-Agonist stimulation also expedites relaxation. Relaxation results when cytosolic calcium is in low concentration or is prevented from binding to troponin C. If troponin C is not bound to calcium, tropomyosin returns to a location that inhibits interaction between actin and myosin. Cytosolic calcium content drops when calcium leaves the myocyte through the sodium–calcium exchanger on the cell surface. The predominant method of lowering cytosolic calcium levels, though, is reuptake by the SR. The pump mediating calcium reuptake by the SR is dependent on ATP and regulated by the phosphorylation of phospholamban. Beta stimulation facilitates relaxation by two mechanisms. First, it

results in phosphorylation of troponin I by PKA, expediting dissociation of calcium from troponin C. Beta stimulation also results in phosphorylation of phospholamban, which speeds up calcium reuptake into the SR.

### MUSCARINIC RECEPTORS

Muscarinic receptors sensitive to acetylcholine are also present on the myocardium. In particular, the heart contains the M2 subtype of muscarinic receptor.[5] Like beta receptors, muscarinic receptors are G protein-coupled, which are incorporated within the cell membrane, span the entire depth of the membrane, and contain components exposed to both the extracellular fluid and the intracellular fluid. The G protein to which the M2 receptor is coupled has inhibitory effects on adenylatecyclase and is sensitive to pertussis toxin. In fact, the negative inotropic effects of M2 receptor stimulation appear to be indirect; that is, they can be demonstrated only in the setting of baseline stimulation adenylatecyclase. Therefore, it appears that their negative inotropy results entirely from this inhibitory effect on adenylatecyclase.

In the atria and nodal myocytes, M2 receptors appear to have a direct effect (i.e., not dependent on baseline stimulation) on the inward rectifying potassium channel that maintains phase 4 (resting) membrane potential. By opening this channel through a direct action of the G protein upon the channel, M2 receptor stimulation hyperpolarizes the resting membrane to slow the automaticity rate of the cells.

### ADENOSINE RECEPTORS

Adenosine receptors are also G-coupled protein receptors. There are three basic subtypes of adenosine receptors ($A_1$, $A_2$, $A_3$). $A_1$ and $A_3$ subtypes inhibit adenylatecyclase via inhibitory G proteins whereas $A_2$ receptors increase adenylatecyclase via stimulatory G proteins.[6] These receptors also regulate other pathways via G proteins. Thus, $A_1$ and $A_3$ subtypes mediate the catabolism of phospholipids whereas $A_2$ receptors regulate phosphoinositide metabolism.

Two clinical effects of exogenous adenosine can be traced back to the distribution and effects of various adenosine receptors. $A_1$ receptors are plentiful in the nodal tissues. $A_1$ receptor stimulation opens the inward rectifying potassium channel that maintains phase 4 (resting) membrane potential. Like the effects of M2 receptor stimulation of this channel, opening inward rectifying potassium channels via $A_1$ receptor stimulation hyperpolarizes the resting membrane to slow the automaticity rate of the cells. In the coronary vasculature, $A_2$ receptors predominate. Their stimulation results in vasodilation, likely through G protein–mediated activation of intracellular adenylatecyclase.

### α-ADRENERGIC RECEPTORS

There is growing evidence that α-adrenergic stimulation of myocytes results in a positive inotropic effect.[7] The mechanism and clinical importance of this is unclear. It may also be coupled to myocardial hypertrophy.

## MYOCARDIAL CONTRACTILE FUNCTION

Cardiac myocytes possess the capacity to contract because they contain a series of protein filaments (myofibrils) oriented along the longitudinal axis of the cell (see later). For myocytes to shorten, these longitudinally oriented myofibrils must interact with each other and slide along each other in the longitudinal axis. A rise in intracellular (cytosolic) calcium is critical for this myofibril interaction. Calcium enters the cytosolic space from two sources. First, extracellular calcium crosses the plasma membrane to enter the cell. This rise in intracellular calcium then induces the release of calcium, the second source—intracellular calcium storage pools (calcium-induced calcium release). At baseline, extracellular calcium concentrations are higher than intracellular calcium concentrations because calcium is actively extruded across the cell's phospholipid plasma membrane. The entrance of calcium back into the cell (across the plasma membrane) is a passive process, driven by the concentration gradient and allowed by the brief opening of channels through the calcium-impermeant phospholipid plasma membrane. The impetus for the stimulation is a change in the transmembrane electrical gradient (see Myocyte Cell Membrane Physiology section).

### The Sarcomere as a Contractile Element

#### CONTRACTILE APPARATUS

The sarcomere is the contractile unit of the myocyte. A sarcomere contains two types of coaxially aligned filaments that differ in their component protein (actin/tropomyosin/troponin vs myosin) as well as in thickness (actin/tropomyosin/troponin filaments are thinner, myosin filaments are thicker). Thin and thick filaments are arranged as follows. Each thin filament is axially aligned with, but not attached to, another thin filament. Each pair of thin filaments is straddled by a single thick filament lying parallel to it. Within the myocyte, the contractile unit (a pair of thin filaments and their associated thick filament) is bound on the ends by a Z band (Fig. 23-4). The Z band (for *Zuckung*, the German word for "contraction") is a dark band visible by electron microscopy and corresponding to the site to which the ends of a series of parallel thick and thin myosin filaments are anchored. This defines the ends of a sarcomere. Under appropriate stimulation, the members of an axially aligned thin-filament pair will move closer to each other through an interaction with the thick filament that straddles them. Because each member of a thin filament pair is anchored to Z bands, this coaxial movement draws the Z bands within the cell closer to one another, shortening the cell.[1,8]

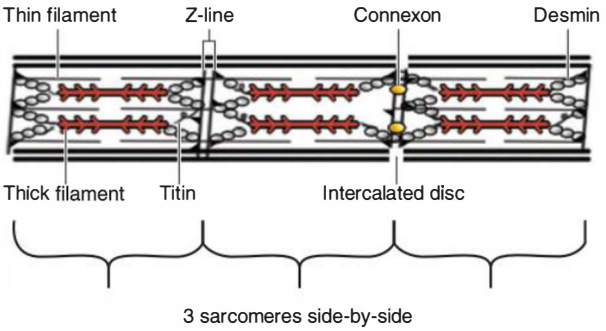

**FIGURE 23-4** Depiction of three sarcomeres located side-by-side. Each sarcomere is depicted with three pairs of axially aligned thin filaments. Each of these three pairs is separated from each other by a thick filament. The filaments are maintained in the proper alignment by desmins, which act as scaffolding. Each thin filament is anchored at one end to the Z-line, with the other end extending centrally into the sarcomere. The connexons are channels between neighboring sarcomeres that allow signals between sarcomeres to be communicated.

Each end of the thick myosin filament is attached to the Z band by a protein called titin or connectin. This protein contains a nonmalleable portion that anchors the filament to the Z band as well as a distensible portion that enfolds on itself if the sarcomere is not stretched. As the sarcomere stretches, the Z bands are pulled farther apart from one another and the enfolded portion of the titin protein is extended. When stretching is relieved, the elastic recoil of the titin molecule helps to actively restore the sarcomere to its resting length.

The movement of thin filaments is an energy-requiring process regulated by local calcium concentrations within the cell. Two thin filaments move toward each other in the axial plane by each "pulling" itself along a shared myosin filament. Under "resting" conditions, physical contact between actin and myosin filaments is prohibited by the tropomyosin component of the thin filament. Tropomyosin is a protein strand that can interdigitate between actin and myosin, preventing their physical contact. Tropomyosin can be moved out of place by the actions of the third protein of the thin filament, the troponin protein. The presence of calcium sterically alters the troponin, causing it to reorient itself within the thin filament and thereby move the tropomyosin strand to which it is attached. The movement of the tropomyosin strand removes the physical barrier preventing actin–myosin interaction and allows the thin filaments to move closer to each other along a shared myosin chain.

## Myocardial Contractile Physiology

Contractility is the ability of a myocyte to shorten, measured at a given preload and a given afterload. Changing the preload will alter contractility due to the length–tension relationship. Changing the afterload will alter contractility because it mandates generation of a different wall stress to achieve shortening.

### LENGTH–TENSION (FRANK–STARLING) RELATIONSHIPS

The force of contraction of a cardiac myocyte increases when the sarcomere is stretched (within the lengths of 1.7–2.4 μm).[9] Mechanistically, this increased contractility can be divided into two parts: (1) an immediate increase in force that is unaccompanied by a change in intracellular calcium concentration and (2) an additional increase in force of delayed (minutes) onset that is associated with an increase in intracellular calcium.[10] The increase in intracellular calcium causing the second phase is probably mediated by changes in the cell membrane. The first phase, which apparently involves a change in myofilament sensitivity to calcium, is the Frank–Starling phenomenon (named for Otto Frank and Ernest Starling, who initiated the concept based on experimental findings they made at the beginning of the 20th century). It was originally hypothesized that sarcomere stretching improved myosin–actin cross-bridge formation. However, the increase in contractile force is observed even if the sarcomere is stretched to distances that would begin to reduce the potential for actin and myosin crossbridge formation. An alternative explanation is that stretching the myocyte narrows the sarcomere, reducing the spacing between myosin and actin filaments. This facilitates myosin–actin interaction. Studies in which the interfilament distance is reduced by cellular dehydration result in an increased calcium sensitivity of contractile strength, similar to that seen with myocyte stretch. A yet unexplained mechanism of stretch-induced change in myofilament sensitivity to calcium remains a third possible explanation.

### FORCE–VELOCITY RELATIONSHIPS

To measure contractile force free of compounding influences from preload, afterload, or heart rate, the concept of measuring the velocity of shortening in a myocyte with no afterload has been developed.[11] In such a scenario, the maximal velocity of shortening ($V_{max}$) would be a measure of the inotropy of a myocyte. Practically speaking, it is difficult to completely remove external resistance from a contracting myocyte. The value of $V_{max}$ must therefore be extrapolated from the maximal velocities observed when a myocyte is made to contract against a series of different afterloads. At one extreme of this series would be the minimal afterload at which the myocyte is no longer able to shorten at all ($V_{max} = 0$). This relationship is hyperbolic rather than linear (Fig. 23-5). Although the reason for this hyperbolic relationship remains unclear, it is felt to be due in part to shortening inactivation and in part to elastic forces that passively resist stretch (at long sarcomere length) or shortening (at short sarcomere length). Such passive elastic forces could be contributed by titin.

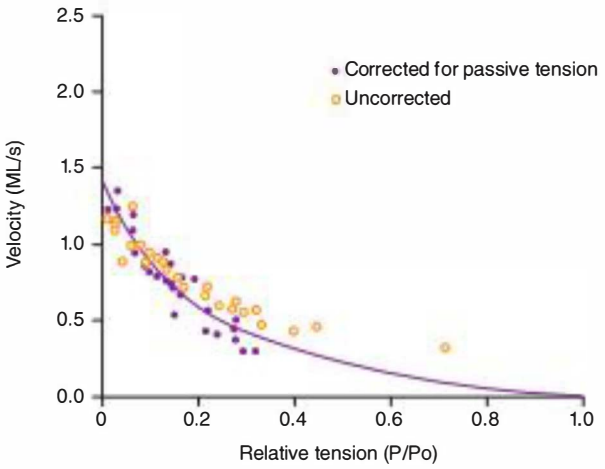

**FIGURE 23-5** The influence of resting tension on the shortening velocity of isolated myocytes. The general relationship of faster shortening velocity observed when resting external tension is decreased can be seen whether passive (intra-myocyte) tension is present (open circles) or mathematically excluded from the calculations (closed circles). (Figure 7 from Sweitzer NK, Moss RL. Determinants of loaded shortening velocity in single cardiac myocytes permeabilized with alpha-hemolysin. *Circ Res* 1993;73:1150–1162, with permission. Copyright Wolters Kluwer Health.)

## "Anrep Effect"

This is a two-phase response of myocytes to an abrupt stretch.[12] The first phase is the Frank–Starling effect—an increase in contractility, which occurs without a change in cytosolic calcium. There is a delayed second phase, which is associated with an increase in cytosolic calcium. The change in intracellular calcium seems to be independent of the SR, although the exact mechanism behind the rise remains obscure.

## "Treppe Effect"

The Treppe effect (*Treppe*, German for "step") is the observed increase in strength of contraction when heart rate is increased. It is associated with an increase in intracellular calcium concentrations,[10] which itself may be due to an inability of the SR and myocyte calcium-extruding pumps to completely return cytosolic calcium to baseline levels between sequential cell depolarizations. The Treppe effect may also be influenced by endocardial–myocyte cross-talk through a process involving endothelin-I.

# CARDIAC PUMP FUNCTION

## Myocyte Cytoskeleton

Synchronized contraction of cardiac myocytes is necessary for most efficient pumping function of the heart.[8] It requires tight adhesion of cells along the axis of their shortening as well as organized propagation of the contractile stimulus. To accomplish this, the basic structure of the myocyte is one of contractile myofibrils attached via fascia adherens to cadherin anchors at the ends of the myocyte (Fig. 23-4). The myofibrils are held in alignment by an intracellular scaffold-like network consisting of the protein desmin. These desmin "scaffolds," traversing the myocyte at intervals along its longitudinal axis, are anchored to the lateral sarcolemmal wall by plaques called costameres. These plaques, rich in the protein vinculin, act both to maintain the spatial interval between the desmin scaffolds and to mechanically link the cells laterally to the sarcolemmal membrane and extracellular matrix. The desmins are anchored to the cadherins at the longitudinal end of the myocyte by desmosomes.

The site of end-to-end adherence between two myocytes is called the intercalated disk. This site physically anchors two myocytes and allows for chemical signaling and intercellular continuity of action potential propagation between these myocytes. The physical anchor is maintained by junctions between cadherins of adjacent cells. Communication between myocytes connected in the longitudinal axis is made possible by channels. Each channel comprises two connexons aligned coaxially. Each connexon comprises six connexin molecules arranged in a circle. There are different types of connexin and different densities of connexon channels among different myocytes.

The characteristics of these intercalated disks are quite important in determining the ease of communication between myocytes in the longitudinal plane. Consistent with this, the composition and number of connexons varies with the electrophysiologic requirements of the myocytes involved. Myocytes of the atria and ventricles, serving principally a contractile function, contain a fair abundance of connexon channels, with connexin 43 being the most abundant connexin present. Cells of the sinus node and atrioventricular node contain few connexon channels joining cells longitudinally. The sparcity of connexon channels in the sinus node allows the natural depolarization of the cells to occur without inhibition by the hyperpolarizing effects of the surrounding contractile myocytes. The sparcity of these channels in the atrioventricular node slows communication between cells, slowing transmission of the electrical impulse. By contrast, the cells of the Purkinje system contain high numbers of large connexon channels composed of the high-conductance connexin 40. This allows rapid transmission of electrical impulses throughout the Purkinje system.

## Cardiac Mechanics

### FRANK–STARLING MODEL

The ability of the heart to contract is influenced by the resting volume within the heart. This is analogous to the way the contractility of the sarcomeres (and myocytes) composing the heart is influenced by the resting length to which they are stretched. Physiologists therefore view the heart as a series of

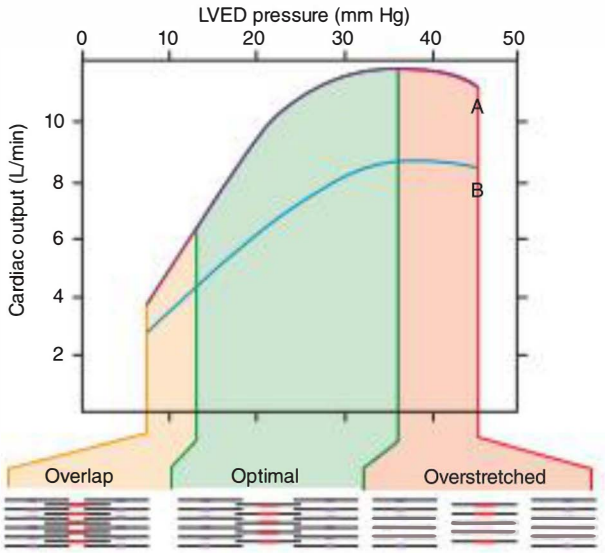

**FIGURE 23-6** Frank–Starling Ventricular Function Curve in normal heart. Top: As depicted in Curve B, an increase in left ventricular end diastolic pressure (LVEDP) increases the volume ejected by the heart. Alternatively, the volume ejected at any given LVEDP can be increased by increasing the inotropic state of the heart (i.e., moving from Curve B to Curve A). Bottom: Increasing the LVEDP stretches the actin:myosin filaments. (Instructors Resource CD ROM to accompany *Porth's Pathophysiology: Concepts of Altered Health States*. 7th ed. With permission. sarcomeres demonstrating length–tension relationships—the model conceptualized by Frank and Starling (Fig. 23-6). In this regard, the capacity of the heart to eject blood against a given resistance increases as the volume within the heart immediately prior to initiating systole (i.e., the end-diastolic volume) increases. This relationship, and its analogy to the length–tension relationship of individual sarcomeres, is demonstrated in Figure 23-6. Because the volume within equally compliant hearts is directly proportional to the pressure within the heart, this Frank–Starling model can also be displayed as an effect of pulmonary capillary wedge pressure on the stroke volume or ejection fraction of the left ventricle (LV).

## PRELOAD AND DIASTOLIC COMPLIANCE

Diastole is the return of the ventricle to the maximal degree of distention it will achieve prior to initiating another contractile effort. This is a two-step process—the passive recoil of previously contracted myocytes followed by the active distension of these myocytes by external forces. In the first step, cessation of contractile efforts by myocytes allows these myocytes, after contracting to a length less than their resting length, to return to their resting length much in the same way that a compressed spring returns to its resting length after contracting forces are removed from it. The ease and extent of recoil is inversely proportional to the amount of fibrosis between the myocytes.

In the second step, filling the ventricular chamber with blood distends the ventricle, stretching the individual sarcomeres of the component myocytes. The magnitude of force required to stretch a sarcomere to a given length varies with the distensibility of the sarcomere (analogous to stretching a spring) and the fibrosis between myocytes. Analogously, the magnitude of the three-dimensional force (i.e., pressure) needed to distend the ventricular chamber to a given volume varies with the compliance of the chamber (Fig. 23-7). Distending two ventricles with the same volume of blood will result in a higher intraventricular pressure within the less compliant ventricle. Furthermore, the compliance of a chamber changes as it fills. Adding 20 mL to a ventricle increases the intraventricular pressure much less when the ventricle is nearly empty than when it already contains 200 mL of blood.

## AFTERLOAD

Under normal circumstances, the pressure preventing a ventricular chamber from contracting (i.e., afterload) is the pressure required to sufficiently distend an arterial bed to accept the blood ejected by the contracting ventricle. Thus, the afterload to the LV is the pressure within the systemic arterial system. As with all elastic chambers, the compliance of the arterial bed decreases as it fills with blood. Thus, the afterload of the LV increases as the ventricle empties and ejects blood into the aorta. At some point, the ventricle stops ejecting because the pressure required to further distend the systemic arterial system exceeds that which the ventricle is capable of generating. This point marks the end of physiologic ventricular systole.

## THE CARDIAC CYCLE

***Pressure–Volume Loops.*** The above discussion emphasizes three points: (1) the extent to which ventricular contractility is facilitated by optimizing sarcomere length at a given point in its pressure-generating cycle is reflected by the effect on strength of contraction of changing the intraventricular volume at that point during systole, (2) LV compliance is reflected by the pressure generated within the LV for any increase in LV volume during relaxation, and (3) the capacity of the LV to eject blood depends on its ability to generate enough pressure to overcome afterload. This illustrates the utility of evaluating ventricular performance in terms of the relationship between the pressure ($x$-axis) and volume ($y$-axis) within the ventricle at any point in time.

Active contraction of the ventricle is indicated by the bottom right-hand corner of the pressure–volume square (Fig. 23-8). At this point, intraventricular volume stops increasing (marking the end of diastole) and intraventricular pressure begins to rise rapidly. At the top right-hand corner of this relationship, the aortic valve opens. Thus, by generating a constant pressure just strong enough to keep the aortic valve open, the ventricle is able to continually eject blood into the aorta. The volume within the ventricle thereby decreases, myocytes subsequently contract, and the sarcomere shortens from its ideal length for force generation. At some point, the ventricular sarcomeres have shortened so much that they are no longer able to generate the force needed to further contract. This point, indicated by the top left-hand corner of the pressure–volume loop, is termed the end-systolic pressure–volume point and represents the dependence of ventricular shortening on the volume of the LV and its capacity to generate pressure. From this point, the myocytes cease generating force and the intraventricular pressure decreases (represented by the vertical line marking the left side of the pressure–volume loop). Finally, the mitral valve opens and blood starts filling the ventricle. Although the ventricle has not yet begun to contract, the pressure within it slowly increases as blood enters across the mitral valve prior to initiation of myocyte shortening.

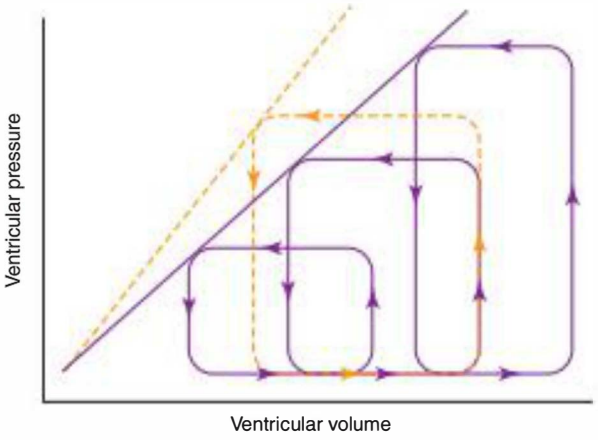

**FIGURE 23-8** The Frank–Starling law of the heart–end-systolic pressure is determined by end-systolic volume and is independent of end-diastolic volume. The end-systolic pressure–volume relationship is altered by the ventricular contractile state. As indicated by dashed line, increased inotropy increases the ejection volume and end systolic pressure at any given end-diastolic ventricular volume. (Reproduced with permission from Konhilas JP, Irving TC, de Tombe PP. Frank-Starling law of the heart and the cellular mechanisms of length-dependent activation. *Pflugers Arch* 2002;445(3):305–310. Copyright Springer.)

***Contractility.*** As indicated above, the end-systolic pressure–volume point on the pressure–volume loop indicates the limit to the pressure-generating capacity of the ventricle at a given preload. By changing the afterload experimentally, a series of pressure–volume loops can be generated such that the minimal preload required to generate any given pressure can be determined. The straight line connecting the end-systolic pressure–volume points of this series of loops is termed the end-systolic pressure–volume relationship (ESPVR). This relationship is an indication of the strength of contraction of the ventricle. A more vertical line or one shifted more to the left indicates greater contractility. A more horizontal line or one shifted more to the right indicates less contractility.

***Compliance (Fig. 23-9).*** Similar to its usefulness in evaluating LV contractility, the pressure–volume loop can be used to monitor the diastolic function of the heart. The bottom right corner of the pressure–volume loop marks the point at which diastole ends and systole begins for the ventricle. This point, the end-diastolic pressure–volume point, indicates the pressure required to fill the relaxed ventricle with the volume of blood it contains at end-diastole. A series of pressure–volume loops can experimentally be created to evaluate the pressure generated within the relaxed heart as it is filled with greater or lesser volumes of blood. The line connecting the end-diastolic pressure–volume points of this series of loops is termed the end-diastolic pressure–volume relationship (EDPVR). Unlike the ESPVR, the EDPVR tends to be curvilinear because the compliance of elastic containers tends to decrease as the container is filled. Nevertheless, an EDPVR line that is more vertical or raised higher along the vertical axis suggests decreased compliance of the ventricle. An EDPVR line that is more horizontal or lowered along the vertical axis suggests an increased compliance of the ventricle.

## MYOCARDIAL WALL STRESS

A circular object is envisioned as a series of 360 straight lines each offset from one another by 1 degree and each tangential to the radius of the circle. The stress on the wall of a distended, elastic circle can then be viewed as the force distending each of these tangential lines. In the case of the heart, the stress on the wall of the ventricle can be thought of as the force stretching each of the myocytes of the wall.

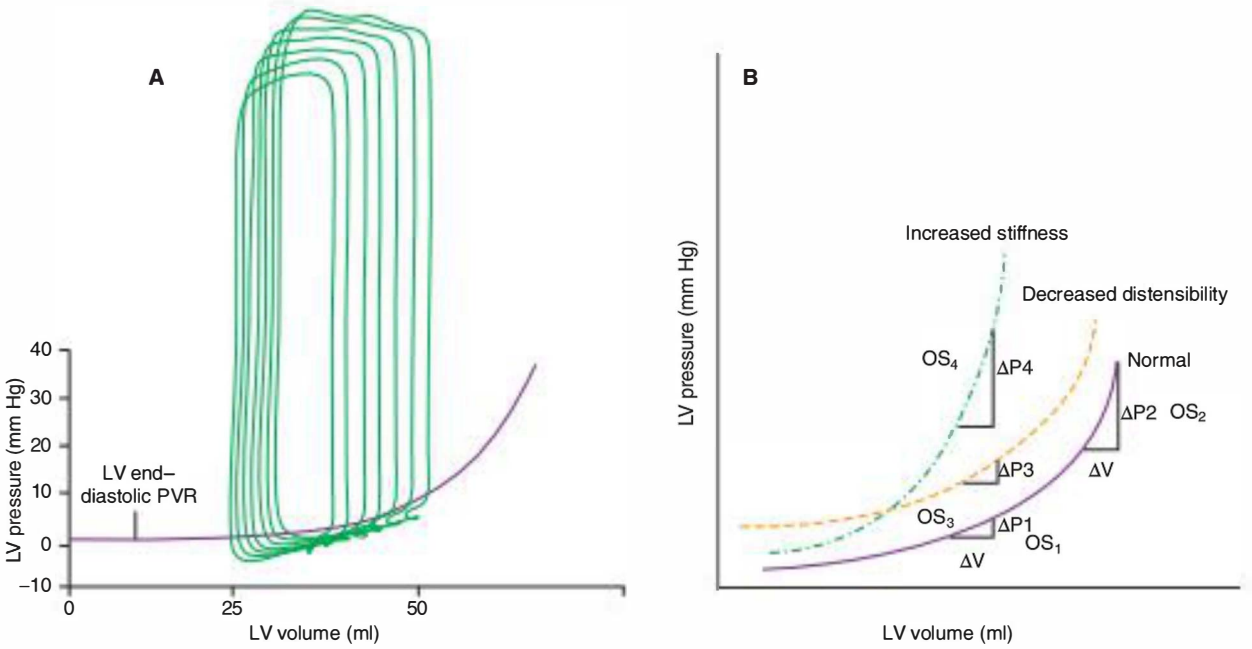

**FIGURE 23-9** **A.** Determining left ventricular compliance by changing left ventricular volume to define end-diastolic pressure–volume relationship (EDPVR). The curvilinear nature of EDPVR suggests that normal LV becomes more resistant to filling as end diastolic volume increases. **B.** Illustration of the effect of different left ventricular operant stiffness (OS) conditions on EDPVR. Increasing slope of EDPVR suggests decreasing compliance of myocardium/intercellular components; decreasing slope of EDPVR suggests lusitropy; parallel shift up of EDPVR (with same slope) suggests extramyocardial forces (RV loading/interventricular forces; pericardial constraint). (Reproduced with permission from Maniu CV, Redfield MM. Diastolic dysfunction: Insights into pathophysiology and pharmacotherapy. *Expert Opin Pharmacother* 2001;2:997–1008.)

The interrelationship of the factors composing this force is a physical principle explained by the law of Laplace. This law states that the tension in the wall is related to the pressure gradient across the wall (P), the radius of the ventricle (R), and the wall thickness (th) as follows (Fig. 23-10):

$$T = [(P)(R)]/[(2)(th)]$$

Thus, distending the ventricle (increasing the radius *R*) increases the stress on the ventricular myocytes. By contrast, hypertrophy of the ventricle (increasing wall thickness th) decreases tension on the wall. This explains why ventricular hypertrophy is a natural adaptation of the LV to hypertension.

## CARDIAC ENERGETICS

Molecules consist of positively charged protons and negatively charged electrons in close proximity. This close proximity is made possible by electromagnetic force or "bonds" between the positively and negatively charged particles. According to the first law of thermodynamics, the energy of these bonds must be converted to another form if the bond is broken. Living organisms break these bonds under controlled conditions, which allow them to harness the energy of the bonds and use if for doing work (moving objects over distance).

The energy form most efficiently used by cells of living organisms is that contained in the bonds joining phosphate residues to certain organic compounds in the form of ATP, adenosine diphosphate (ADP), or creatine phosphate (CP) (Fig. 23-11). The energy ingested by organisms is often in the form of fatty acids, proteins, and carbohydrates. The energy in these ingested compounds is in the form of nonphosphate bonds, not in the form of ATP. To convert the energy from the ingested form (nonphosphate bonds) to the usable form (phosphate bonds of ATP), the following cascade of enzyme-mediated reactions is employed: (1) Glucose, amino acids, and fatty acids are converted to acetyl CoA (glycolysis converts glucose to acetyl CoA via pyruvate as an intermediary; diverse processes convert amino acids to acetyl CoA; beta oxidation converts fatty acid to acetyl CoA). (2) The Kreb cycle allows acetyl CoA to donate the electron-containing hydrogen ions needed to convert FAD to $FADH_2$ and convert NAD to NADH + $H^+$. (3) A subsequent enzyme-mediated transfer of electrons from $FADH_2$ and NADH + $H^+$ to oxygen creates a high concentration of electrons within the intermembrane space of the mitochondria. (4) The electron gradient between the mitochondria's intermembrane space and the mitochondria's cytosol then drives the formation of ATP from ADP and inorganic phosphate.[13]

Under normal circumstances, 60 to 80 percent of the ATP used by the heart is generated from fatty acids; the

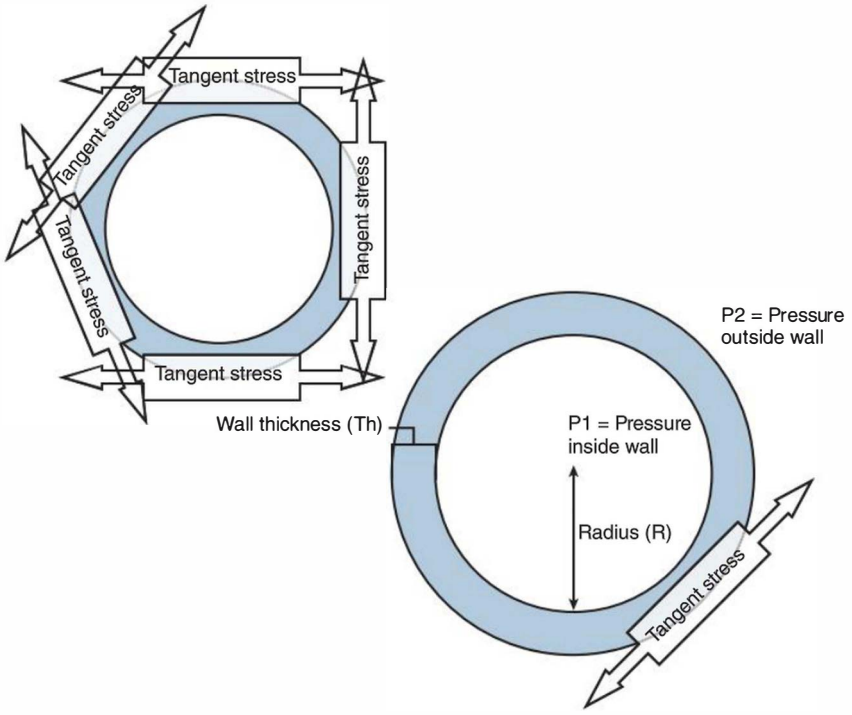

**FIGURE 23-10** Top left: Depiction of circle comprising multiple lines tangential to the radius of the circle. Bottom right: Tangential stress (T) = Pressure gradient across wall (P) × Radius of circle (R)/2 × Thickness of wall (Th), where P = P2 – P1.

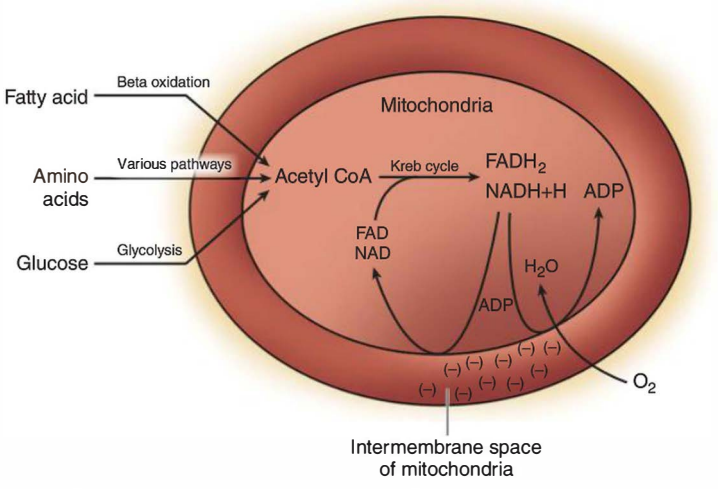

**FIGURE 23-11** Step 1: Conversion of fatty acid, proteins, a nd glucose to acetyl CoA. Step 2: Kreb cycle for production of electron donors. Step 3: Creation of electron gradient within mitochondrial intermembrane space. S tep 4: Utilization of electron gradient and oxygen to create ATP and water.

remainder is generated predominantly from glucose. Fatty acid oxidation produces more ATP than does glucose oxidation, but does so at the expense of less-efficient utilization of oxygen. Fatty acids are, however, maintained as the heart's primary energy source during ischemia because of modifications to fatty acid metabolism during ischemia. Nevertheless, the lack of oxygen reduces the cellular capacity to bind phosphate to ADP. Phosphate residues are sequentially removed from ADP, degrading it first to AMP and then to adenosine. The adenosine exits the myocyte to stimulate adenosine receptors, causing pain (angina).

As an alternative to oxidative phosphorylation, the body can also restore ATP levels by transferring a phosphate moiety from phosphocreatine (PC) to ADP. This phosphate transfer is used by the heart, skeletal muscle, and brain [the three organs containing the enzyme creatinine phosphokinase (CPK) under conditions of inadequate perfusion]. The PC is formed by the transfer of phosphate from ATP to creatine, a transfer occurring most readily under conditions of adequate tissue perfusion.

# CORONARY BLOOD FLOW

## Normal Coronary Blood Flow

Coronary blood flow supplies 60 to 90 mL/min of blood per 100 g of resting myocardium. The energy driving this perfusion is the pressure gradient between the proximal aorta (the origin of the coronary arteries) and the intraventricular pressure.[14] The influence of the intraventricular pressure derives from the fact that the same wall stresses responsible for generating intraventricular pressure also act to both decrease the pressure gradient driving the blood through the coronaries and compress the coronary vessels traveling through the myocardial wall. Because the gradient between intra-aortic pressure and intraventricular pressure is greatest when the ventricle is not contracting, the majority of coronary blood flow occurs during ventricular diastole. Coronary blood flow is both autoregulated and influenced by changing energy demands of the myocardial tissue. The factors affecting flow during periods of increased metabolic demand likely include neurohumoral factors as well as the factors responsible for autoregulation.

## Autoregulatory Mechanisms of Coronary Blood Flow

Factors intrinsic to the heart and its vasculature adjust the tone of coronary vessels smaller than 100 to 150 μm in diameter to assure that flow to the heart is kept constant in spite of changes in perfusion pressure to the heart. The mechanism includes a mixture of metabolic products, myogenic factors, and extrinsic compression by surrounding tissue.[14]

Metabolic products incriminated in coronary autoregulation include adenosine, prostaglandin, oxygen, carbon monoxide, carbon dioxide, and potassium concentrations in the tissue. Adenosine is an obvious candidate because, as stated earlier, it is produced in the heart at higher amounts during hypoxia. But removal of adenosine from interstitial spaces does not prevent coronary autoregulation, leaving other candidates as contributors. Prostaglandins can also cause dilation through stimulation of G protein-coupled receptors. This influence may be more pronounced when nitric oxide is less abundant, as in severe atherosclerotic disease. Hypoxia of the circulating blood or surrounding tissue may play a direct role by stimulating the opening of vascular smooth muscle cell K channels, which are coupled to the hypoxia sensitive cytochrome $b_{558}$. Similarly, low ATP levels can stimulate the opening of ATP-sensitive K channels in smooth muscle cells, causing vascular dilation. Nitric oxide dilates coronary vasculature through the activation of soluble guanylate cyclase. The release of nitric oxide is stimulated by hypoxia. Carbon monoxide can also activate soluble guanylate cyclase, making carbon monoxide (produced from the breakdown of heme to biliverdin) a possible mediator. Similarly, carbon dioxide has been shown to cause coronary dilation, possibly through a mechanism involving nitric oxide and/or cyclic guanosine monophosphate (GMP).

Myogenic contribution to autoregulation is the ability of smooth muscle cells to "sense" flow and alter tone to maintain flow constant. Mechanisms by which smooth muscle cells accomplish this are both unclear and difficult to evaluate in vitro. The majority of this response seems to occur in vessels between 30 and 70 μm in diameter. The cascade probably involves the sensing of altered intraluminal pressure or shear stress, the activation of nonspecific ion channels in the smooth muscle cell, and the phosphorylation of myosin light chains in the smooth muscle cell by myosin light chain kinase.

External compression of the coronary microvasculature by contraction of the surrounding tissue can also act as a feedback control of coronary blood flow. As coronary blood flow becomes inadequate, the force of myocyte contraction decreases due to limited energy supplies. This decreases the magnitude of the external forces acting to compress small coronary microvasculature, facilitating coronary blood flow.

## Physiologic Consequences of Coronary Insufficiency

### MYOCARDIAL ISCHEMIA

Myocardial ischemia is the condition whereby the myocardial blood flow and/or oxygen supply is insufficient to satisfy the demands of the myocardial tissue. This can reflect either an inappropriate limitation to blood flow (i.e., low-flow ischemia), an inappropriate excess in myocardial demand (i.e., high-flow ischemia), or low blood oxygen content such that oxygen delivery is insufficient in spite of appropriate blood volume supply and tissue demand (i.e., hypoxia or anemia). Myocytes respond by shifting their energy metabolism from

aerobic (mitochondrial) to anaerobic (glycolytic) pathways. Alternative sources of stored energy (other than ATP) are used, such as CP. These stores, however, are quite limited. As a result, metabolites of the complete breakdown of ATP (e.g., adenosine), metabolites of glycolysis (e.g., lactate), and a host of other substances (e.g., bradykinin, angiotensin) are released into the interstitial fluid.

During myocardial ischemia, energy reserves begin to decrease. This can result in dysfunction of any of the myocyte's energy-dependent diastolic function, systolic function, automaticity, and/or intercellular communication. Diastole, driven by ATP-dependent calcium uptake by the SR, is more sensitive to limited energy supplies than is systole. Diastolic dysfunction hinders relaxation, making it more difficult to fill the ventricle with blood. This lack of ventricular filling impairs the Frank–Starling mechanism, and thus limits the ability to compensate for systolic dysfunction. With more dramatic imbalances between myocardial oxygen supply and demand, all contractile capacity of the ventricle is lost. Whether this loss of contractile function is temporary or permanent depends in part upon the severity and duration of the energy supply–demand mismatch. Finally, insufficient energy impairs maintenance of membrane potentials by the nodal cells. This compromises the normal development of automaticity by SA node cells as well as conduction through AV node and Purkinje cells.

## MYOCARDIAL INFARCTION

An insufficient myocardial oxygen supply, if maintained too long, results in the utilization of all energy reserves by the myocardium. This leads to irreversible myocyte damage and begins to be seen after 20 min to 2 h of ischemia. With no energy, even the basic requirements for cell survival (i.e., exclusive of contractile function) cannot be maintained. Transmembrane ion concentrations are lost, and osmotic forces cause cell expansion to the point of membrane disruption and lysis of intracellular organelles. The tight junctions of intercalated disks between cells are disrupted, and cell-to-cell communication is lost. Recovery cannot occur following such catastrophic changes.

## "STUNNED" MYOCARDIUM

Reperfusion of ischemic myocardium does not always result in the return of normal myocyte function.[15,16] Dysfunction of reperfused tissue can persist in spite of blood and energy delivery capable of supporting much greater energy expenditure by the myocytes. The dysfunction that persists under these conditions is termed "stunning," an important characteristic of which is that it persists in the setting of a relative abundance of energy delivery. Other characteristics include the retained capacity of stunned myocardium to increase the force of contraction on exposure to inotropes as well as the lack of influence of β-agonists or β-blockers on the rate of recovery of stunned myocardium. The duration of stunning depends on factors such as the severity and duration of ischemia as well as the adequacy and immediacy of return of normal blood flow.

The cascade responsible for stunning is incompletely understood. Still, it is felt to involve oxygen-derived free radicals released during the early moments of reperfusion. Furthermore, it can be attenuated by using iron chelators such as deferoxamine. This suggests that hydroxyl radicals, generated from superoxide by an iron-catalyzed reaction, mediate at least part of the reaction. There is speculation that nitric oxide released during reperfusion may contribute through the formation of peroxynitrite after binding with the superoxide radicals. Unfortunately, free-radical scavengers have thus far been only inconsistently beneficial in preventing myocardial stunning. In any case, altered availability of calcium or sensitivity of myocyte myofibrils to calcium is chief suspect as to the mechanism by which contractile function is impaired.

## "HIBERNATING" MYOCARDIUM

Myocardial hibernation is another state of reversible myocyte dysfunction related to an insufficient blood supply.[17] In contrast to myocardial stunning, which occurs after formerly ischemic tissue has been reperfused with abundant blood supply, myocardial hibernation occurs while impaired blood delivery is ongoing. Thus, it is felt to be a way by which the myocyte preserves itself through decreasing energy expenditures to meet the energy supply available. The mechanism of myocardial hibernation is also unclear. Light-microscopically, there is a decrease in contractile elements, an increase in glycogen accumulation, and an alteration in the morphology of both the mitochondria and the T tubules. These changes are reversible, and contractile function is restored with the return of a normal blood supply. Positron emission tomography scanning, which utilizes labeled indicators of perfusion ($^{13}NH_3$) and of metabolism ($^{18}$FDG), remains the gold standard for distinguishing poorly contracting myocardium as potentially viable (hibernating).

## CORONARY ENDOTHELIAL FUNCTION

Rather than serving as a passive lining between the blood and vascular smooth muscle, coronary endothelial cells play an active role in preventing the development of myocardial ischemia.[18] Thus, the endothelium promotes anticoagulation, fibrinolysis, and vasodilation. It produces nitric oxide, which inhibits inflammation, platelet aggregation, leukocyte adhesion, and smooth muscle cell proliferation. It also provides vasodilatory and antioxidant effects.

The anticoagulation role of the endothelium evolves from the fact that the endothelium covers tissue factor (preventing contact between circulating factor VII and tissue factor) and is itself covered by antithrombin, protein C, protein S, and tissue plasminogen activator. When the endothelium is disrupted, then, circulating factor VII binds with the now-exposed tissue factor. This converts factor VII to its active form, and initiates the formation of thrombin. Thrombin

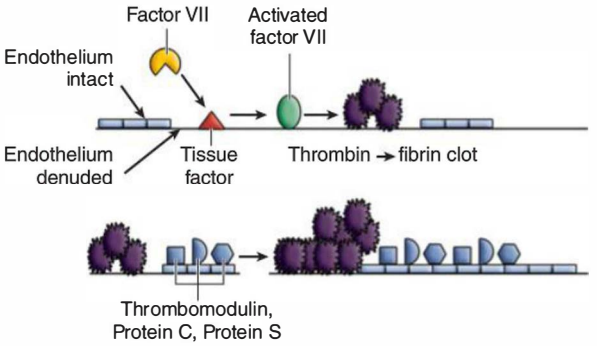

**FIGURE 23-12** Top: Disruption of endothelium exposes tissue factor to circulating factor VII. Tissue factor activates factor VII, initiating a cascade that ultimately results in production of fibrin clot. Bottom: As thrombin encounters thrombomodulin on surface of intact endothelium, the interaction allows for activation of protein C and protein S. This reverses prothrombotic reactions and leads to inhibition of clot progression.

converts fibrinogen to a fibrin clot. This cascade continues until thrombin contacts healthy endothelium. Exposure of thrombin to thrombomodulin on the healthy endothelial surface leads to the activation of protein C and protein S. Activation of these proteins *in*activates factors V and VIII. Because the activity of factors V and VIII expedite the production of thrombin, inactivation of these factors greatly reduces the prothrombotic cascade. Finally, tissue plasminogen activator, a serine protease released by the endothelium, is responsible for the conversion of inactive plasminogen to plasmin, which mediates fibrinolysis (Fig. 23-12).

This cascade highlights two concepts: (1) protein C and protein S are important in limiting clot propagation. They are vitamin K-dependent anticoagulant proteins, which can be more sensitive to Coumadin than is the production of many vitamin K-dependent procoagulant factors. The initiation of Coumadin therapy can therefore cause hypercoaguability prior to resulting in an anticoagulated state. (2) Although this antithrombotic cascade shows redundancy, optimal function requires the presence of all components. The opportunity for any single deficiency explains the relative abundance of hypercoaguable (vs hypocoaguable) conditions in the general population.

The vasodilatory effects of nitric oxide result from its stimulation of soluble guanylate cyclase, leading to a decrease in intracellular calcium. Nitric oxide's anti-inflammatory effect results principally from its ability to inhibit nuclear factor K-B, a transcription factor important in the regulation of many inflammatory proteins. It inhibits platelet aggregation by decreasing intraplatelet concentrations of calcium through a cascade similar to that by which nitric oxide causes vasodilation. It reduces leukocyte adhesion by decreasing the expression of vascular cell adhesion molecule via inhibition of nuclear factor K-B. Nitric oxide's capacity to inhibit smooth muscle cell proliferation is poorly understood but may involve its activation of PKA. The effect of nitric oxide on free radical balance is complex, although it is a potent inhibitor of free fatty acid, phosphatidylcholine, and low-density lipoprotein (LDL) oxidation.

Nitric oxide can be stimulated by neurohumoral mediators (e.g., acetylcholine), by products released by circulating cells (e.g., bradykinin, serotonin), or by mechanical forces (e.g., shear stress). Nitric oxide production is impaired by atherosclerosis through a series of mechanisms. First, atherosclerotic plaques physically exclude endothelial cells from the stimulants for its release (e.g., shear stress). Second, there is a direct effect of cholesterol components (e.g., lysophosphatidylcholine, a component of oxidized LDL) on the nitric oxide signaling pathway [i.e., protein kinase C, G proteins, and caveolin–endothelial nitric oxide synthase (eNOS) interaction]. Finally, cholesterol enhances the activity of the superoxide-producing reduced nicotinamide adenine dinucleotide phosphate oxidase and xanthine oxidase enzyme systems within the vascular wall. Since oxygen radicals scavenge nitric oxide, this effectively decreases the bioavailability of the decreased amounts of nitric oxide produced.

## PHYSIOLOGY OF HEART FAILURE

### Systolic Dysfunction

Heart failure is a syndrome of dyspnea, fatigue, and fluid retention that may result from the inability of the heart to fill with, and/or eject blood. It can be asymptomatic (stage A or stage B) or symptomatic (stage C or stage D). In stage A, the asymptomatic patient essentially has no heart failure but has medical risk factors that predispose to heart failure (coronary artery disease, hypertension, diabetes). In stage B, the asymptomatic patient has structural indications of impending heart failure (LV hypertrophy, impaired LV function). Stage C indicates current or past symptoms and stage D indicates refractory symptoms. These stages emphasize the progressive nature of this disease. This classification is meant to complement the New York Heart Association (NYHA) functional classification, which characterizes the functional limitations being experienced at a point in time by the patient with stage C or stage D disease. (Class I—symptoms only with severe exertion, Class II—symptoms with ordinary exertion, Class III—symptoms with less-than-ordinary exertion, Class IV—symptoms at rest.) Thus, though a patient may vary from NYHA classification III to NYHA classification I, they will not regress from stage C to stage A.

Systolic dysfunction is the impaired ability of the ventricle to generate force and shorten.[19] The symptoms depend on which ventricle fails. Left ventricular failure prohibits egress of blood from the pulmonary vasculature, leading to pulmonary symptoms of shortness of breath. Right ventricular failure prevents blood from exiting the systemic vasculature (viscera, lower extremities, head), leading to hepatic congestion, lower extremity edema, and distended jugular veins. The precipitating events can be ischemic, infectious, or idiopathic. Although infiltrative (e.g., amyloidosis) processes

may cause systolic dysfunction, these usually lead primarily to diastolic dysfunction. Prognosis is worse when the etiology is ischemic rather than nonischemic in origin.

In patients without heart failure symptoms (stage A or stage B), reduction in risk factors (hypertension, diabetes, elevated cholesterol) is recommended. β-Blockers are suggested if history of myocardial infarction, and coronary revascularization if ACC/AHA Guidelines indicate. In patients with symptoms (stage C or stage D) from systolic dysfunction, aseries of randomized placebo-controlled studies have documented the beneficial effects of various medication classes on progression and mortality. β-Blockers, likely due (at least in part) to their inhibition of the adrenergic pathway, improve both clinical status and overall mortality. Angiotensin-converting enzyme (ACE) inhibitors, likely due to their effect on the renin–angiotensin–aldosterone system, show benefits similar to those of beta blockade. The effects of ACE inhibitors may be additive to those of β-blockers. There is growing evidence that angiotensin-receptor antagonists demonstrate benefits similar to those of ACE inhibitors, also likely through inhibition of the renin–angiotensin–aldosterone system. The effects of this class of medications may be additive to those of both β-blockers and ACE inhibitors. Although growing evidence as well as our current understanding of the pathophysiology of systolic dysfunction suggests that the role of angiotensin II receptor blockers will be similar to that of ACE inhibitors in the therapy of systolic dysfunction, they are currently not recommended as an alternative to ACE inhibitors except in those patients who cannot tolerate the latter. Similarly, although hydralazine with a nitrate may help to reduce the progression of abnormal myocardial/vascular growth, there is currently not enough evidence to recommend this combination as an alternative to ACE inhibitors except in those patients who cannot tolerate the latter. Digoxin has been shown to improve symptoms, but it does not alter mortality. Calcium channel blockers may actually worsen mortality in patient with compromised LV systolic function, if the history of cardiac arrest, ventricular fibrillation, or hemodynamically destabilizing tachycardia, an implantable cardioverter-defibrillator (ICD) is recommended to prolong survival. In those with ischemic heart disease, an ICD is also recommended if LV ejection fraction (LVEF) ≤30 percent in patient with at least 40 days post-myocardial infarction and life expectancy >1 year. If nonischemic heart disease, an ICD is recommended if NYHA functional class II or III symptoms on optimal medical therapy and life expectancy >1 year. In those with cardiac dyssynchrony (QRS >0.12 ms) and NYHA functional class III or IV with LVEF ≤35 percent, cardiac resynchronization is recommended if no contraindications exist.

## Diastolic Dysfunction

Diastolic dysfunction is the inability of the myocardium to stop generating force, to shorten, and/or to completely return to its unstressed force and length in the normal time period.[20,21] Though it can occur in combination with systolic dysfunction, diastolic dysfunction may be the sole cause of dysfunction in up to 50 percent of heart failure patients. As there is no consensus definition of what normal diastolic function is, the diagnosis of isolated diastolic dysfunction requires verification of the presence of heart failure, the absence of systolic dysfunction, and the exclusion of other processes (e.g., anemia, pulmonary dysfunction, hypothyroidism) that can masquerade as heart failure.

Isolated diastolic heart failure appears more frequently in older (vs younger), hypertensive (particularly isolated systolic hypertension), and female patients. It mimics systolic dysfunction in symptoms, hospitalizations, and mortality. The mechanism leading to its development is unclear, although increasing interest is being directed at the role of aldosterone. Aldosterone also acts via mineralocorticoid receptors to stimulate deposition of collagen and extracellular matrix. The RALES (Randomized ALdactone Evaluation Study) trial showed that the aldosterone inhibitor spironolactone, at doses devoid of blood pressure effects and having little or no effect on LV mass, prevents cardiac collagen accumulation in renovascular hypertension with high aldosterone levels. There are no randomized double-blind prospective studies demonstrating that a specific drug can reduce mortality or morbidity in patients with diastolic heart failure. The role of beta blockade has been debated. Although myocardial relaxation is more energy-dependent than is contraction, canine studies suggest that early diastolic relaxation is impaired by β-adrenergic inhibition. Furthermore, a lack of reduction of episodes of pulmonary edema following coronary revascularization in patients with isolated diastolic dysfunction suggests that ischemia does not play a predominant role. Still, the general long-term benefits of beta blockade combined with its ability to reverse LV hypertrophy make it difficult to exclude. The perindopril in elderly people with congestive heart failure (PEP-CHF) and candesartan in heart failure assessment of reduction in mortality and morbidity (CHARM)-preserved studies failed to demonstrate a reduction in death (all-cause death in PEP-CHF and cardiovascular death in CHARM-preserved) by using the ACE-inhibitor perindopril or the angiotensin receptor blocker candesartan, respectively. Still, these studies each suffer major weaknesses. In PEP-CHF, many patients withdrew and started taking open-label ACE inhibitors. In CHARM-preserved studies, many of the patients did not show echocardiographic signs of diastolic dysfunction. These study limitations, combined with the theoretical role of the renin–angiotensin–aldosterone pathway, suggest that ACE inhibitors, angiotensin II receptor blockers, and a reduction in aldosterone, have sustained hope that interrupting this axis may reduce morbidity in diastolic heart failure. The results of two large-scale, randomized studies (I-PRESERVE comparing irbesartan to placebo, and TOPCAT comparing spironolactone to placebo) are expected soon. There are not consistent data to suggest that calcium channel blockade, particularly using dihydropyridine calcium channel antagonists, are effective in reversing this process.

## Adaptive Changes in Chronic Congestive Heart Failure

Chronic heart failure results in myocardial adaptations teleologically consistent with optimizing distribution of wall stress as explained by Laplace's law. Thus, when pressure overload increases wall stress, the myocyte wall thickens through parallel hypertrophy to reduce the tension sensed by each myocyte back down to normal levels. By contrast, the myocyte's replication is predominantly serial, with only mild parallel replication when volume overload is the predominant stimulus.

The pathways leading to these changes seem to involve a number of mediators. There is reexpression of fetal proteins which, although increase myocyte mass, contract less effectively than their adult counterparts. There is an increase in collagen and fibrous tissue deposition, both interstitial and perivascular. This may decrease diastolic compliance and limit dilatory reserve of the coronaries. There is a paucity of mitochondrial and vascular growth relative to myocyte replication, decreasing the vascularity and energy available relative to the number of myocytes. Calcium handling deteriorates, due to a relative decrease both in the amount of SR and in the function of the calcium pumps on the SR. Finally, the composition of the myosin light chains in the ventricular sarcomeres changes. This decreases the effectiveness of the actin–myosin unit and possibly its sensitivity to calcium. As stated earlier, the cascades leading to this remodeling appear to involve the adrenergic system, the renin–angiotensin–aldosterone system, neurohumoral pathways, and dysfunction of the endothelial system. This understanding has led to our current therapy profile to prevent the progression of remodeling from beneficial to maladaptive. In addition, there is anecdotal evidence suggesting that mechanical unloading of decompensated hearts may lead to a regression of the maladaptive changes by a yet unclear mechanism.

## Cardiac Chamber Remodeling after Surgical Correction

### CORONARY ARTERY BYPASS GRAFTING

Revascularization is felt to improve regional and global ventricular function in addition to reducing infarct size.[22] Thus, complete revascularization of patients with recent heart failure, LVEF below 40 percent, and large areas of myocardium at risk (as evidenced by thallium imaging or nitrate-enhanced 99m-technetium sestamibi) increases LVEF and decreases LV end-systolic volume. This correlates with a significant trend toward improved 40-month survival. Though unproven, it is hypothesized that the salutary effect of revascularization on remodeling derives from reducing wall stress by recapturing maximal function in previously hibernating and stunned myocardium. Furthermore, vascular stenosis leads to thickening and perivascular fibrosis of arteries and small vessels distal to the stenosis. This may limit the vasodilatory reserve of these vessels, compounding the ischemia associated with vascular remodeling.

### AORTIC VALVE REPLACEMENT

***Aortic Stenosis.*** Aortic stenosis leads to systolic and/or diastolic LV dysfunction. Aortic valve replacement (AVR) is currently recommended for patients with symptomatic aortic stenosis and hemodynamic evidence that their aortic stenosis is severe (i.e., with an aortic valve area $<0.9$ cm$^2$). If asymptomatic, it is recommended for those patients who have a hypotensive response to exercise, evidence of progressive LV dysfunction, or who are undergoing another cardiovascular surgery.

Cardiac remodeling after AVR is quite dramatic when it is performed to relieve aortic stenosis.[23] Complete recovery of both systolic and diastolic function is possible. Recovery of systolic function usually precedes recovery of diastolic function. Recovery is more likely, and operative mortality is lower, if preoperative impairment is less severe (i.e., not NYHA class III or IV). Still, the poor prognosis with medical treatment alone often makes AVR the most advisable option in NYHA class III and IV aortic stenosis patients. The elevated LV mass characteristic of severe aortic stenosis is reduced 18 months following AVR and almost completely resolved by 5 years following AVR. Regression may be more rapid when stentless aortic valves are used. It is hypothesized that patients with aortic stenosis who have the deletion/deletion polymorphism for the ACE gene are more predisposed to left ventricular hypertrophy (LVH), and more likely to have LVH regress following AVR.

***Aortic Insufficiency.*** Surgical repair of aortic valvular insufficiency is indicated in symptomatic patients and in asymptomatic patients with evidence of progressive deterioration of LV function (LVEF <50 percent or LV end-diastolic diameter >5.5 cm).

Like AVR for stenotic disease, AVR for insufficiency results in a regression of the adaptive changes precipitated by the insufficiency.[24,25] Thus, myocardial hypertrophy is regresses toward normal at 1.6 years following surgery and is often normal by 8.1 years. Regression is delayed and less complete in patients with severe preoperative dysfunction (NYHA classification III or IV or LV ejection fraction below 25 percent).

### MITRAL VALVE REPLACEMENT AND REPAIR

***Mitral Stenosis.*** Mitral valve surgery for mitral stenosis involves either dilation (i.e., commissurotomy), repair (i.e., reconstruction), or replacement. The relative benefits of mitral commissurotomy versus replacement (MVR) vary among investigators.[26–28] Universally, however, commissurotomy is associated with a higher likelihood of traumatic insufficiency as well as higher reoperation rates (due to insufficiency and/or restenosis). In contrast, commis-

surotomy can often be performed with equal success using transvenous or open procedures, dramatically reducing early postprocedure morbidity and recovery time. This makes transvenous commissurotomy an attractive alternative for the older patient with limited life expectancy.

The benefit of MVR for mitral stenosis is inconsistent, possibly reflecting the varied pathology and progression of rheumatic mitral valve stenosis. In addition, the maintenance of an intact subvalvular apparatus (i.e., mitral ring, chordae, and papillary muscles) is both possible and important in MVR surgery. This apparatus can be responsible for 25 percent of LV contractile function.

***Mitral Insufficiency.*** Mitral valve surgery for insufficiency can involve either repair (e.g., reconstructive) or replacement. Options for repair include annuloplasty, resection of the prolapsing segment(s), and repair (i.e., shortening, elongating, reimplanting, replacing) of dysfunctional chordae tendineae or papillary muscle(s). Surgical repair is more likely to be successful when patients are younger (more pliable valves), the procedure requires chordal/papillary muscle shortening (rather than lengthening), and the etiology is endocarditis or ischemia (vs rheumatic heart disease).

The increasing interest in mitral valve repair rather than replacement surgery stems from dissatisfaction with the effects of replacement surgery upon LV function.[29] LV contractile function, as depicted by LVEF, is depressed following MVR for mitral insufficiency. This was initially felt to represent an unmasking, by the removal of the low pressure "pop-off" of regurgitant flow into the low-pressure left atrium, of preexisting LV dysfunction. It is more recently appreciated, however, that the subvalvular apparatus (i.e., annulus, chordae, and papillary muscle structure) helps prepare the LV for normal contraction and accounts for up to 25 percent of the LV systolic function. Conservation of an intact subvalvular apparatus is therefore a priority in mitral valve surgery.

Unlike remodeling following AVR for aortic stenosis, the LV typically does not improve its contractile function following MVR for mitral insufficiency. Although the majority of patients improve symptomatically, their left ventricular ejection fraction often deteriorates. Preoperative predictors of poor outcomes include NYHA classification III or IV, age above 60 years, end-systolic left ventricular diameter greater than 5.2 cm, and LVEF less than 50 percent. For patients below age 60 in NYHA classification I or II, with end-systolic left ventricular diameter less than 4.5 cm and LVEF greater than 60 percent, functional survival is excellent.

## CARDIOVASCULAR FUNCTION AND PHYSIOLOGY BOARD REVIEW QUESTIONS (CHAPTER 23)

1. Which of the following is correct regarding hibernating myocardium?
   A. Does not contract despite adequate energy supply
   B. Decreases force of contraction as a response to inadequate energy supply
   C. Continues to contract poorly after return of adequate energy supply
   D. Actively stores energy because immediate demands are low
   E. Has discontinued all metabolic activity due to complete absence of energy supply

2. Which is true regarding function of the endothelium?
   A. Stores protein C and presents tissue factor to circulating blood
   B. Prevents exposure to thrombomodulin
   C. Limits initiation of clots by covering tissue factor
   D. Blocks release of nitric oxide from underlying smooth muscle cells
   E. Provides fertile surface for initiation of thrombus

3. Which of the following influences speed of myocardial contraction?
   A. Resting length of the myocyte
   B. Sudden stretch of the myocyte
   C. Rapid repeated contraction of the myocyte
   D. All of the above
   E. None of the above

4. Which is correct regarding cardiac remodeling after surgery?
   A. Aortic stenosis: begins with systolic recovery and is complete by 18 months.
   B. Ischemic heart disease: demonstrates an increase in LVEF and a decrease in left ventricular end-diastolic volume (LVEDV) with complete revascularization.
   C. Aortic insufficiency: rapid recovery complete by 6 months.
   D. Mitral stenosis: recovery easily predicted by preoperative TEE.
   E. Mitral insufficiency: sustainable recovery is unlikely in young patients.

5. Which is true for myocardial function?
   A. The primary energy source for the myocardium is glucose.
   B. Diastole is more energy dependent than systole.
   C. LV hypertrophy compromises endothelial perfusion on the sole basis of increasing distance of capillary blood flow.
   D. Increased wall thickness increases wall stress.
   E. The uniform distribution of ion channels throughout the heart stabilizes electrical activity.

## ANSWERS

1. **Answer: B.** Hibernating myocardium decreases force of contraction when there is inadequate energy supply. It will contract normally when there is adequate energy supply but does not actively store energy. The energy supply is enough to provide basic metabolic needs.
2. **Answer: C.** Endothelium limits the initiation of clots by covering tissue factor, which prevents activation of circulating factor VII. This layer contains thrombomodulin, which also limits clots, and produces nitric oxide. The endothelium is therefore not a fertile surface for thrombus.
3. **Answer: E.** Speed of myocardial shortening is determined by afterload. Strength of contraction, however, is influenced by all of the above factors.
4. **Answer: B.** After revascularization, myocardial recovery is seen as an increase in LVEF and a decrease in LVEDV. Recovery after AVR for aortic stenosis may not be complete for up to 5 years. Remodeling after AVR for aortic insufficiency may be even further delayed for up to 8 years. Operations for mitral stenosis are varied and prediction of recovery after surgery is inconsistent. Mitral valve repair is most likely to be successful and durable in young patients.
5. **Answer: B.** Diastole is more energy-dependent, and ischemia may therefore present as diastolic dysfunction before systolic dysfunction occurs. The primary energy source for the myocardium is fatty acids. There are at least three mechanisms that compromise LV myocardial perfusion, including distance of blood flow across the thickened wall, elevated LVEDP, and compression of myocardial vessels. Increased wall thickness decreases wall stress. Ion channels are not uniformly distributed throughout the heart.

# 24 Cardiopulmonary Bypass

*Edward H. Kincaid*
*John W. Hammon*

Cardiopulmonary bypass (CPB) has developed into an invaluable tool for operations on the thoracic viscera. By interfacing with the cardiovascular system, total CPB completely replaces the function of the heart and lungs for a short time. Modifications of CPB have been designed to partially replace or control more specific aspects of the cardiopulmonary systems. To fully utilize the tremendous flexibility available with "the pump," one must understand its components, operation, and potential for complications.

## HISTORY

The development of CPB is a testament to personal perseverance and collaboration and demonstrates how cardiac surgery has truly evolved as a science. Initial progress in the field of extracorporeal circulation required mastery of the principles of total-body oxygen delivery and consumption. Later, further refinements in the understanding of metabolic demands at the cellular level served to enhance the safety and flexibility of circulatory support. Undoubtedly the most important milestone in the development of CPB is John Gibbon's use of the first clinical application of CPB. In 1953, after devoting most of his career to this work, he successfully repaired an atrial septal defect in a young woman with a pump-oxygenator. Additional milestones include the work of Bigelow, who, in the early 1950s, reported on systemic hypothermia with topical cooling as a means to reduce oxygen demand during the periods of reduced oxygen delivery inevitably encountered during operations on the heart. Shortly thereafter, Lillehei began performing congenital repairs using "cross circulation," employing a parent's cardiopulmonary system to support a child's during cardiac surgery. Finally, in the mid-1950s, Kirklin and colleagues at the Mayo Clinic ushered in the era of routine congenital repairs using the Mayo–Gibbon pump-oxygenator. Modern refinements in equipment and techniques have subsequently evolved as a consequence of the proliferation of coronary revascularization surgery and increased industrial interest.

## COMPONENTS OF THE CPB CIRCUIT

Current-generation CPB circuits maintain much of the simplicity of older perfusion equipment but have much more flexibility and ability to more precisely control various perfusion parameters. Core components of any circuit include cannulas, tubing, a pump, and an oxygenator (Fig. 24-1). In reality, however, even basic circuits used in routine clinical practice include many other features such as additional pump heads for suction, venting of the heart, and delivery of cardioplegia. Venous reservoirs are also needed to maintain adequate circuit volume and remove air. Filters are required at various levels to prevent embolic complications. Finally, a heat exchanger facilitates systemic and myocardial cooling and rewarming.

## CANNULAS

### Arterial Cannulation

Cannulation for CBP is typically performed centrally with an inflow cannula in the ascending aorta and outflow cannula(s) in the right atrium. Basic requirements for an arterial cannula include a size large enough to permit adequate flows without creating excessive back pressure at the pump head. At the same time, the size and design of the cannula must allow for easy placement with minimal vessel trauma. Beyond these basic requirements, a multitude of other aspects of cannula design may arguably affect performance. Such features include tip angle, size and number of end or side holes, wire reinforcement, and filters. Most arterial catheters are rated by a performance index, which relates external diameter, flow, and pressure differential. High-velocity jets may damage the aortic wall, dislodge atheroemboli, produce dissections, disturb flow to nearby vessels, and cause cavitation and hemolysis. Aortic catheters with only side ports are designed to minimize jet effects and better distribute arch vessel perfusion and pressure; they may be associated with fewer strokes.[1]

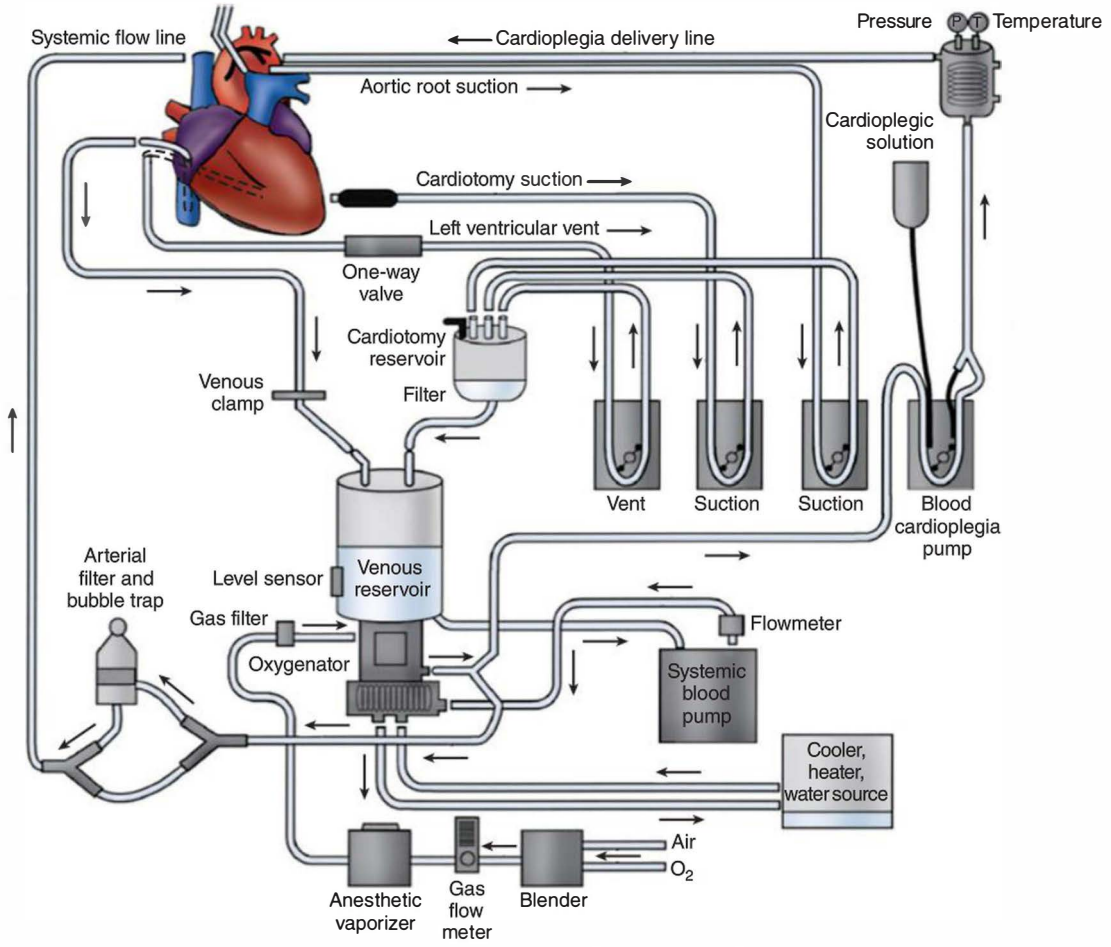

**FIGURE 24-1** Schematic of typical CPB circuit. (Reprinted with permission from Cohn LH, Edmunds LD Jr (eds). *Cardiac Surgery in the Adult*, 2nd ed. New York: McGraw-Hill, 2003.)

## AORTIC CANNULATION

Various locations on the ascending aorta and aortic arch are most often used as sites for insertion of the arterial cannula because of the simplicity and maintenance of antegrade blood flow. In patients with no significant ascending aortic atherosclerosis, this location is also associated with the least risk of inflow-related complications in routine cardiac cases. However, multiple other locations can be good alternatives, including the common femoral, axillary, and innominate arteries; descending thoracic aorta; and rarely the left ventricular (LV) apex. The choice is influenced by the planned operation and the distribution of atherosclerotic disease.

To cannulate the ascending aorta, most surgeons place two purse-string sutures with or without pledgets partially through the aortic wall to encompass a diameter of approximately 1 to 1.5 cm. Next, with a systolic blood pressure preferably less than 100 mm Hg, a 4- to 5-mm full-thickness stab wound is made, occasionally dilated, and then controlled under finger or forceps pressure. The cannula is then inserted under the finger or forceps approximately 1 to 2 cm into the lumen of the aorta. Backbleeding is detected to ensure that the tip is completely within the lumen and positioned to direct flow to the midtransverse aorta. A long catheter with the tip placed beyond the left subclavian artery may also be used. Proper cannula placement is critical and is confirmed by noting pulsatile pressure in the aortic line monitor and equivalent pressure in the radial artery.

Complications of ascending aortic cannulation include bleeding from tears in the aortic wall, malposition of the cannula tip, atheromatous or air emboli, and aortic dissection. It is essential to monitor aortic line and radial artery pressures and to carefully observe the aorta for possible cannula-related complications during the onset of CPB and placement of aortic clamps. Asymmetrical cooling of the face or neck may suggest a problem with cerebral perfusion. Late bleeding and infected or uninfected false aneurysms are delayed complications of aortic cannulation.

### FEMORAL ARTERY CANNULATION

The common femoral artery is probably the second most common location for CPB inflow. Reasons for cannulating the femoral artery include inadequacy or inavailability of the ascending aorta in cases such as aortic dissection, reoperation, descending aortic surgery, and minimally invasive cardiac procedures. Severe atherosclerosis of the ascending aorta is generally not a good indication for femoral cannulation because of the likely coexistence of severe disease in distal segments of the aorta and iliac arteries. Alternative strategies for CPB in this scenario are discussed later in this chapter.

Exposure of the femoral artery is through a small oblique incision just below the inguinal ligament. Only the anterior surface of the vessel needs to be exposed. After placement of a 5-0 monofilament purse-string suture, the common femoral artery is punctured and a guidewire is passed to the aorta. Transesophageal echocardiography (TEE) guidance can be used to confirm the location of the wire. A long, thin-walled cannula is then passed over the wire into the distal aorta. Most adult men can be perfused adequately with a 21F cannula; in women, a 19F cannula usually suffices.

Disadvantages of femoral cannulation include local complications such as vessel injury or groin wound complications and perfusion-related problems. These include abdominal aortic dissection or perforation, embolic phenomena from retrograde flow through a diseased abdominal aorta, and malperfusion of aortic branches in acute aortic dissection. In addition, ischemic complications of the distal leg may occur during prolonged retrograde perfusions; these may result in the release of myoglobin and subsequent renal injury. Finally, some speculate that retrograde flow to the cerebral and coronary arteries may result in lower perfusion pressures or oxygen saturation of blood at the end of the perfusion stream.

### OTHER SITES OF ARTERIAL CANNULATION

The axillary subclavian artery is increasingly used for cannulation.[2,3] Advantages include freedom from atherosclerosis, antegrade flow into the arch vessels, and protection of the arm and hand by collateral flow. Due to these advantages and the dangers of retrograde perfusion in patients with aortic dissection, some surgeons prefer this cannulation site for this and other conditions involving the aortic arch. The right axillary artery is usually used and is approached through a subclavicular incision, taking care not to damage the adjacent brachial plexus. In order to prevent injury to the fragile axillary or subclavian artery, some prefer to anastamose a small-caliber graft end to side to the axillary artery followed by insertion of the cannula into the graft.

## Venous Cannulation

In most applications, venous blood enters the circuit through negative pressure generated by siphonage. Thus, venous return flow rates are determined largely by the height differential between the right atrium and venous reservoir. Venous return can be impeded by resistance in cannulas, tubing, and connectors and may cease completely with entrainment of significant amounts of air into the venous line, creating an "air lock." This situation can be managed by correcting the source of air entrainment (e.g., tightening a loose purse-string suture) and then elevating the venous tubing such that the air rises in the direction of the venous reservoir. Continued arterial inflow from the pump creates positive central venous pressure, which will eventually drive the air into the reservoir, where it evacuates. Venous cannulas are usually made of flexible plastic, which may be stiffened against kinking by wire reinforcement. The size required is determined by the patient's size, the anticipated flow rate, and cannula flow characteristics, such as resistance. Catheters are typically inserted through purse-string–guarded incisions in the right atrial appendage, lateral atrial wall, or directly in the superior vena cava (SVC) and inferior vena cava (IVC).

Two basic approaches for central venous cannulation are used. For coronary artery or aortic valve operations, single venous cannulation of the right atrium alone suffices. In adults, this is usually performed with a 40F to 46F "two-stage" device that has a set of drainage holes in the distal portion and a second set located more proximally (Fig. 24-2). The distal end is positioned in the IVC while the proximal side holes drain the right atrium. This cannula may provide for better drainage than a single-stage cannula, especially when positioning of the heart may kink the venae cavae. Bicaval cannulation is used primarily for isolating the right atrium when surgery dictates opening this chamber. Caval tourniquets are also necessary in this situation to prevent bleeding and air entry into the system. Because of coronary sinus return, caval tourniquets should not be tightened without decompressing the right atrium. Bicaval cannulation is often preferred to facilitate venous return during exposure of the left atrium and mitral valve, mainly because of the potential

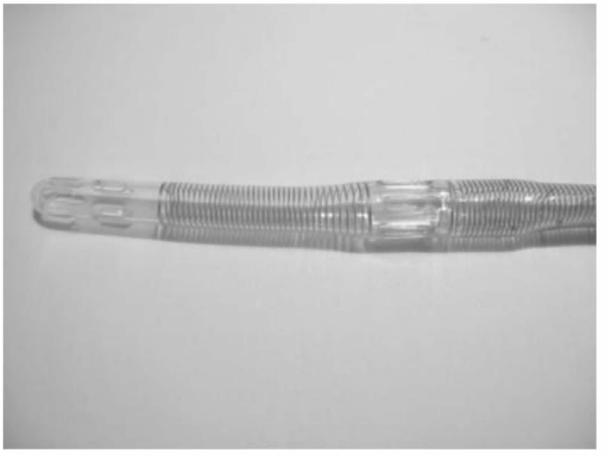

**FIGURE 24-2** Two-stage venous cannula with separate drainage holes for the inferior vena cava and right atrium.

for obstruction of the SVC or IVC during exposure. Using both techniques, the operative team should carefully monitor central venous pressure to prevent obstruction of the SVC.

Placement of a single venous cannula is most easily accomplished through the right atrial appendage. After application of a vascular clamp, the right atrial appendage is excised, or it may be opened longitudinally when the appendage is small. A purse-string suture is then placed just below the free edges, which are controlled with forceps. After release of the clamp, the cannula is inserted toward the IVC. The height of blood within the unclamped cannula is a good measure of central venous pressure. During bicaval cannulation, the IVC cannula is generally placed on the lateral wall of the right atrium near the junction with the IVC. During placement of the purse-string suture, the right atrium is gently retracted with the assistant's hand or forceps while monitoring hemodynamics. A stab incision is made in the middle of the purse-string, the defect is dilated with a curved clamp, and the cannula, either straight or right-angled, is then directed into the IVC. The cannula should not be inserted with the proximal side holes located too distally within the IVC, as this may impede hepatic venous drainage. SVC cannulation is typically accomplished with either a straight cannula placed through the lateral wall of the atrium, as in IVC cannulation, or with a right-angled cannula placed directly into the SVC. In this procedure, the anterior surface of the SVC is exposed by dividing the pericardial reflection overlying its superior border. An oval-monofilament purse-string suture oriented longitudinally is placed, and an incision is made along the length of the purse-string suture while controlling the free edges with forceps. The tip of the cannula is then directed superiorly, taking care to avoid tip placement in the azygos vein.

Access to the central venous system for blood return can also be obtained through the common femoral or internal jugular veins. Remote cannulation for CPB is particularly beneficial for reoperative cardiac procedures, minimally invasive "on-pump" cardiac procedures such as mitral valve repair via right thoracotomy/thoracoscopy, and aortic surgery through a left thoracotomy. Depending on the size of the cannula, either open or percutaneous methods can be used. Most surgeons would recommend a maximum size of 21F to 22F for percutaneous venous access without the need for direct vessel repair after decannulation. Typically, a long, wire-reinforced cannula with an ultrathin wall is advanced over a guidewire through the femoral vein to the right atrium under transesophageal TEE guidance. For bicaval drainage, some femoral venous cannulas are designed to be advanced into the SVC; multiple levels of side holes subsequently drain both venae cavae individually. An alternative strategy for bicaval drainage employs two individual venous cannulas, one in the femoral vein to drain the IVC and one in the right internal jugular vein to drain the SVC.

As an adjunct to remote cannulation for venous drainage, most surgeons employ some means of active assist over the standard gravity or siphonage power for blood return. "Assisted venous return" can be achieved by applying a regulated vacuum to a closed hard-shell venous reservoir or by kinetically assisting return via a centrifugal pump placed in the venous return line. Assisted venous return is also useful in cases using standard central cannulation sites but where the use of smaller cannulas may be beneficial, such as a MAZE procedure or operation through a ministernotormy. The most significant disadvantage of assisted venous drainage is an increased risk of air entrainment and subsequent microembolization to the arterial circulation.[4,5]

## TUBING AND CONNECTORS

The various components of the heart–lung machine are connected by polyvinyl tubing and fluted polycarbonate connectors. Medical-grade polyvinyl chloride tubing is universally used because it is flexible, compatible with blood, inert, smooth, transparent, resistant to kinking and collapse, and can be heat-sterilized. In adults, 1/2-in. tubing is generally used for inflow and 5/8-in. tubing for outflow. Wider tubing improves flow dynamics but also increases priming volume. Tubing lengths between patient and pump should also be minimized so as to reduce priming volume.

One controversy that continues over tubing is the use of herparin bonding to the interior surfaces, a technique that has many theoretical advantages associated with a reduced blood–plastic interface. The use of heparin-coated circuits during CPB has some proven advantages,[6–8] such as reduced activation of complement pathways. However, there is only weak evidence that heparin-coated perfusion circuits reduce the need for systemic heparin or reduce bleeding or thrombotic problems associated with CPB, and the overall inflammatory response to CPB is not reduced.

## PUMPS

Two types of pumps can be used, and each has its own set of advantages and disadvantages. Centrifugal pumps consist of a vaned impeller or of nested, smooth plastic cones, which, when rotated rapidly, propel blood by centrifugal force. An arterial flowmeter is required to determine forward blood flow, which varies with the speed of rotation and the afterload of the arterial line. Centrifugal pumps produce pulseless flow and generate less negative pressure; therefore, they may produce less cavitation and fewer gaseous microemboli. They can pump small amounts of air but become "deprimed" if more than 30 to 50 mL of air enters the blood chamber. Centrifugal pumps are probably superior to temporary extracorporeal assist devices and left-heart bypass, for assisting venous return. They are often used as the arterial inflow pump on the CPB circuit.

Roller pumps consist of two rollers situated 180 degrees apart inside a curved raceway. Forward flow is generated by roller compression of tubing, which can be sized from 1/4 to 5/8 in. ID depending on flow requirements. Flow rate depends on the diameter of the tubing, rate of rotation, length

of the compression raceway, and completeness of compression, which is adjusted to be barely nonocclusive against a standing column of fluid that produces 45 to 75 mm Hg of back pressure. At this degree of compression, hemolysis and tubing wear are minimal. Flow rate is determined from calibration curves for each pump for different tubing sizes and rates of rotation. Roller pumps are inexpensive, reliable, and safe; they are insensitive to afterload, have small priming volumes, but can produce high negative pressures and may shed microparticles from compressed tubing. Roller pumps are used almost exclusively for vents, sucker systems, and the delivery of cardioplegia.

One advantage roller pumps have is the ability to produce pulsatile blood flow. Normally, standard roller pumps produce a sine-wave pulse of around 5 mm Hg, but they can be set to generate pulse pressures above 20 mm Hg as detected on peripheral arterial pressure monitors. Theoretically, pulsatile perfusion delivers more energy to cells and may result in improvements in peripheral resistance, renin release, and cellular hypoxia. However, studies on the clinical benefits of pulsatile perfusion are inconclusive. Complications that may occur during operation of either type of pump include loss of electricity; loss of the ability to control pump speed, producing "runaway pump" or "pump creep" when turned off; loss of the flowmeter or revolutions per minute (RPM) indicator; rupture of tubing in the roller pump raceway; and reversal of flow by improper tubing in the raceway. A means to provide pumping manually in case of electrical failure should always be available.

## VENOUS RESERVOIR

The venous reservoir serves as a receiving chamber for venous return; facilitates gravity drainage; is a venous bubble trap; provides a convenient place to add drugs, fluids, or blood; and adds storage capacity for the perfusion system. During full CPB, as much as 1 to 3 L of blood may be stored in the reservoir, depending somewhat on the patient's preoperative volume status. Reservoirs may be rigid (hard) plastic canisters ("open" types) or soft, collapsible plastic bags ("closed" types). The rigid canisters facilitate volume measurements and the management of venous air, often have larger capacity, are easier to prime, permit suction for vacuum-assisted venous drainage, and may be less expensive. Soft bag reservoirs minimize the blood–gas interface and reduce the risk of pumping massive air emboli. A closed system is preferred to avoid the large amount of air–blood contact in open systems.

## OXYGENATORS

Membrane oxygenators are most commonly used and imitate the natural lung by interspersing a thin membrane of either microporous polypropylene (0.3- to 0.8-μm pores) or silicone rubber between the gas and the blood phases. Compared with bubble oxygenators, membrane oxygenators are safer, produce less particulate and gaseous microemboli, are less reactive to blood elements, and allow superior control of blood gases. The plasma-filled pores prevent gas from entering blood but facilitate transfer of both oxygen and $CO_2$. The most popular design uses sheaves of hollow fibers (120–200 μm) connected to inlet and outlet manifolds within a hard-shell jacket. Arterial $P_{CO_2}$ is controlled by gas flow, and $P_{O_2}$ is controlled by the fraction of inspired oxygen ($FIO_2$) produced by an air-oxygen blender, which also adds in variable amounts of volatile anesthetics. Modern membrane oxygenators add up to 470 mL of $O_2$ and remove up to 350 mL of $CO_2$ at 1 to 7 L of flow with priming volumes of 220 to 560 mL. Most units combine a venous reservoir, heat exchanger, and hollow-fiber membrane oxygenator into one compact unit.

Bubble oxygenators are obsolete in most Western countries but are used elsewhere for short-term CPB because of their low cost and good efficiency. Because each bubble presents a new foreign surface to which blood elements react, bubble oxygenators cause progressive injury to blood elements and entrain more gaseous microemboli. In bubble oxygenators, venous blood drains directly into a chamber into which oxygen is infused through a diffusion plate that produces thousands of small oxygen bubbles within the blood. Gas exchange occurs across a thin film at the blood–gas interface around each bubble. Bubbles and blood are separated by settling, filtration, and defoaming surfactants in a reservoir. Commercial bubble oxygenators incorporate a reservoir and heat exchanger within the same unit and are placed upstream to the arterial pump.

## HEAT EXCHANGERS

Heat exchangers control body temperature by heating or cooling the blood passing through the perfusion circuit. Frequently, hypothermia is used during cardiac surgery to reduce oxygen demand or facilitate operative exposure by temporary circulatory arrest. Gases are more soluble in cold than in warm blood; therefore, rapid rewarming of cold blood in the circuit or body may cause the formation of bubble emboli. Most membrane oxygenator units incorporate a heat exchanger upstream of the oxygenator so as to minimize bubble emboli. Blood is not heated above 40°C to prevent denaturation of plasma proteins, and temperature differences within the body and perfusion circuit are limited to 5°C to 10°C to prevent bubble emboli. The heat exchanger may be supplied by hot and cold tap water, but separate heater/cooler units with convenient temperature-regulating controls are preferred.

## FILTERS

Filters are universally used within CPB circuits to prevent both macro- and microemboli, which, in both gaseous and particulate form, likely produce much of the morbidity

associated with cardiac operations using CPB. As compared with no filter, studies indicate that all commercially available filters effectively remove gaseous and particulate emboli. Most investigations find that the Dacron wool depth filter is most effective, particularly in removing micro- and macroscopic air. Pressure differences across filters vary between 24 and 36 mm Hg at a flow of 5 L/min. Filters cause slight hemolysis and tend to trap some platelets.

Because of significant debris present within cardiotomy suction blood, the need for microfilters in the cardiotomy suction reservoir is universally accepted, and most commercial units contain an intergrated micropore filter. Most circuits also contain an arterial line filter of some type, although efficacy in this location remains unsettled. These filters are usually also of the Dacron wool type and must be used with a bypass line during priming to purge trapped air. Leukocyte-depleting arterial filters have not been proven effective at limiting the inflammatory response or other complications.

## CARDIOTOMY RESERVOIR AND FIELD SUCTION

Blood aspirated from the surgical wound may be directed to the cardiotomy reservoir for defoaming, filtration, and storage before it is added directly to the perfusate. A sponge impregnated with a surfactant removes bubbles by reducing surface tension at the blood interface, and macro-, micro-, or combined filters remove particulate emboli. Negative pressure is generated by either a roller pump or vacuum applied to the rigid outer shell of the reservoir. The degree of negative pressure and blood level must be monitored to avoid excessive suction or introducing air into the perfusate.

The cardiotomy suction and reservoir are major sources of hemolysis, particulate and gaseous microemboli, fat globules, cellular aggregates, platelet injury and loss, cytokine-generated thrombin formation, and fibrinolysis. Air aspirated with wound blood contributes to blood activation and destruction and is difficult to remove because of the high proportion of nitrogen, which is poorly soluble in blood. High suction volumes and the admixture of air are particularly destructive of platelets and red cells. Commercial reservoirs are designed to minimize air entrainment and excessive injury to blood elements. The removal of air and microemboli is also facilitated by allowing aspirated blood to settle within the reservoir before it is added to the perfusate.

An alternative method for recovering field-aspirated blood is to dilute the blood with saline and then remove the saline to return only packed red cells to the perfusate. Centrifugal cell washers automate this process and remove air, thrombin, and nearly all biologic and nonbiologic microemboli from the aspirate at the cost of discarding plasma. A third alternative is to discard all field-aspirated blood. Increasingly, field-aspirated blood is recognized as a major contributor to the thrombotic, bleeding, and inflammatory complications of CPB.

## VENTS AND DECOMPRESSION OF THE HEART

During CPB, blood escaping atrial or venous cannulas and from the coronary sinus and Thebesian veins may pass through the unopened right heart into the pulmonary circulation. This blood plus bronchial venous blood, blood regurgitating through the aortic valve, and blood from undiagnosed abnormal sources (patent foramen ovale, patent ductus, etc.) may distend the left ventricle. Venting of the heart during CPB aids in myocardial protection by preventing ventricular distention and keeping warm blood out of the heart during hypothermic cardioplegic arrest. Ventricular overdistention can be a particularly serious problem in the presence of severe aortic valvular insufficiency.

There are several methods for venting the left heart during cardiac arrest. The most common techniques include placement of a multihole catheter from the right superior pulmonary vein across the mitral valve; use of an aortic root vent, often in combination with an antegrade cardioplegia catheter; placement of a suction catheter in the main pulmonary artery, which decompresses the left atrium across the pulmonary capillary bed; and, less commonly, placement of a suction catheter directly into LV apex. Vent catheters are drained to the cardiotomy reservoir, usually by a dedicated roller pump. The most common complication of left heart venting is residual air when the heart is filled and begins to contract. De-airing maneuvers (Table 24-1)—such as manual displacement, Valsalva breaths, and TEE detection of residual pockets—are important methods for ensuring its removal.

## CARDIOPLEGIA DELIVERY SYSTEMS

Cardioplegic solutions are delivered through a separate perfusion system, which includes a reservoir, heat exchanger, roller pump, bubble trap, and perhaps microfilter. The system may be completely independent of the main perfusion circuit, or it may branch from the arterial line. The system may also be configured to vent the aortic root between infusions.

**TABLE 24-1: Strategies for Management of Intracardiac Air**

| |
|---|
| Preventive measures |
| Limited use of vents |
| Vents off or on low suction while aorta or heart chamber is open |
| Instillation of $CO_2$ into the operative field |
| De-airing maneuvers |
| Aortic venting during and after cross-clamp release |
| Needle aspiration of left ventricular apex |
| Valsalva breaths |
| Rotation of operating table |
| Manual dislodgment, e.g., inversion of left a trial appendage |
| Maintenance of partial cardiopulmonary bypass with left ventricular ejection |

## HEMOCONCENTRATORS

Hemoconcentrators, like oxygenators, contain one of the several available semipermeable membranes (typically hollow fibers) that transfer water, electrolytes (e.g., potassium), and molecules up to 20 kDa out of the blood compartment. Hemoconcentrators may be connected to either venous or arterial lines or a reservoir in the main perfusion circuit, but they require high pressure in the blood compartment to effect fluid removal. Thus, a roller pump is needed unless the unit is connected to the arterial line. Suction may or may not be applied to the air side of the membrane to facilitate filtration. At flows from 500 mL/min, up to 180 mL/min of fluid can be removed. Hemoconcentrators conserve platelets and most plasma proteins as compared with centrifugal cell washers and may allow greater control of potassium concentrations than is possible with the use of diuretics. Aside from cost, disadvantages are few and adverse effects rare.

## CONDUCT OF CARDIOPULMONARY BYPASS

The performance of CPB requires constant interaction between the surgeon, the perfusionist, and the anesthesiologist, especially during periods of transition to and from artificial perfusion. Although frequent dialogue is important, often a member of the team, usually the surgeon, may be focused on other aspects of the operation and unavailable to discuss nonemergent aspects of perfusion in a particular case. For this reason, written protocols and procedures developed in a multidisciplinary fashion are important for ensuring the safe conduct of CPB.

## ASSEMBLY OF THE CPB CIRCUIT

The perfusionist is responsible for setting up and preparing the heart–lung machine and all components necessary for the proposed operation. Most perfusionists use commercial, sterile, preprepared, and customized tubing packs, which are connected to the various components that constitute the heart–lung machine. This dry assembly takes about 10 to 15 min; the unit can then be kept in standby for up to 7 days. Once the system is primed with fluid, which takes about 15 min, it should be used within 8 h. After assembly, the perfusionist conducts a safety inspection and completes a written prebypass checklist.

## PRIMING

Adult extracorporeal perfusion circuits require 1.5 to 2.0 L of balanced electrolyte solution (lactated Ringer's solution, Normosol-A, or Plasma-Lyte). Before connections are made to the patient, the prime is recirculated through a micropore filter to remove particulates and air emboli. The priming volume represents approximately 30 to 35 percent of the patient's blood volume and reduces the hematocrit to about two-thirds of the preoperative value. Hemodilution is an important cause of intraoperative and postoperative anemia. Priming requirements can be reduced by using smaller-diameter and shorter tubing lengths and operating the machine with minimal perfusate in the venous and cardiotomy reservoirs. Autologous blood prime, usually with retrograde venous blood into the pump, is another method to reduce crystalloid priming volume, but this risks hypovolemic sequelae prior to the initiation of CPB. Improvements in clinical outcomes have not been definitively proven with these techniques.

The use of colloids (albumin, gelatins, dextrans, and hetastarches) in the priming volume is controversial. Colloids reduce the fall in colloid osmotic pressure and may reduce the amount of fluid entering the extracellular space. However, prospective clinical studies have failed to document significant clinical benefits with albumin, which is expensive and may have adverse effects.[9,10] Hetastarch may contribute to postoperative bleeding.

## ANTICOAGULATION AND REVERSAL

Porcine heparin (300–400 U/kg IV) is given before arterial or venous cannulas are inserted, and CPB is not started until anticoagulation is confirmed by activated clotting time (ACT). Most would agree that the minimum ACT to begin CPB is 400 s, but many groups prefer a goal of 480 s because heparin only partially inhibits thrombin formation during CPB. Inadequate anticoagulation risks thrombosis of the circuit at the extreme end of the spectrum, but it may also result in less dramatic consumption of clotting factors and postoperative coagulopathy. Excessively high concentrations of heparin (ACT >1000 s) may cause remote bleeding away from operative sites.

Failure to achieve a satisfactory ACT may be due to inadequate heparin or to low concentrations of circulating antithrombin. If a total of 500 U/kg of heparin fails to prolong ACT adequately, fresh frozen plasma or recombinant antithrombin is needed to increase antithrombin concentrations and overcome "heparin resistance," a phenomenon more commonly seen in patients on preoperative intravenous heparin therapy.

Antifibrinolytic agents such as aminocaproic acid or tranexamic acid are routinely used during CPB and have been shown to improve postoperative chest tube drainage but not clinical outcome. Another pharmacologic strategy to reduce bleeding complications is the use of aprotinin, a serine-protease inhibitor with general anti-inflammatory properties. Extensive literature exists on the beneficial effects of aprotinin on a variety of clinical outcome measures, especially with reoperative cardiac surgery.[11] The most important of these benefits may be a reduction in the risk of stroke, noted in a large retrospective analysis.[12] Drawbacks to aprotinin include significant cost and possibly an adverse effect

on renal function in the presence of angiotensin converting enzyme inhibitors.[13] In 2008, the results of the blood conservation using antifibrinolytics in a randomized trial (BART) trial, a randomized-prospective study on the use of aprotinin in cardiac surgery, was published and demonstrated excess rates of renal failure and mortality with aprotinin.[14] Since then, this drug has minimal availability and usage. During CPB, the ACT is measured every 30 min. If the ACT goes below the target level, more heparin is given. Usually, one-third of the initial heparin bolus is given every hour even when the ACT is within the normal range. Hepcon tests, which measure heparin concentration, may also be used; although, their results are more reproducible than ACT, ACT is less time-consuming and provides satisfactory monitoring of anticoagulation.

One milligram of protamine (not to exceed 3 mg/kg) is given for each 100 U of heparin injected in the initial bolus dose. The heparin–protamine complex activates complement and often causes acute hypotension, which may be attenuated by adding calcium (2 mg/1 mg protamine). After one-third of the planned protamine dose has been administered, blood must not be returned to the cardiotomy reservoir from the surgical field. Rarely, protamine may cause an anaphylactic reaction in patients with antibodies to protamine insulin. Neutralization of heparin is usually confirmed by an ACT or Hepcon test, and more protamine (50 mg) is given if either of the tests remains prolonged and bleeding is a problem. "Heparin rebound" is the term used to describe a delayed heparin effect due to the release of tissue heparin after protamine is cleared from the circulation. Although protamine is a mild anticoagulant, one or two supplemental 25- to 50-mg doses can be given empirically if heparin rebound is suspected. In most instances, the heart–lung machine should be available for immediate use until the patient leaves the operating room.

## STARTING CPB

CPB is started at the surgeon's request with concurrence of the anesthesiologist and perfusionist. As venous return enters the machine, the perfusionist progressively increases arterial flow while monitoring the patient's blood pressure and volume levels in all reservoirs. Important observations include adequacy of venous drainage, acceptable flow rates, acceptable arterial line pressure, oxygenation of arterial blood, appropriate systemic arterial pressure, and adequate decompression of the heart. Once full stable CPB is established, lung ventilation is discontinued, systemic cooling may begin, and the aorta may be clamped for arresting the heart.

## CARDIOPLEGIA

After aortic cross-clamping, cardiac arrest is usually achieved with antegrade blood or crystalloid cardioplegia administered directly into the aortic root by a dedicated cardioplegia roller pump. The heart usually arrests within 30 to 60 s. A delay may indicate problems with delivery of the solution, incomplete aortic occlusion, or unrecognized aortic regurgitation. Retrograde cardioplegia is often given after an antegrade dose to facilitate cardioplegia delivery distal to atherosclerotic stenoses of the coronary arteries. In contrast to antegrade cardioplegia, epicardial and intracardiac procedures are not much hindered by delivery of retrograde cardioplegia. The usual flow of retrograde cardioplegia is 200 to 400 mL/min at coronary sinus pressures between 30 and 50 mm Hg. Induction of electrical arrest is slower (2–4 min) than with antegrade, and retrograde cardioplegia may provide incomplete protection of the right ventricle.

## DETERMINANTS OF SAFE PERFUSION

### Blood Flow Rate

The generally accepted flow rate at 35°C to 37°C and hematocrit of 25 percent is approximately 2.4 L/min/$m^2$ in deeply anesthetized and muscle-relaxed patients. Hemodilution reduces blood oxygen content and dictates that flow rate must increase over resting normal cardiac output or oxygen demand must decrease. As long as mean arterial pressure remains above 50 to 60 mm Hg (i.e., above the autoregulatory range), cerebral blood flow is preserved even if systemic flow is less than normal. However, as total systemic flow is progressively reduced, there is a hierarchal reduction of flow to other organs. First skeletal muscle flow falls, then flow to the abdominal viscera and bowel, and finally flow to the kidneys.

### Arterial Pressure

Systemic arterial blood pressure is a function of flow rate, blood viscosity (hematocrit), and vascular tone. Perfusion of the brain is normally protected by autoregulation, which appears to be lost somewhere between 55 and 60 mm Hg during CPB at moderate hypothermia and 24 percent hematocrit. This pressure is thus generally regarded to be the lowest safe pressure for routine CBP. In older patients, who may have vascular disease and/or hypertension, mean arterial blood pressure is generally maintained between 70 and 80 mm Hg at 37°C. Higher pressures are undesirable because collateral blood flow to the heart and lungs increases blood in the operative field. Hypotension during CPB may be due to low pump flow, aortic dissection, measurement error, or vasodilatation. Phenylephrine is most often used to elevate blood pressure, but arginine vasopressin (0.05–0.1 U/min) may also be used. If anesthesia is adequate, hypertension is generally treated by nitroprusside or nitroglycerin.

Mean blood pressure is an important perfusion parameter in nonpulsatile CPB, the most common mode of perfusion. Pulsatile CPB theoretically reduces vasoconstrictive reflexes and neuroendocrine responses and may increase oxygen

consumption, reduce acidosis, and improve organ perfusion. Effective generation of pulse pressure, however, requires a larger-diameter aortic cannula and higher nozzle velocities, which may increase trauma to blood elements.

### Hematocrit

The ideal hematocrit during CPB remains controversial because of competing advantages and disadvantages.[15,16] Low hematocrits reduce blood viscosity and hemolysis, reduce oxygen-carrying capacity, and reduce the need for blood transfusion. Hypothermia reduces oxygen consumption and permits perfusion at 26°C to 28°C with hematocrits between 18 and 22 percent; at higher temperatures, however, limits on pump flow may not satisfy oxygen demand. Neurologic and renal function appear to be most susceptible to damage with low hematocrits, a problem that may be overcome with increasing pump flows to maintain adequate oxygen delivery.[17] A good generalization is that hematocrit should not be maintained below 22 to 24 percent.

### Temperature

The ideal temperature for uncomplicated adult cardiac surgery is controversial, although most routine adult cardiac operations are performed with mild systemic hypothermia (28°C–32°C). This allows for some organ protection by means of reduced cellular metabolism but avoids complications associated with lower temperatures, such as interference with enzyme and organ function, increased systemic vascular resistance, delays in cardiac recovery, lengthened duration of CPB, and increased risk of cerebral hyperthermia with rewarming. Increasingly, efforts are made to avoid cerebral hyperthermia during and after operation.

### Acid/Base Management

There are two strategies for managing blood pH during hypothermia: pH-stat and alpha-stat. In adults, alpha-stat may be better for neurologic protection, as the microembolic burden may be lessened. pH-stat maintains temperature-corrected pH 7.40 at all temperatures and requires the addition of $CO_2$ as the patient is cooled. Alpha-stat allows the pH to increase during cooling, so that blood becomes alkalotic. Cerebral blood flow is higher, while pressure is passive and uncoupled from cerebral oxygen demand with pH-stat. With alpha-stat, cerebral blood flow is lower, autoregulated, and coupled to cerebral oxygen demand.

## PATIENT MONITORING

Systemic arterial pressure is typically monitored by radial, brachial, or femoral arterial catheter; central venous pressure is routinely monitored by a jugular venous catheter. Routine use of a Swan–Ganz pulmonary arterial catheter is controversial and not necessary for uncomplicated operations in low-risk patients. Bladder or rectal temperature is usually used to estimate the temperature of the main body mass but does not reflect brain temperature, which is estimated by nasopharyngeal or tympanic membrane sensors. The jugular venous bulb temperature is considered the best surrogate for brain temperature but is more difficult to obtain.

TEE examination is an important monitor during most applications of CPB[18,19] to assess catheter and vent insertion and location, severity of aortic atherosclerosis, myocardial injury, infarction, dilatation, contractility, thrombi and residual air, valve function after repair or replacement, diagnosis of dissection, and adequacy of de-airing at the end of CPB.

Mixed venous oxygenation ($SvO_2$), which assesses the relationship between $DO_2$ and $VO_2$, is monitored on the CPB circuit. $SvO_2$ below 60 percent indicates inadequate oxygen delivery; but because of differences in regional vascular tone, higher $SvO_2$ does not assure adequate oxygen delivery to all vascular beds. When adequacy of perfusion is questionable, more frequent blood gas monitoring should be performed to assess for metabolic acidosis.

## TERMINATION OF CPB

Discontinuation of CPB involves a complex interplay of physiologic manipulation and operating room personnel. Requirements for termination of CPB include physiologic systemic temperature, adequate heart and lung function, acceptable acid–base and electrolyte status, and no trapped intracardiac air. De-airing maneuvers are important to prevent coronary embolization and cardiac failure (Table 24-1). Once preparations are completed, surgeon, anesthesiologist, and perfusionist begin to wean the patient off CPB. The perfusionist gradually occludes the venous line and simultaneously reduces pump input as cardiac rate and rhythm, arterial pressure and pulse, and central venous pressure are monitored and adjusted. Initially blood volume within the pump is kept constant, but as pump flow approaches zero, volume is added or removed from the patient to produce arterial and venous pressures within the physiologic ranges. During weaning, cardiac filling and contractility is often monitored by TEE, and intracardiac repairs and regional myocardial contractility are assessed. Pulse oximetry saturation near 100 percent, end-tidal $CO_2$ >25 mm Hg, and mixed venous oxygen saturation >65 percent confirm satisfactory ventilation and circulation. When cardiac performance is satisfactory and stable, all catheters and cannulas are removed, protamine is given to reverse heparin, and blood return from the surgical field is discontinued. Once the patient is hemodynamically stable as determined by surgeon and anesthesiologist and after starting wound closure, the perfusate may be returned to the patient in several ways. The entire perfusate may be washed and returned as

packed cells, or excess fluid may be removed by a hemoconcentrator. At least some of the perfusate, which still contains heparin and coagulation factors, is gradually pumped into the patient to maintain intravascular volume, which can fluctuate significantly after separation from CPB. Occasionally, some of the perfusate must be bagged and given later. The circuit should not be completely disassembled until the chest is closed and the patient is ready for transfer.

## CIRCUIT COMPLICATIONS

Life-threatening incidents occur in 0.4 to 2.7 percent of operations with CPB. Massive air embolism, aortic dissection, dislodgement of cannulas, and clotting within the circuit during perfusion are the principal causes of serious injury or death. Malfunction of the heater-cooler, oxygenator, pumps, and electrical supply are the most common threatening incidents related to equipment. Other threatening incidents include premature takedown or clotting within the perfusion circuit. Complications related to connections to and from the heart–lung machine and perfusion during operation are described above, with descriptions of the various components of the perfusion circuit.

## METABOLIC COMPLICATIONS AND ORGAN INJURY

Depending on the degree of investigation, untoward systemic and organ-specific effects of CPB can be found in essentially all patients placed on the pump. Minor complications predominate, but in 0.1 to 0.5 percent, serious and life-threatening events can be attributed to the effects of CPB (Table 24-2).

**TABLE 24-2: Adverse Manifestations of CPB**

| | Common and Mild | Uncommon and Severe |
|---|---|---|
| Systemic | SIRS | Multiorgan failure |
| Cardiac | Tachycardia, a trial arrhythmias | Low-cardiac-output state, ventricular arrhythmias |
| Pulmonary | Mild hypoxia, tachypnea | ARDS |
| Neurologic | Anxiety, drowsiness, neuropsychological deficit | Delirium, encephalopathy, stroke |
| Renal | Oliguria, <50% increase in serum creatinine | Acute renal failure |
| Gastrointestinal | Nausea, vomiting, anorexia | Ileus, perforation, stress gastritis, pancreatitis |
| Hepatic | Mild serum transaminase and bilirubin elevation | Jaundice, fulminant liver failure |
| Hematologic | Anemia, mild thrombocytopenia, leukocytosis | HIT with thrombosis, disseminated intravascular consumption |

SIRS, systemic inflammatory response syndrome; ARDS, acute respiratory distress syndrome; HIT, heparin-induced thrombocytopenia.

## GENERAL MECHANISMS AND THE SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

CPB preempts normal reflex and chemoreceptor control of the circulation, initiates coagulation, generates vasoactive and cytotoxic substances, and produces a variety of microemboli. Ischemia/reperfusion is also an important cause of reversible and irreversible cell injury and may not be detected because regional hypoperfusion may not be evident. Regional perfusion is also influenced by acid–base relationships during cooling and may affect postoperative organ function. Temperature differences within the body and within organs produce regional temperature-perfusion mismatch, which can precipitate regional hypoperfusion and acidosis due to inadequate oxygen delivery. There is no method to monitor regional perfusion during CPB, and even direct temperature surveillance of vital organs may fail to detect temperature differences within the organ.

The subsequent inflammatory response produces the terminal complement attack complex, anaphylatoxins, cytotoxic proteases, collagenases, metalloproteinases, reactive oxidants, endotoxin, and activated neutrophils and monocytes, which can destroy nonhost organisms as well as tissue cells. These agents directly access the specialized cells of every organ by passing between endothelial cell junctions to reach the interstitial compartment. Reduced plasma colloid osmotic pressure, elevated venous pressure, and widened endothelial cell junctions increase the volume of the interstitial space during CPB in proportion to the duration of bypass, magnitude of the dissection, transfusions, and other factors. In prolonged bypass runs, the interstitial compartment may increase from 18 to 33 percent, but intracellular water does not increase during CPB.

The systemic inflammatory response syndrome (SIRS) can be detected to some degree in nearly all patients subjected to a pump-oxygenator. Clinically, this is manifest as fevers, leukocytosis, tachypnea, tachycardia in the non–beta-blocked heart, as well as fatigue, malaise, anorexia, and nausea. Elevated levels of circulating catecholamines are also present and contribute to the development of atrial and ventricular arrhythmias. Besides exposure to the circuit, other factors contributing to the development of SIRS include anemia and blood

transfusions, hypotension, surgical trauma, pain, and preexisting patient factors such as infection or advanced heart failure. Strategies to limit the severity of SIRS are thus aimed at minimizing time on pump, avoiding other precipitating factors, and medical optimization of the patient prior to surgery. No pharmacologic strategies are effective in prevention.

## MICROEMBOLIZATION

Microemboli, which are defined as particles <500 μm in diameter, that enter the circulation during CPB are important causes of regional ischemia. Air entry into the perfusion circuit produces the most dangerous gas emboli because nitrogen is poorly soluble in blood and is not a metabolite. Carbon dioxide is rapidly soluble in blood and is sometimes used to flood the surgical field to displace air. Foreign emboli, largely generated in the surgical wound, reach the circulation from the surgical field via the cardiotomy reservoir. The cardiotomy reservoir is the primary source of foreign emboli and the major source of blood-generated emboli, particularly fat emboli.[20] Extensive activation and physical damage to blood elements produce a wide variety of emboli, which tend to increase with the duration of perfusion.

The principal methods for reducing circulating microemboli include the following: adequate anticoagulation, membrane oxygenator, washing blood aspirated from the surgical wound,[21] filter in the cardiotomy reservoir, secure purse-string sutures around cannulas, strict control of all air entry sites within the perfusion circuit, removal of residual air from the heart and great vessels, and avoidance of atherosclerotic emboli.

Many intraoperative strategies are available to reduce cerebral atherosclerotic embolization. These include routine epicardial echocardiography of the ascending aorta to detect both anterior and posterior atherosclerotic plaques and sites free of atherosclerosis for placing the aortic cannula. Recently, special catheters with or without baffles or screens have been developed to reduce the number of atherosclerotic emboli that reach the cerebral circulation.[22,23] In patients with moderate or severe ascending aortic atherosclerosis, a single application of the aortic clamp as opposed to partial or multiple applications is strongly recommended and has been shown to reduce postoperative neuronal and neurocognitive deficits in a large clinical series.[24] In these patients, retrograde cardioplegia is preferred over antegrade cardioplegia to avoid a sandblasting effect of the cardioplegic solution. No aortic clamp may be safe or even possible in some patients with severe atherosclerosis or "porcelain aorta," and other techniques may be required (see "Special Topics"). Filter placement within the CPB circuit is likely an important step to prevent emboli. However, air and fat can pass through filters and air and atherosclerotic emboli may enter the circulation downstream of the filter.

## SPECIFIC ORGAN INJURY

### Cardiac Injury

It is difficult to separate postoperative cardiac dysfunction from injury due to CPB, ischemia/reperfusion, direct surgical trauma, the disease being treated, and inadequate myocardial protection. The heart, like all organs and tissues, is subject to microemboli, protease and chemical cytotoxins, activated neutrophils and monocytes, and regional hypoperfusion during CPB. Some degree of myocardial "stunning" during the period when coronary blood flow is interrupted is inevitable, as is some degree of reperfusion injury after ischemia. Both myocardial edema and distention of the flaccid cardioplegic heart during aortic cross-clamping reduce myocardial contractility. Last, if myocardial contractility is weak, excessive preload or high afterload during weaning from CPB will increase ventricular end-diastolic volume, myocardial wall stress, and oxygen consumption. Thus, the postoperative performance of the heart depends on many variables and not just the injuries produced by CPB.

### Neurologic Injury

The brain is the most sensitive organ exposed to damage by CPB and also the most important organ to protect. Even small injuries may produce detectable, functional losses that are not detectable or important in other organs. Regional hypoperfusion, edema, microemboli, and circulating cytotoxins may cause subtle losses in cognitive function, behavioral patterns, and physiologic and physical function that can pass unnoticed, be accepted and dismissed, or profoundly compromise the patient's quality of life. The most obvious neuropsychologic abnormalities are coma, delirium, and confusion, but often transitory episodes of delirium and confusion are dismissed as due to anesthesia or medications. More subtle losses are determined by comparison of preoperative and postoperative performance using a standard battery of neuropsychologic tests.

Advancing age increases the risk of stroke or cognitive impairment, especially after the age of 60, at least in part because other risk factors for neurologic injury also increase with age. Hypertension and diabetes occur in approximately 55 and 25 percent of cardiac surgical patients, respectively. Fifteen percent have carotid stenosis of 50 percent or greater, and up to 13 percent have had a transient ischemic attack or prior stroke. The severity of atherosclerosis in the ascending aorta as detected by epiaortic ultrasound scanning adds to the risk of stroke or cognitive dysfunction. Palpable ascending aortic atherosclerotic plaques markedly increase the risk of right carotid arterial emboli as detected by Doppler ultrasound.[25] The incidence of severe aortic atherosclerosis is 1 percent in cardiac surgical patients below 50 years and is 10 percent in those between 75 and 80 years.

Mechanisms of cerebral injury during CPB are microemboli and hypoperfusion, which are to some extent mutually exclusive. Microemboli are distributed in proportion to blood flow; thus reduced cerebral blood flow reduces microembolic injury but increases the risk of hypoperfusion.[26] In clinical practice, air, atherosclerotic debris, and fat are the major types of microemboli causing brain injury and all cause neuronal necrosis by blocking small cerebral vessels. Massive air embolism causes a large ischemic injury, but gaseous cerebral microemboli may directly damage endothelium in addition to blocking blood flow.

Besides protecting against embolic events, recommended conditions for protecting the brain during CPB include mild hypothermia (32°C–34°C) and a hematocrit above 25 percent. Temporary increases in cerebral venous pressure caused by SVC obstruction and excessive rewarming above blood temperatures of 37°C should be avoided. Barbiturates reduce cerebral metabolism by decreasing spontaneous synaptic activity and provide a definite neuroprotective effect during clinical cardiac surgery using CPB. Unfortunately, these agents delay emergence from anesthesia and prolong ICU stays. Although the use of aprotinin has been associated with fewer strokes in retrospective analysis, currently no agent is strongly recommended for protection of the central nervous system during CPB.

Off-pump myocardial revascularization theoretically avoids many of the causes of cerebral injury due to CPB, but, as noted above, many causes of neuronal injury are independent of CPB and related to atherosclerosis and the entry of air into the circulation. Measurements of carotid emboli by Doppler ultrasound indicate fewer emboli and improved neurocognitive outcomes in patients who have off-pump surgery as compared to those with on-pump revascularization.[27,28] Unfortunately, metanalyses of randomized trials comparing on- and off-pump CABG have not demonstrated a definitive reduction in stroke risk.[29,30]

## Lung Injury

Hypoxia of some degree is a nearly universal finding after CPB. Patient factors and the separate effects of operation and CPB combine to compromise lung function early after operation. Chronic smoking and emphysema are the most common patient factors, but muscular weakness, chronic bronchitis, occult pneumonia, preoperative pulmonary edema, and unrelated respiratory disease are other contributors to postoperative pulmonary dysfunction. Incisional pain, lack of movement, shallow respiratory sighs, reduced pulmonary compliance, weak cough, increased pulmonary arteriovenous shunting, and interstitial edema, to some degree, are consequences of anesthesia and any operation. CPB significantly adds to this injury.

During CPB, the lungs are supplied by the bronchial arteries and pulmonary arterial blood flow may be absent or minimal. Whether or not alveolar cells suffer an ischemia/reperfusion injury is unclear, but the lungs are subject to many insults that combine to increase pulmonary capillary permeability and interstitial lung water. Hemodilution, reduced plasma oncotic pressure, and temporary elevation of left atrial or pulmonary venous pressure during CPB or during weaning from CPB increase extravascular lung water. Microemboli and circulating cellular, vasoactive, and cytotoxic mediators of the inflammatory response reach the lung via bronchial arteries during CPB and with resumption of the pulmonary circulation during weaning. These agents increase pulmonary capillary permeability, perivascular edema, and bronchial secretions and perhaps cause observed changes in alveolar surfactant. All of these changes combine to enhance regional atelectasis, increase susceptibility to infection, and increase the physiologic arteriovenous shunt, which reduces systemic arterial $PaO_2$.

Postoperative respiratory care is based on restoring normal pulmonary capillary permeability and interstitial lung volume, preventing atelectasis, reinflating atelectatic segments, maintaining normal arterial blood gases, preventing infection, and facilitating removal of bronchial mucus. Improved postoperative respiratory care, an understanding of the mechanisms of lung injury during CPB, and efforts to prevent or control the causes of injury can markedly reduce the incidence of pulmonary complications.

## Renal Injury

Some degree of renal injury is inevitable during CPB, and postperfusion proteinuria occurs in all patients. The incidence of acute renal failure requiring dialysis after CPB is 1 to 5 percent, depending on the complexity of surgery and preoperative factors. As with other organs, the preoperative health of the kidneys is a major factor in the ability of that organ to withstand the microembolic, cellular, and regional malperfusion injuries caused by CPB. Risk factors for postoperative renal dysfunction include age over 70, diabetes mellitus, previous cardiac surgery, congestive heart failure, and a complex, prolonged operation. Hemoglobin is toxic to renal tubules and its precipitation can block both blood and urine flow to the tubules. Hemodilution dilutes plasma hemoglobin; improves flow to the outer renal cortex; improves total renal blood flow; increases creatinine, electrolyte, and water clearance; and increases glomerular filtration and urine volume.

Perioperative periods of low cardiac output and/or hypotension added to the microembolic, cellular, and cytotoxic injuries of CPB and to any preoperative renal disease are the major cause of postoperative renal failure. Low cardiac output reduces renal perfusion pressure and causes angiotensin II production and renin release, which further decreases renal blood flow. Kidneys, already compromised by preoperative disease and the CPB injury, are particularly sensitive to ischemic injury secondary to low cardiac output and hypotension. Thus perioperative management includes efforts to maximize cardiac output using dopamine or dobutamine if necessary, avoiding renal arterial vasoconstrictive drugs,

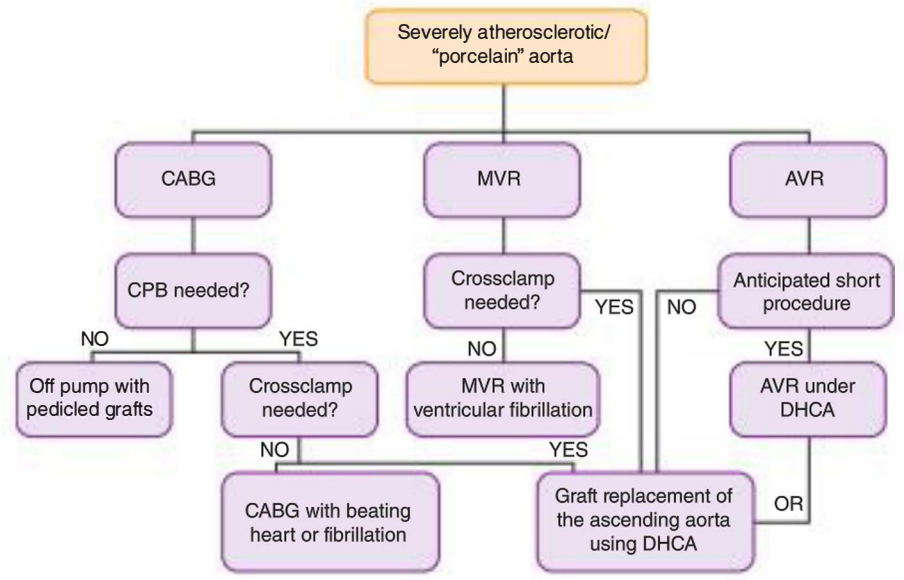

**FIGURE 24-3** Algorithm for management of the severely atherosclerotic ascending aorta.

providing adequate crystalloid infusions to maintain urine volume, and alkalinizing urine to minimize the precipitation of tubular hemoglobin if excessive hemolysis has occurred. Unfortunately, no pharmacologic strategies have proven beneficial in protecting renal function after CPB.

### Pancreatic Injury

Less than 1 percent of patients develop clinical pancreatitis after CPB, but approximately 30 percent develop a transitory, asymptomatic increase in plasma amylase and/or lipase. A history of recurrent pancreatitis, perioperative circulatory shock or hypotension, excessively prolonged CPB, and continuous, high doses of inotropic agents are risk factors for the development of postoperative clinically relevant pancreatitis. Experimentally and clinically, high doses of calcium increase intracellular trypsinogen activation and histologic evidence of pancreatitis. Fulminant pancreatits is very rare but often fatal.

## SPECIAL TOPICS

### The "Bad Aorta"

Some degree of atherosclerosis of the ascending aorta is a common finding during cardiac surgery. Simple palpation can often detect local areas of plaque that must be avoided in cannulating, clamping, or manipulating the aorta. Epiaortic scanning is more sensitive for the detection of ascending aortic atherosclerosis and is preferred for all patients who have a history of transient ischemic attack, stroke, severe peripheral vascular disease, palpable calcification in the ascending aorta, calcified aortic knob on chest radiograph, age above 50 to 60 years, or TEE findings of moderate aortic atherosclerosis.[31]

Some findings on examination of the aorta can dramatically alter the conduct of an operation. Calcified aorta (porcelain aorta), which occurs in 1 to 4 percent of patients, is one such finding. This condition increases the risks of dislodgement of atheromatous debris from the aortic wall due to manipulation, cross-clamping, or the sandblasting effect of the cannula jet and greatly increases the risks of perioperative stroke, aortic dissection, and postoperative renal dysfunction.[32] Many strategies exist for patient management in this setting; these depend on the surgeon's preference and the cardiac condition being treated (Fig. 24-3). For coronary artery bypass, the first question one must ask is "Is the pump necessary?" Conversion from on-pump to off-pump CABG is a good alternative, especially when manipulation of the ascending aorta can be completely avoided. In this scenario, pedicled single or sequential arterial grafts, T or Y grafts from a pedicled mammary artery, or vein grafts anastomosed to arch vessels can be used.

If CPB is deemed necessary, minimal manipulation of the aorta should remain a primary focus. Initially, the best site for cannulation must be determined. Femoral cannulation in this setting is usually not a good alternative because of the likely coexistence of severe atherosclerosis in the aortoiliac and femoral circulations. In contrast, the axillary artery is usually free of significant disease and is often a good alternative. Another option is cannulation of a "soft spot," if one exists, atraumatically on the ascending aorta or aortic arch.

Next, one must decide whether aortic cross-clamping is necessary. Many coronary operations can be performed

without a cross clamp on the empty, beating heart. Alternatively, ventricular fibrillation can be induced electrically or with hypothermia for coronary or mitral valve operations with cross-clamping. Finally, deep hypothermic circulatory arrest (DHCA) can be used to replace the aortic valve without ever placing a clamp.[33] If aortic cross-clamping is deemed necessary, DHCA can be used initially to replace the ascending aorta with a graft using an open technique. The graft can then be clamped for reinstitution of CPB and maintenance of cardiac arrest.

Severe aortic atherosclerosis is a risk factor for the still rare but dramatic complication of intra- or postoperative aortic dissection. The first clues may be discoloration beneath the adventitia near the cannula site, proximal vein anastomosis or clamp location, an increase in arterial line pressure, or a sharp reduction in return to the venous reservoir. TEE may be helpful in confirming the diagnosis, but prompt action is necessary to limit the dissection and maintain perfusion. If a localized dissection occurs immediately upon removing the cross clamp, the clamp should be reapplied to limit proximal and distal extension of the dissection flap. Local suture or partial graft repair is then performed. For more extensive dissections, the cannula must be promptly transferred to a peripheral artery or uninvolved distal aorta. Blood pressure should be controlled pharmacologically and perfusion cooling to temperatures less than 20°C initiated. During hypothermic circulatory arrest, the aorta is opened at the original site of cannulation and repaired by direct suture, patch, or circumferential graft. When dissection is recognized early, survival rates range from 66 to 85 percent, but when this problem occurs late or is discovered after operation, survival is approximately 50 percent.

## PERSISTENT LEFT SVC

The presence of a persistent left SVC (PLSVC) is rare but should be suspected when the left innominate vein is small or absent and a large coronary sinus or the PLSVC itself is seen on baseline TEE, as the PLSVC usually drains into the coronary sinus. A PLSVC may thus complicate retrograde cardioplegia or entry into the right heart. For epicardial operations, standard single- or two-stage venous cannulation remains effective, although retrograde cardioplegia cannot be used. For other cases, if an adequate-sized innominate vein is present (30 percent of patients), the PLSVC can simply be occluded during CPB and cerebral venous return will not be impeded. If the innominate vein is absent or small (about 75 percent of patients) or if the right SVC is not present, occlusion of the PLSVC may cause venous hypertension and possible cerebral injury. In these patients, the SVC may be cannulated directly or through the coronary sinus ostium. Alternatively, for simple cases such as repair of a secundum atrial septal defect, standard cannulation can be performed and a sump suction cathether placed into the coronary sinus while the right atrium is open.

## MASSIVE AIR EMBOLISM

Massive air embolism during perfusion is a rare but catastrophic event. When this is detected, perfusion should stop immediately and clamps should be placed on both venous and arterial lines. Air in the circuit should be removed rapidly by recirculation and entrapment of all air in a reservoir or bubble trap. The patient should immediately be placed in steep Trendelenburg and blood and air at the site of entry should be aspirated until no air is retrieved. TEE should rapidly be employed to search for air, but perfusion must resume promptly, depending on body temperature, to prevent ischemic brain damage. Cooling to deep hypothermia should be considered to protect the brain and other organs while the air is located and removed. As soon as possible, retrograde perfusion of the brain should be undertaken while the aortic arch is simultaneously aspirated with the patient in steep Trendelenburg. Corticosteroids and/or barbiturates may be considered. Depending on circumstances and availability, hyperbaric oxygen therapy may be helpful if patients can be treated within 5 h of operation.[34]

## DEEP HYPOTHERMIC CIRCULATORY ARREST

DHCA is used for operations involving the aortic arch, porcelain aorta, thoracoabdominal aneurysms, pulmonary thrombendarterectomy, selected uncommon cardiovascular and neurologic procedures, and certain complex congenital heart procedures. The technology involves reducing body temperature to less than 20°C, arresting the circulation for a short period and then rewarming to 37°C. Most surgical teams cool to either electroencephalographic (EEG) silence, jugular venous saturation above 95 percent, or for at least 30 min before stopping circulation at nasopharyngeal or tympanic membrane temperatures below 20°C. Perfusion cooling is usually supplemented by surface cooling using hypothermia blankets and/or packing the head in ice. During rewarming, hyperthermia is avoided by keeping the arterial inflow temperature below 37°C.

Changes in temperature affect acid–base balance, which must be monitored and managed during deep hypothermia. In adults, the pH-stat protocol ($CO_2$ is added to maintain temperature corrected blood pH at 7.4) is often used during cooling instead of the alpha-stat protocol, which allows cold blood to become alkalotic. Compared with alpha-stat, pH-stat increases the rate and uniformity of brain cooling and slows the rate of brain oxygen consumption by 30 to 40 percent. pH-stat is even more commonly used in pediatric DHCA applications. Alpha-stat management is often substituted during rewarming when more potential microemboli may be present. Hyperglycemia appears to increase brain injury and is avoided during deep hypothermia. The value of high-dose corticosteroids or barbiturates remains unproven.

The "safe" duration of circulatory arrest during deep hypothermia is unknown. In adults, arrest times as short as 25 min are associated with reduced performance on neuropsychologic tests of fine motor function and memory.[35] At 18°C, cerebral metabolism and oxygen consumption are 17 to 40 percent of normothermia, and abnormal EEG patterns and cerebrovascular responses can be detected after 30 min of circulatory arrest. Most investigators report increased mortality and adverse neurologic outcomes after 40 to 65 min of circulatory arrest. Thus, the maximal "safe" duration of DHCA is considered to be approximately 45 min by most surgeons. Advanced age or a preoperative history of stroke may leave less safety margin for brain injury.

Cerebral perfusion can often be maintained during DHCA in either antegrade or retrograde fashion. Interval resumption of normal circuit flow is ideal but is usually not technically possible except in cases not involving open work on the aortic arch, i.e., pulmonary thromboendarterectomy. Antegrade cerebral perfusion, which appears to have more clinical benefit than retrograde perfusion, is most easily applied after cannulation of the right axillary artery. The innominate artery can then be occluded to achieve corporeal circulatory arrest while maintaining flow to the brain via the right carotid artery. Flows usually range between 8 and 12 mL/kg to keep mean pressure in the range of 40 to 70 mm Hg in the right radial artery or pressure sensor on the end of the cannula. Less commonly, the cerebral vessels can be cannulated separately. Selective antegrade cerebral perfusion risks dislodging atheromatous emboli, air embolism, cerebral edema, or injury from excessive perfusion pressure.

Retrograde cerebral perfusion is achieved by placing a perfusion cannula (often a retrograde coronary sinus catheter) into the SVC, which is then perfused at flows between 250 and 400 mL/min and blood pressures usually between 25 and 40 mm Hg. A snare is usually placed around the SVC catheter cephalad to the azygos vein to reduce runoff. As minimal cortical perfusion has been detected with this technique, its main theoretical benefit is the retrograde flush of air and debris from the cerebral vessels. After increased use in the 1980s, retrograde cerebral perfusion was not widely employed because many studies had failed to demonstrate clinical benefit.

## CANNULATION FOR MINIMALLY INVASIVE SURGERY

Peripheral cannulation sites as described above may be used for minimal-access cardiac surgery, but often central cannulation of the aorta, atrium, or central veins is accomplished using specially designed or smaller cannulas placed through the small operative incision or through a separate small incision in the chest wall. Venous return is often augmented by applying negative pressure (see "Venous Cannulation," above). Specially designed cross clamps, some with flexible handles, can also be used through small incisions. Other options include complete cannulation by remote access, using equipment such as the Port Access System, which provides a means for full CPB, cardioplegia administration, and aortic cross clamping without exposing the heart and can be used for both valvular and coronary artery operations.[36] Separate transcutaneous catheters are inserted through the right internal jugular vein into the coronary sinus for retrograde cardioplegia and the pulmonary artery for left heart venting. A multilumen catheter is inserted through the femoral artery and, using TEE and/or fluoroscopy, is positioned in the ascending aorta for arterial pump inflow, for balloon occlusion of the ascending aorta, and for administration of antegrade cardioplegia into the aortic root. Venous return is captured by a femoral venous catheter advanced into the right atrium.

Minimally invasive surgery using CPB is associated with potential complications that include perforation of vessels or cardiac chambers, aortic dissection, incomplete de-airing, systemic air embolism, and failure of the balloon aortic clamp. As $CO_2$ is heavier than air and more soluble in blood, the surgical field is sometimes flooded with $CO_2$ at a flow of 5 to 10 L/min to displace air when the heart is open. The balloon clamp can leak, prolapse through the aortic valve, or move distally to occlude arch vessels. Early use of the balloon clamp appeared to be associated with higher risks of aortic dissection; with more experience, however, this complication appears less common. For safety, the position of the occluding balloon is closely monitored by TEE, bilateral radial arterial pressures, and occasionally transcranial Doppler ultrasound.

## CARDIOPULMONARY BYPASS BOARD REVIEW QUESTIONS (CHAPTER 24)

1. Which surgeon pioneered "cross-circulation"?
   A. Gibbon
   B. Bigelow
   C. Lillehei
   D. Kirklin
   E. Mayo

2. Which of the following is not an advantage of a roller pump over a centrifugal pump?
   A. Reduced cost
   B. Minimal effects by afterload changes
   C. Low priming volume
   D. Generation of microparticles
   E. Ability to generate pulsatile flow

3. Which of the following is not an advantage of an open venous reservoir compared to a closed venous reservoir?
   A. Facilitation of volume measurements
   B. Easier to manage venous air
   C. Larger capacity
   D. Minimizes air–blood interface
   E. Reduced cost

4. Which is not an advantage of centrifugal cell-saving compared to cardiotomy suction?
   A. Removal of microparticles
   B. Reduced inflammatory response
   C. Lower incidence of neuropsychologic deficits
   D. Improved field clearance and visualization
   E. Reduced hemodilution

5. Which is true regarding alpha-stat management?
   A. pH of 7.40 at 28°C
   B. Increased cerebral blood flow
   C. Autoregulation of cerebral blood flow
   D. Increased administration of $CO_2$ during cooling
   E. Increased cerebral microembolization

## ANSWERS

1. **Answer: C.** Lillehei used cross-circulation to repair congenital defects prior to the advent of cardiopulmonary bypass. Bigelow utilized systemic hypothermia with topical cooling for early cardiac repairs. Gibbon was the first to clinically use the heart–lung machine, but it was Kirklin at the Mayo Clinic who ushered in the modern area of intracardiac surgery with modifications of the cardiopulmonary bypass circuit.
2. **Answer: D.** High negative pressures generated by a roller pump can cause cavitation and generation of microparticles. In general, roller pumps are less expensive and can function with lower priming volumes. There is minimal effect on the roller pump during afterload changes. The roller mechanism can be adjusted to generate pulsatile flow.
3. **Answer: D.** Open venous reservoirs have a larger air–blood interface and, therefore, may be associated with a higher risk of microgaseous emboli. Volume measurements and air management is easier with an open reservoir, which is larger and cheaper than a closed system.
4. **Answer: E.** Cell-saving with a centrifugal device has been shown to remove microparticles, reduce inflammation and neuropsychologic deficits, and improve operative visualization and field clearance. The disadvantage is the loss of plasma that occurs during the cell washing process.
5. **Answer: C.** Alpha-stat management is associated with better autoregulation of blood flow. It keeps the pH at 7.40 regardless of temperature, reduces cerebral blood flow according to autoregulation, and also reduces cerebral microembolization. pH-stat, not alpha-stat, management requires increased administration of $CO_2$ during cooling.

# 25 Myocardial Protection

*Constantine L. Athanasuleas*
*Gerald D. Buckberg*

**KEY CONCEPTS**

- Cardioplegia markedly reduces oxygen demand in the arrested heart and must be delivered uniformly in sufficient quantity to match this low demand.
- "Integrated myocardial protection" is a myocardial protection strategy that includes antegrade and retrograde delivery of cold-blood cardioplegia and warm cardioplegia perfusion for induction and resuscitation.
- Hypothermia reduces myocardial oxygen demand and ischemic injury when coronary flow is interrupted; however, it does not completely prevent injury in chronically ischemic hearts.
- Blood cardioplegia, which typically comprises four parts blood to one part crystalloid solution, is a natural buffering agent, maintains oncotic pressure, possesses advantageous rheologic properties, and is a free-radical scavenger.
- High potassium in cardioplegia maintains cardiac arrest and prevents sudden intracellular calcium accumulation and sarcolemma disruption.
- Complete myocardial recovery occurs after 4 h of ischemia in normal hearts when protected with cold-blood cardioplegia.
- Antegrade or retrograde delivery of cardioplegia alone does not provide homogeneous distribution even with normal coronary arteries.
- Paradoxical septal motion, seen in up to 40 percent of cardiac surgical patients, can lead to acute right ventricular failure and may be caused by inadequate distribution of cardioplegia.
- Warm-blood cardioplegia induction limits reperfusion injury in ischemic hearts.
- During antegrade infusion of cardioplegia, aortic pressure should be maintained between 60 and 80 mm Hg at a flow rate of 200 $cm^3$/min or, in hypertrophied hearts, at 250 $cm^3$/min.

## INTRODUCTION

A successful outcome after cardiac surgery depends on many factors. Accurate recognition of the pathology and the judicial choice of methods to achieve cardiac repair are essential. Equally important are the physiologic consequences of the operation. Ventricular function must be preserved or improved during cardiac procedures. Myocardial protection is therefore the crucial component of success in cardiac surgery.

The mainstay of myocardial protection is cardioplegia. This chapter is a brief review of myocardial protection as currently applied in the vast majority of cardiac operations worldwide. We offer a brief review of the components of cardioplegia and their effects on cardiac metabolism and function, followed by a detailed description of "how to do it."

Much has been written about cardioplegia regarding (1) route of delivery (antegrade vs retrograde or both), (2) method of delivery (continuous vs intermittent), and (3) temperature (warm vs cold). This has often led to confusion and adversarial positions. Surgeons appropriately want to keep things simple, but as Einstein once said: "Everything should be made as simple as possible, but not simpler." In this chapter, we present a method of cardioplegia that has been extensively applied clinically. It is called the "integrated method" of protection because it combines the salient features of the above elements in a manner that suits the ongoing physiologic needs of the heart during the course of an operation and expedites the time phase of the procedure.

## BASIS OF CARDIOPLEGIA

Cardioplegia markedly reduces oxygen demand in the arrested heart and must be delivered uniformly in sufficient quantity to match this low demand (Fig. 25-1). These

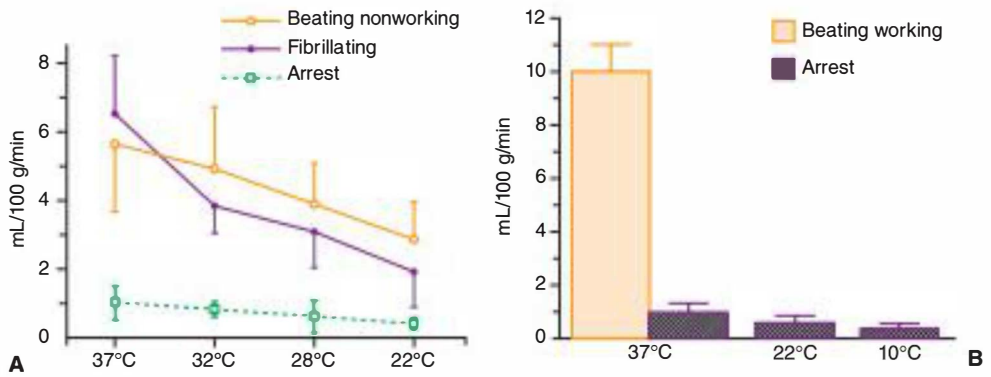

**FIGURE 25-1** Left ventricular (LV) oxygen requirements of the beating, empty, fibrillating, and arrested heart from 37°C to 22°C. Note in (**A**) the low oxygen demands of arrest and the negligible change between 22°C and 10°C as the heart rewarms from collateral flow. **B.** Higher demands exist if electromechanical activity returns when systemic perfusate washes out t he cardioplegic solution.

requirements are met by antegrade and retrograde delivery, cold-blood cardioplegia to reduce oxygen demands, and warm cardioplegia perfusion for induction and resuscitation. "Integrated myocardial protection" is a strategy that addresses each of these requirements in a manner that allows the operation to be performed without interruption.[1] This method (1) provides a bloodless operative field, (2) avoids unnecessary ischemia and cardioplegia overdose, and (3) permits aortic unclamping and discontinuation of bypass shortly after cardiac repair.

Electromechanical activity of the heart raises oxygen demand during arrest. Hypothermia reduces this demand and ischemic damage when coronary flow is interrupted in the course of the revascularization procedure provided that the cardioplegic perfusate is distributed adequately with reinfusions. Hypothermia alone, however, does not completely avoid injury in chronically "energy-depleted" (ischemic) hearts (Fig. 25-2).

## TYPES OF CARDIOPLEGIA

Blood cardioplegia consists of four parts of blood to one part crystalloid solution. It is a natural buffering agent, maintains oncotic pressure, has advantageous rheologic properties, and is a free-radical scavenger. Blood cardioplegia replenishes substrate in vulnerable hearts, limits reperfusion injury, and reverses ischemia/reperfusion changes in the acutely ischemic myocardium. Complete myocardial recovery occurs after 4 h of ischemia in normal hearts when protected with cold-blood cardioplegia. However, it is uncommon to address normal hearts. The sequences described below

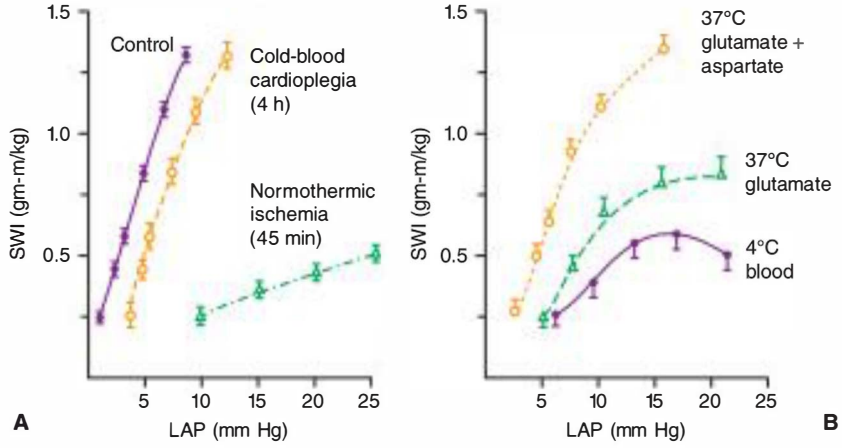

**FIGURE 25-2** **A**. LV function every 20 min in normal hearts subjected to 4 h of aortic clamping with blood cardioplegia compared with depressed function after 45 min of normothermic arrest without cardioplegia. **B**. LV function when jeopardized hearts undergoing 45 min of normothermic ischemia are subjected to 2 h more of aortic clamping. Note (1) no further improvement when only cold cardioplegic perfusate is given o ver the 45-min arrest period and (2) progressively increased recovery when the cardioplegic solution is supplemented with warm glutamate and aspartate during induction of cardioplegia and reperfusion with intermittent cold doses o f blood every 20 min of supplemental aortic clamping. These data suggest the value of amino acid enrichment in jeopardized hearts. LAP, left atrial pressure; SWI, stroke-work index.

**TABLE 25-1: Induction and Terminal "Hot Shot" Cardioplegia (Bag 1)**

| Cardioplegia additive | Volume added (mL) | Component modified | Concentration delivered[a] |
|---|---|---|---|
| Potassium chloride (2 mEq/mL) | 15 | Potassium ion | 16–20 mEq/L |
| Tromethamine (THAM) (0.3 mol/L) | 225 | pH | pH 7.5–7.7 |
| Citrate-phosphate-dextrose | 225 | Calcium ion | 0.2–0.4 mmol/L |
| Aspartate, glutamate | 250 | Substrate | 13 mmol/L each |
| 50% dextrose in water | 40 | Glucose | <400 mg/dL |
| 5% dextrose in water | 200 | Osmolarity | 380–400 mOsm |

were developed experimentally and are now clinically used routinely in the jeopardized hearts that are currently commonplace in cardiac surgical practice.

Cold-crystalloid cardioplegia does not have the rheologic advantages of blood cardioplegia. When administered in multiple doses, it often results in systemic hemodilution. Crystalloid cardioplegia also shifts the oxyhemoglobin disassociation curve leftward, retarding $Na^+/K^+$ adenosine triphosphatase, and thereby produces edema and activation of platelets, leukocytes, and complement.[2]

## COMPONENTS OF BLOOD CARDIOPLEGIA

Blood cardioplegia consists of four parts blood to one part crystalloid solution. The components (Table 25-1) of blood cardioplegia are reviewed briefly here and have been well described in detail previously.[3] Other more concentrated constituent dilutions (1:8 to 1:50) may be used if the crystalloid component is appropriately varied to include the components described in this chapter (Tables 25-2, 25-3, and 25-4).

A high level of potassium maintains cardiac arrest and prevents sudden intracellular calcium accumulation and disruption of the sarcolemma, as observed when reoxygenation occurs. A low level of calcium is used to limit calcium loading during the conditions of impaired ionic balance in the early period of reperfusion. The amino acid substrates aspartate and glutamate increase the energy-depleted heart's ability to use oxygen and hasten ionic recovery. Hyperosmolarity reduces edema. Tromethamine (THAM) is alkalotic to (1) limit the evolution of acidosis during ischemia and (2) hasten enzymatic recovery. It is used in preference to bicarbonate, which yields more $CO_2$ and acidosis.

We routinely use two formulations of cardioplegia (bags 1 and 2) during elective cardiac operations and switch between them based on the metabolic requirements of the heart during specific phases of the operation. Bag 1 is called "induction/terminal" cardioplegia and is a high-potassium (20 mEq/L), aspartate, and glutamate-enriched solution (Table 25-1). It is infused as a cold solution after aortic cross-clamping to arrest the heart and then infused as a warm solution just prior to the release of aortic cross-clamping after all cardiac repairs are completed to resuscitate the energy-depleted ischemic myocardium ("hot shot"). Bag 2 is called "maintenance" cardioplegia and consists of a low-potassium (7–10 mEq/L) mixture without the amino acid additives (Table 25-2). It is administered as a cold solution intermittently during the operation. A third cardioplegia (bag 3) is called "rescue" cardioplegia and is used following myocardial infarction as a controlled reperfusate (Table 25-3). Its rationale and use are described later in this chapter.

## DELIVERY OF CARDIOPLEGIA

Cardioplegia is effective only if it is well distributed. Adding retrograde perfusion via transatrial cannulation of the coronary sinus improves subendocardial perfusion, avoids

**TABLE 25-2: Cold Maintenance Cardioplegia (Bag 2)**

| Cardioplegia additive | Volume added (mL) | Component modified | Concentration delivered[a] |
|---|---|---|---|
| Potassium chloride (2 mEq/mL) | 10 | Potassium ion | 8–10 mEq/L |
| Tromethamine (THAM) (0.3 mol/L) | 200 | pH | pH 7.6–7.8 |
| Citrate-phosphate-dextrose | 50 | Calcium ion | 0.5–0.6 mmol/L |
| 5% dextrose in water 1/4 isotonic saline solution | 550 | Osmolarity | 340–360 mOsm |

[a]When mixed in a 4:1 ratio with blood.

ostial cannulation during aortic valve procedures, limits the removal of retractors during mitral procedures, and permits flushing of air and atheromas during coronary reoperations. Experimentally, right ventricular nutritive flow is limited by retrograde perfusion. Antegrade or retrograde cardioplegia alone are each inhomogeneous in their distribution in animals with normal coronary arteries as shown by microsphere studies. Therefore, both are needed to insure a uniform distribution in the myocardium.[4]

Clinical studies show that switching from antegrade to retrograde perfusion raises oxygen uptake and lactate washout, indicating that each modality perfuses different areas.[5] Therefore, both antegrade and retrograde perfusion is required for complete protection (Fig. 25-3). The clinical benefits of the addition retrograde cardioplegia after coronary surgery were seen in a controlled prospective randomized trial. Three months after surgery, there was an increase in resting and exercise ejection fraction in patients who had retrograde cardioplegia as compared to those who did not.[6] Adding retrograde to antegrade cardioplegia also reduces troponin levels after induced ischemia in patients with reduced ejection fraction less than 36 percent.[7,8] In patients with left-main coronary disease, adding retrograde cardioplegia during coronary bypass reduces the incidence of postoperative atrial fibrillation and troponin levels.[9]

Recent studies have shown that combined benefits occur by *simultaneous* delivery of retrograde and antegrade cardioplegia in coronary bypass procedures.[10,11] After vein grafting to a coronary artery, cardioplegia may be given through the graft in an antegrade manner and simultaneously through the coronary sinus. Myocardial venous hypertension is prevented by drainage through the Thebesian veins.

Noncoronary collateral flow from mediastinal collaterals displaces cardioplegia with warmer systemic blood. Topical hypothermia slows rewarming but may cause pulmonary complications (phrenic palsy) without supplementing the cardioprotective effects. Hence, continuous or intermittent cardioplegia is required. Continuous cardioplegic perfusion has been advocated to avoid ischemia, but adequate protection may not be achieved at usual flow rates, and the surgeon's vision becomes obscured during infusion. Intermittent cardioplegia, delivered at 10- to 20-min intervals, maintains arrest, slows rewarming, and restores substrates depleted during ischemia. In addition, it flushes accumulated metabolites and counteracts acidosis and edema.

## SEPTAL FUNCTION AND CARDIOPLEGIA

Paradoxical septal motion, seen in as many as 40 percent of patients after cardiac surgery can lead to acute right ventricular failure.[12] This may be caused by inadequate distribution of cardioplegia. We recently evaluated septal function

**TABLE 25-4: Modified Noncardioplegic Cold Blood (Bag 4)**

| Solution additive | Volume added (mL) | Component modified | Concentration delivered[a] |
|---|---|---|---|
| Tromethamine (THAM) (0.3 mol/L) | 50 | pH | pH 7.5–7.6 |
| Citrate-phosphate-dextrose | 50 | Calcium ion | 0.5–0.6 mmol/L |
| Magnesium chloride (2 mEq/mL) | 10 | Magnesium ion | 4–6 mg/L |
| 5% dextrose in water 1/4 isotonic saline solution | 1000 | Osmolarity, glucose | 340–360 mOsm |
| Mannitol (25%) | 50 | Osmolarity, oxygen-radical scavenger | 340–360 mOsm |

[a]When mixed in a 4:1 ratio with blood.

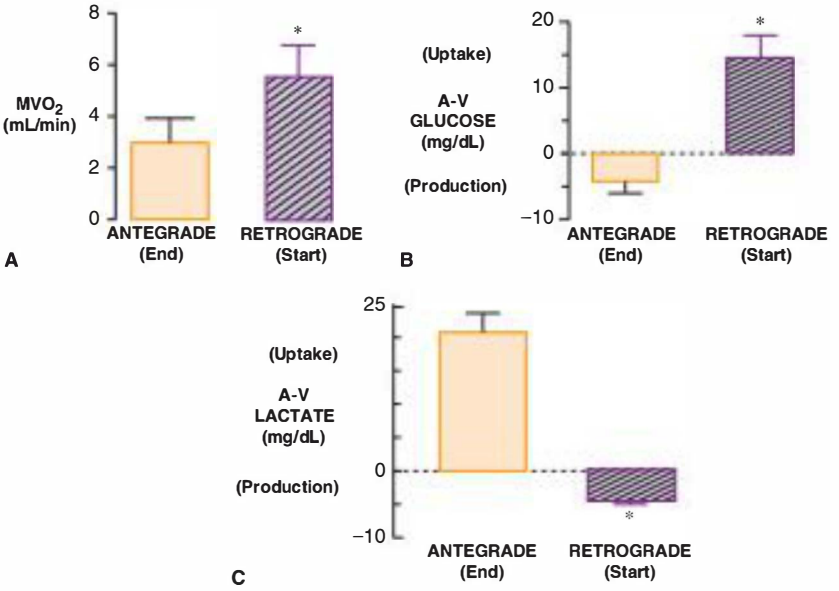

**FIGURE 25-3** Myocardial metabolic changes in coronary patients when cardioplegic induction solution is converted from antegrade to retrograde. Note the increase in myocardial oxygen uptake ($MVO_2$), glucose uptake, and lactate production, suggesting different areas of perfusion by the antegrade and retrograde methods of delivery. This implies an advantage to both methods.

by a commonly used qualitative scoring system and reported septal function among 119 patients undergoing a variety of cardiac surgical procedures.[13] By using the integrated method of myocardial protection, paradoxical septal motion was not seen in any patient, strongly suggesting that this phenomenon is an iatrogenic injury or stunning of the septum. A prospective randomized clinical trial is currently underway with newer echocardiographic data including spectral tracking and velocity vectors.

## TEMPERATURE OF CARDIOPLEGIA

Integrated myocardial management also addresses the special needs of the myocardium based on nutritive needs and underlying pathology. Hence, both cold and warm cardioplegia is used in this method at various times.

During routine elective operations in patients with good ventricular function, cardioplegic arrest is done with cold-blood cardioplegia (bag 1). If ventricular function is impaired or there is active ischemia, induction is carried out with warm cardioplegia (bag 1). In both cases, cardioplegia is first given antegrade and then retrograde. If the heart is arrested with a warm induction, low-potassium nonenriched cardioplegia (bag 2) is then given antegrade and retrograde to cool the heart. Temperature is always monitored in the septum to assure optimal cooling and distribution.

Warm-blood cardioplegia (37°C) given initially (induction) limits reperfusion damage in ischemic hearts.[14] It enhances metabolic repair by channeling aerobic adenosine triphosphate production to reparative processes. Other cardioplegic components, citrate–phosphate–dextrose (CPD), and buffers (THAM) limit calcium influx and acidosis. Clinical studies confirm our experimental findings and show that warm-blood cardioplegia ("hot shot") after ischemia improves recovery. Warm cardioplegic induction and reperfusion solutions are augmented with the amino acids glutamate and aspartate to replenish key Krebs cycle intermediates depleted by ischemia. These additions enhance the reparative processes after a period of myocardial ischemia. The use of warm induction and reperfusion has been shown to decrease troponin levels after a period of ischemia clinically.[15] A modified warm cardioplegia known as "rescue" cardioplegia may be used to resuscitate the arrested heart after acute myocardial infarction or cardiac arrest occurring soon after bypass surgery.[16] The solution (bag 3, Table 25-3) contains the amino acid–enriched solutions with the addition of diltiazem, which limits calcium influx into the injured myocardium. This solution may be infused for 20 min selectively into the infarcted artery via a saphenous vein bypass prior to its attachment to the aorta. During this phase, the ventricle is vented via the right superior pulmonary vein. Rescue cardioplegia may also be used globally (antegrade and retrograde, alternating 5 min each for 20 min). We have observed marked rhythm and hemodynamic improvement after witnessed cardiac arrest of up to 120 min with this approach.

## AORTIC CLAMPING

Coronary artery bypass grafting (CABG) is the most common cardiac operation, and the risk of intraoperative cerebral atheroemboli is increased among elderly patients undergoing revascularization. Atherosclerotic emboli are more

likely after repeated aortic tangential clamping for proximal anastomoses. The integrated approach of myocardial protection permits bypass grafting and all cardiac procedures to be performed with single clamping of the aorta. The use of single-aortic cross-clamping has been avoided by some owing to concern that this method will extend the ischemic time. There is evidence that morbidity and cost are reduced despite a longer aortic clamp time when integrated protection is applied.[17] These findings contradict the notion that surgeons must battle the clock when the aorta is clamped. The extent of cardiac damage is related to *how* the heart is protected rather than *how long* the aorta is clamped. Blood cardioplegia provides sufficient cardiac nourishment during aortic clamping to permit excellent myocardial protection.

## CARDIOPLEGIC TECHNIQUE

This is a general overview of how cardioplegia is used in typical operations. Special situations and details pertaining to specific operations are further reviewed.

Cardiopulmonary bypass is initiated with core cooling to about 34°C. The aorta is clamped and cold bag 1 is infused antegrade at a flow of 300 mL/min over a 2-min period. The cold bag 1 is then infused via a retrograde cannula into the coronary sinus at a flow of 200 mL/min for 2 min. Septal temperature is monitored throughout. A temperature below 14°C indicates good distribution of cardioplegia and adequate cooling. All cardiac repairs are done while the aorta is clamped, including proximal anastomosis. Intermittent maintenance cardioplegia, bag 2, is given at 15-min intervals, both antegrade and retrograde. After cardiac repairs are completed, a warm reperfusate ("hot shot") is infused antegrade for 2 min (150 mL/min) and then retrograde (150 mL/min). This is followed by a continuous infusion of warm noncardioplegic blood antegrade into the aortic root while the cross-clamp is still in place at a flow of 300 to 350 mL/min at a pressure equal to or less than 80 mm Hg. The aortic clamp is released usually within 3 to 5 min after adequate contractility is observed. The aortic vent is activated and the patient tilted with the head slightly down to evacuate any air while the heart is ejecting.

Alternatively, bag 1 ("warm induction") is used initially to arrest the heart where acute ischemia is present or in cases of severely depressed systolic function. The administration of substrates in this situation has been proven to improve postoperative function. After the warm induction, bag 2 maintenance cold-blood cardioplegia is infused antegrade and retrograde as above.

## CARDIOPLEGIA DELIVERY SYSTEMS

All operations include the use of a heat exchanger to cool or warm the cardioplegia (Fig. 25-4), cannulas for antegrade and retrograde delivery, and a monitoring-infusion system. The system we use is shown in Figure 25-5. The three controls are color-coded and easily within reach.

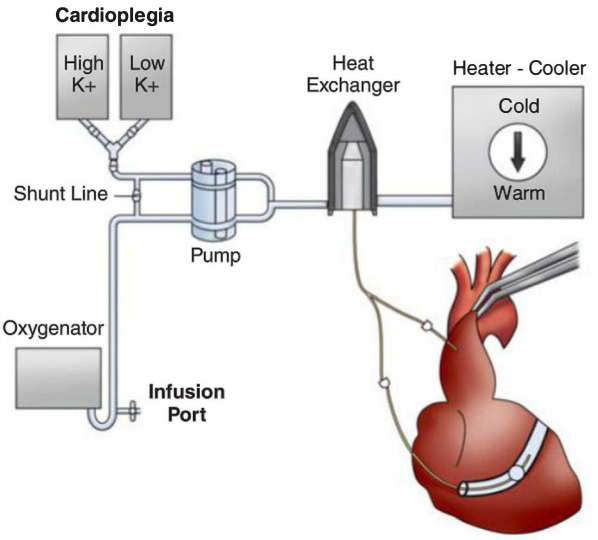

**FIGURE 25-4** Blood cardioplegic delivery system for high-dose (bag 1) and low-dose (bag 2) cardioplegia solutions. These are mixed 4:1 with blood from the oxygenator. The shunt line allows delivery of blood through the roller head of the pump after the warm reperfusate is given.

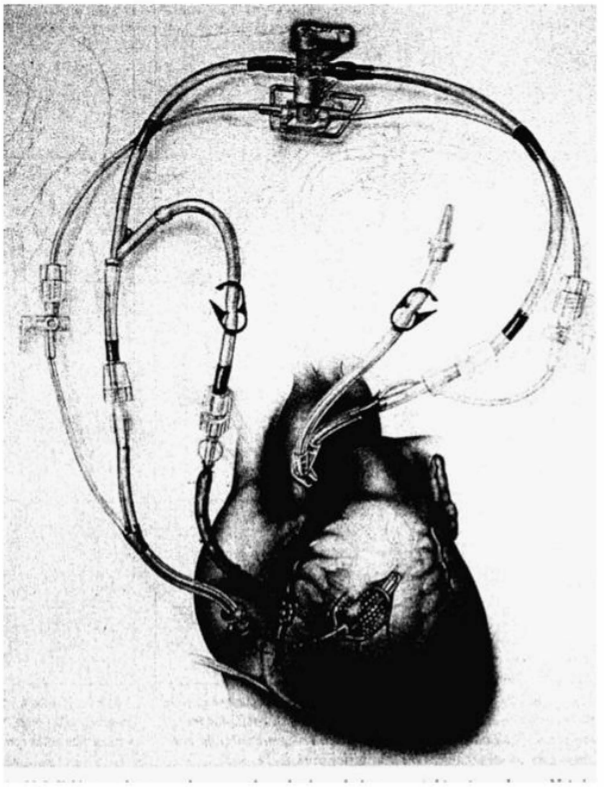

**FIGURE 25-5** Tubing use for antegrade, retrograde, and vein perfusion connected to the retrograde arm. Note the stopcock that allows simultaneous delivery of cardioplegic perfusate and monitoring of arterial or coronary sinus pressure. The tubing connected to the retrograde limb allows simultaneous retrograde/antegrade perfusion down the vein graft or right coronary ostium during aortic valve replacement.

1. A stopcock that switches between antegrade and retrograde infusion. Attached to these infusion lines are thinner ones for infusion-pressure monitoring.
2. A flow clamp to activate the aortic vent.
3. Flow clamps on the retrograde line and on a line attached to this line. The latter can be used to deliver cardioplegia through a vein graft or directly into the coronary ostia via a handheld cannula during aortic valve operations (Fig. 25-5).

An *antegrade* cannula is placed high in the right ascending aorta and slightly to the right side. This cannula contains a pressure line and a vent port to suction air and blood between infusions. Since we use a single-aortic clamping for all operations, when proximal grafting of vein is performed, blood can be vented from the aorta while giving continuous retrograde cold noncardioplegia blood. Placing this cannula slightly to the side of the aorta away from the anterior surface allows pooled blood to be effectively suctioned, thereby permitting good visualization of the anterior surface of the aorta for grafting. This site is not used for proximal grafting and is secured with a purse-string suture at the end of the operation.

The *retrograde* cannula has a self-inflating or manually inflated balloon at its tip; it also contains a line for monitoring infusion pressure. It is placed low in the right atrium, anterior to the venous cannula, and just above the caval junction. It is directed into the coronary sinus by aiming at the left shoulder. The cannula is advanced until it meets resistance within the coronary sinus, usually adjacent to the left atrial appendage (Figs. 25-6 and 25-7).

The coronary sinus can be injured by forceful cannulation or continued administration of cardioplegia when coronary sinus pressure exceeds 50 mm Hg. This can occur while the heart is elevated during circumflex artery grafting. The perfusionist notes high pressure, then low pressure as a consequence of acute perforation, or the surgeon sees red blood accumulate in the pericardial well. Perforation can be repaired directly with 5-0 polypropylene sutures or pericardial pledgets if the tear site is not distinct. Hematomas are often self-contained after heparin reversal.

## MONITORING CARDIOPLEGIA LINE PRESSURE

The regulation of cardioplegia infusion pressure avoids edema and endothelial damage. It also detects aortic insufficiency produced by distortion of the noncoronary aortic cusp by the venous cannula or clinically insignificant regurgitation. Slight manual compression of the right ventricular outflow tract will push the septum against the posterior left ventricle and close the aortic valve, allowing adequate root pressure. During retrograde infusion, measurement of pressure verifies correct placement of the coronary sinus cannula.

During antegrade infusion, aortic root pressure is maintained between 60 and 80 mm Hg at a flow rate of 200 mL/min or, in hypertrophied hearts, 250 mL/min. Blood cardioplegia is given over time to ensure maximal oxygen delivery. Failure

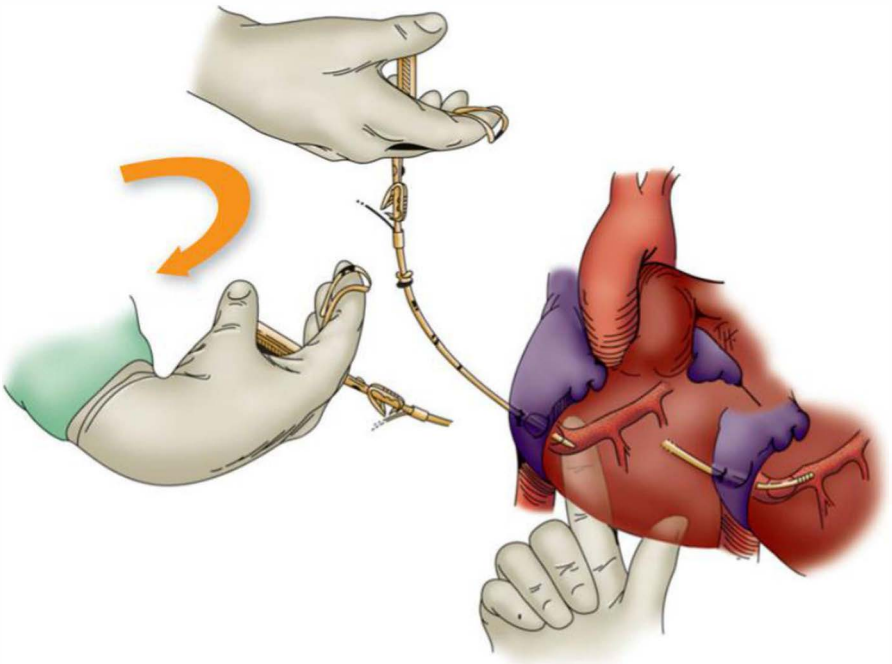

**FIGURE 25-6** Method for introducing the retrograde cannula. Note that the cannula is rotated anteriorly and toward the left shoulder to follow the course of the coronary sinus.

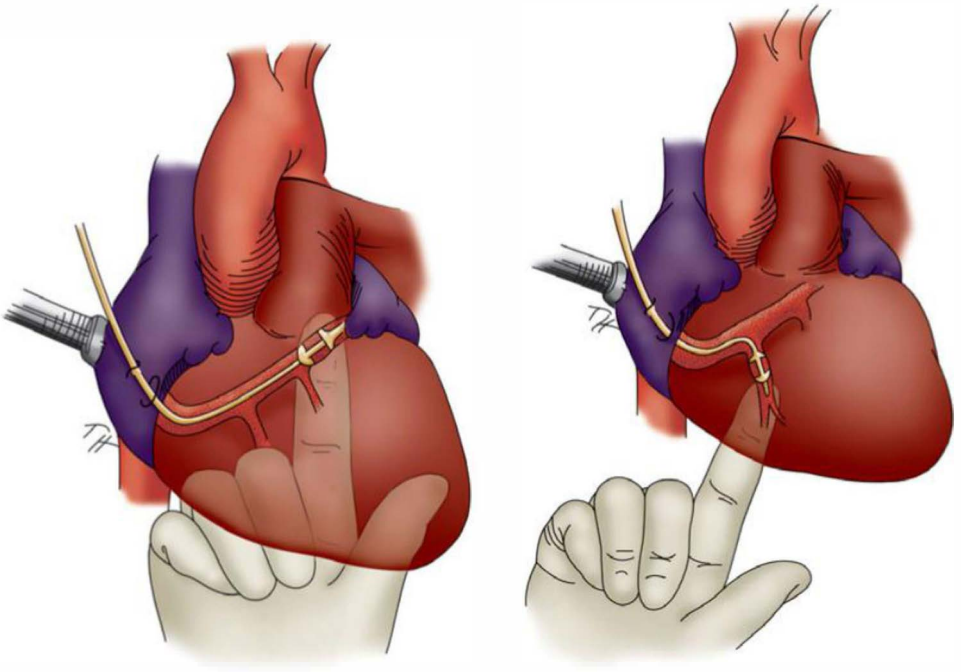

**FIGURE 25-7** **A.** Correct placement of retrograde catheter. **B.** Incorrect placement of catheter into coronary vein, confirmed by palpation.

to arrest means inadequate systemic venous drainage (full heart), incomplete aortic clamping, or aortic insufficiency. Aortic pressure of below 30 mm Hg means that antegrade flow is insufficient and only retrograde infusion should be used. High aortic pressure (greater than 100 mm Hg) may occur with extensive obstructive coronary disease. If this happens, the infusion rate should be slowed to give the correct dose over time. During the final warm cardioplegia infusion ("hot shot"), the aortic root pressure should not exceed 50 mm Hg to avoid endothelial dysfunction.

During retrograde infusion, coronary sinus pressure is maintained between 20 and 40 mm Hg at a flow of 200 mL/min. A coronary sinus pressure greater than 50 mm Hg means improper positioning or cardiac retraction. This is corrected by reducing the flow rate immediately, repositioning the catheter, and then resuming the flow. Textured balloons should not be moved during infusion because of coronary sinus wall traction and possible injury. A coronary sinus pressure below 20 mm Hg indicates that the balloon is not inflated or not occluding the coronary sinus. The cannula tip and balloon should then be repositioned by palpation. Added maneuvers to improve retroperfusion include compressing the junction of the coronary sinus and right atrium or placing a snared suture around the coronary sinus, thus, fixing it in place and preventing regurgitation of cardioplegia into the atrium. Other rarer causes of low pressure include persistent left superior vena cava (SVC) and left atrial unroofing of the coronary sinus. The presence of a left SVC is usually determined before cardiopulmonary bypass and the vessel occluded with a tourniquet only if an intact innominate vein is present. If the innominate vein is absent, only antegrade cardioplegia is used to avoid myocardial underperfusion.

## APPLICATIONS OF CARDIOPLEGIA

### Coronary Artery Bypass Grafting

During CABG operations, the body is cooled to 34°C. The heart is arrested with high-potassium *cold*-blood cardioplegia (bag 1) in elective low-risk operations with good ventricular function. For simplicity, this solution is enriched with aspartate and glutamate, rather than preparing another solution without these. Cardioplegia is delivered antegrade (300 mL/min for 2 min), then retrograde (200 mL/min for 2 min). Alternatively, this same potassium-enriched *warm*-blood cardioplegia ("warm induction") is used initially to arrest the heart in cases of acute ischemia or severely depressed systolic function. After the warm induction, maintenance low-potassium cold-blood cardioplegia (bag 2) is infused into the aortic root and retrograde into the coronary sinus. This same solution is used intermittently during the course of the grafting.

Following cardioplegic arrest, all anastomoses are constructed in a dry operative field using distal/proximal grafting in sequence. The right coronary is grafted first because retrograde nutritive perfusion is limited. Maintenance

cardioplegia (bag 2) is then given retrograde simultaneously via the coronary sinus cannula and its side-arm antegrade into the newly grafted vessel at a flow rate of 200 mL/min for 1 min. Air is purged from the graft as the distal coronary suture is tied. This maneuver protects the right ventricle by antegrade direct coronary perfusion. The left ventricle is simultaneously protected by retrograde perfusion. The aortic vent is temporarily closed to distend the aortic root. While cardioplegia is infusing retrograde and simultaneously through the unattached vein graft, determination of graft length in the distended vein becomes quite easy.

During proximal grafting of vein to the aorta, retrograde cold noncardioplegic blood is infused at 200 mL/min. Cold blood maintains arrest and limits potassium overdose. This solution can be enhanced with CPD, THAM, magnesium, and mannitol, which prevent resumption of low-level electromechanical activity (bag 4, Table 25-4). The aorta is vented by active suction during proximal grafting, allowing good visualization. When proximal grafting is completed, cardioplegia infusion is then switched to the antegrade mode. Air is evacuated from the aortic root as the proximal suture line is secured. Air is also evacuated from the grafts during antegrade infusion with a 27-gauge needle.

Newly constructed grafts perfuse the heart after each proximal connection. The next distal graft is then constructed in a dry operative field while the heart is vented. The sequence is repeated for each distal and proximal anastomosis, leaving one proximal graft to be connected to the aorta after the final distal left internal mammary artery (LIMA) anastomosis is constructed. While the LIMA anastomosis is begun, systemic rewarming is started and the cardioplegic solution is rewarmed.

After the LIMA is grafted, antegrade warm enriched cardioplegia (bag 1) is delivered for 2 min at a flow of 150 mL/min, followed by retrograde warm cardioplegia, also at a flow of 150 mL/min. During the retrograde infusion, the last proximal vein graft is sewn to the aorta, followed immediately by infusion of warm noncardioplegia blood at a flow of 250 to 300 mL/min until the proximal grafting is complete. The heart usually begins contracting and systolic compression of the capillary bed raises coronary sinus pressures, but this is of no concern. Antegrade flow is started to de-air the aortic root, as before, and the grafts are de-aired with the 27-gauge needle to prevent air embolus.

## Combined Operations

In combined valve/coronary procedures, distal coronary grafting is performed first. The valve is then replaced or repaired. Every 15 to 20 min, maintenance cold cardioplegia (bag 2) is delivered through the unattached vein grafts and simultaneously into the coronary sinus. All proximal anastomoses are then constructed while the aorta is clamped. The proximal right graft is sewn last to maximize right ventricular perfusion. Warm cardioplegic reperfusion (bag 1, "hot shot") is started at the end of the next to the last proximal anastomosis. The perfusionist then delivers retrograde warm blood and the aorta is vented gently while the final right graft is sewn to the aorta. As the high-potassium cardioplegia is washed out, the heart begins contracting slowly. The stopcock is switched to antegrade infusion of warm blood as described earlier. When good contractility is observed, the aortic clamp is removed and the patient weaned from cardiopulmonary bypass, usually with minimal inotropic support. Phenylephrine infusion at 0 to 2 μg/kg/min is often needed, since the enriched solutions tend to cause a transient mild vasodilation.

## Evolving Myocardial Infarction

The procedure is slightly modified for patients with acute evolving myocardial infarction and total occlusion of a coronary artery. Cardiopulmonary bypass is instituted in the usual manner with systemic cooling to 34°C. The left ventricle is vented via the right superior pulmonary vein to minimize myocardial oxygen demands. The aorta is clamped and the heart arrested with a warm induction (bag 1), as previously described, followed by maintenance cold cardioplegia (bag 2). The noninfarct vessels are grafted first, as described previously for treating high-risk coronary patients. All proximal anastomoses are made except for one graft, which will be connected to the aorta during the 20-min interval for infarct vessel reperfusion described below. The whole heart receives a final "hot shot" cardioplegia, followed by retrograde warm-blood infusion as in the standard CABG operation.

Following completion of distal and proximal grafting of the compensating remote muscle (except one graft to remote noninfracted muscle), the infarct-related artery is grafted last, following perfusion with warm "rescue cardioplegia" (bag 3) at 50 mL/min (≤50 mm Hg pressure) for 20 min (Table 25-3). This is a substrate-enriched, hyperosmotic, hypocalcemic, alkalotic, and diltiazem-containing solution. Connection of the last proximal graft going to remote muscle is made during prolonged infarct graft perfusion. This interval allows ongoing surgical activity during this 20-min warm infusion via the infarct vessel.

The last proximal anastomosis (from the infarct region) is made after the prolonged reperfusion via the infarct graft. Warm retrograde normal blood perfusion is distributed to the infarct region during this interval of making the aortic connection so as to avoid additional ischemia. Cardiopulmonary bypass with the vented heart is continued for 30 min more, to allow recovery of the newly revascularized infarcted myocardium. We have observed significant return of regional contractility despite more than 6 h of ischemia. The details and outcome of this technique have been previously described.[8]

## Cardiac Reoperations

The integrated cardioplegia method described above has been found to be particularly useful in repeat operations. In

coronary bypass operations, a generally accepted rule is that old grafts should be left undisturbed. This "no touch" technique prevents embolization of friable atherosclerotic debris into the distal vasculature.

Following sternotomy, only the aorta and right atrium are dissected free of surrounding adhesions. Following cannulation and institution of cardiopulmonary bypass, cardioplegia is delivered as in no repeat operations. The aorta is vented to decompress the heart, and only then is the heart freed of surrounding pericardial adhesions. This avoids compression of old vein grafts and remobilization. Distal and proximal grafts are constructed in sequence, as with all coronary operations. The single-aortic cross-clamping technique avoids compression of old grafts and ischemia, which can be induced by the side-biting aortic clamping method, where graft flow is temporarily interrupted.

Clinical outcomes with this method in repeat CABG have demonstrated no increased mortality, even in patients with markedly reduced systolic function preoperatively.[18]

## Myocardial Protection During Aortic Root Replacement

The myocardium must be carefully protected during repair of ascending aortic aneurysm or dissection. The coronary ostia are often isolated for reimplantation into a graft. Intermittent cardioplegia can be administered directly into the unattached ostia, but care must be taken to avoid injury, particularly in cases of aortic dissection. An approach we have found useful is to first graft the right coronary artery with saphenous vein. The proximal right coronary artery is temporarily occluded with a Silastic vascular loop. Cardioplegia can then be administered intermittently antegrade via the right coronary artery and simultaneously retrograde into the coronary sinus. This permits maximum distribution throughout the myocardium and does not interfere with the operation. The aortic root and ascending aorta can be repaired with ease in a dry field. After the root has been reconstructed, the ostia are reimplanted into the graft and the saphenous vein graft ligated at the anastomosis to the right coronary artery, with either a running suture or a large clip. This method assures global myocardial protection and avoids injury to the friable coronary ostia.

## CONCLUSIONS

"Integrated myocardial management" as described above allows cardiac procedures to proceed smoothly and rapidly, since there is no interruption or delay for infusion of cardioplegia. The duration of cardiopulmonary bypass is actually shortened while simultaneously taking advantage of the benefits of different methods. Ongoing studies will likely lead to the incorporation of additional cardioprotective methods, such as preconditioning agents, white blood cell filters, oxygen-radical scavengers, endothelium-enhancing agents, and molecular factors, which will further improve the safety of ischemic intervals and limit reperfusion damage.

## MYOCARDIAL PROTECTION BOARD REVIEW QUESTIONS (CHAPTER 25)

1. Which of the following is not a basic requirement of cardioplegic arrest?
   A. Creation of a dry, bloodless field
   B. Cessation of electromechanical activity
   C. Reduction of myocardial oxygen demand
   D. Retrograde cardioplegia
   E. Uniform delivery of cardioplegia

2. Which of the following is correct regarding blood cardioplegia?
   A. Only method available for cardiac arrest
   B. Allows complete recovery of function after 4 h of arrest
   C. Can only be used in anticipated arrest time is under 2 h
   D. Shifts the oxyhemoglobin dissociation curve to the left
   E. Must ideally be given cold

3. Which is correct regarding the composition of blood cardioplegia?
   A. Has high levels of calcium added to improve contractility
   B. Is hypoosmolar
   C. May contain amino acid substrates to hasten recovery
   D. Has low levels of potassium to prevent systemic hyperkalemia
   E. Typically consists of one part blood and one part crystalloid

4. Which of the following is true for retrograde cardioplegia?
   A. Perfuses the same areas as antegrade cardioplegia
   B. Is cumbersome and technically demanding
   C. Often requires bicaval cannulation and insertion of the catheter under direct vision
   D. Can be given simultaneously with antegrade cardioplegia
   E. Has no proven clinical benefit

5. Which is correct regarding delivery techniques for cardioplegia?
   A. Adequacy of delivery can be determined by manual palpation of the aorta or coronary sinus
   B. Adequacy of delivery can be monitored by the perfusion line pressure
   C. Retrograde infusion pressures above 50 mm Hg require repositioning of the retrograde catheter
   D. If the aortic root pressure exceeds 100 mm Hg during antegrade delivery, retrograde cardioplegia should be initiated
   E. Adequacy of delivery can be monitored by direct measurement of pressure in the delivery catheter

## ANSWERS

1. **Answer: D.** Delivery mode is not a basic requirement of cardioplegia. Antegrade, retrograde, and combination delivery have all been shown to be effective. Creation of a dry, motionless, and bloodless field provides the surgeon optimal working conditions. The cardioplegia should reduce myocardial oxygen demand and be uniformly delivered to all regions of the heart for protection.
2. **Answer: B.** Experimental and clinical outcomes have shown excellent recovery of myocardial function even after several hours of arrest using blood cardioplegia. It can be delivered at a variety of temperatures and is suitable even for short arrest periods.
3. **Answer: C.** A wide range of additives have been proposed for blood cardioplegia. The amino acid substrates aspartate and glutamate have been experimentally shown to become depleted during cardiac arrest. Addition of these substrates results in a more complete recovery of myocardial function.
4. **Answer: D.** Simultaneous antegrade and retrograde cardioplegia can be accomplished because there is adequate drainage through Thebesian veins. Another approach is simultaneous retrograde coronary sinus cardioplegia and antegrade delivery down a vein graft. Retrograde cardioplegia can be associated with decreased perfusion of the right heart. It is simple and is typically easily accomplished with blind insertion of the catheter into the coronary sinus. It has particular benefit in patients with active ischemia and high-grade coronary artery disease.
5. **Answer: C.** A pressure exceeding 50 mm Hg during retrograde cardioplegia indicates that the catheter has advanced too far and there is risk of coronary sinus rupture. High antegrade pressures do not require switching to retrograde cardioplegia but rather signal high-grade coronary artery disease. Adequacy of delivery is not determined by pressure measurements.

# Postoperative Management of the Cardiac Surgical Patient

*Rashna Ginwalla*
*Nauder Faraday*
*Glenn Whitman*

**KEY CONCEPTS**

- Cardiac surgery involves unique anatomic and physiologic stresses that tax the reserve of every organ system. Continuous postoperative surveillance is required for early recognition of pathology and for rapid institution of organ and life-preserving therapies.
- Cardiac surgery causes transient (lasting 12–24 h) myocardial injury, sympathetic hyperreactivity, and the systemic inflammatory response syndrome (SIRS) in nearly all patients. As a result, hemodynamic instability requiring transient pressor and/or vasodilator infusions and intravascular volume expansion should be expected in all patents during the first 6 to 24 postoperative hours.
- Atrial fibrillation/flutter occurs in 30 percent of patients after cardiac surgery, and its incidence can be reduced by half through prophylactic administration of β-blockers, amiodarone, or sotalol.
- Significant pulmonary compromise should be expected in all cardiac surgical patients postoperatively, with 5 percent of patients experiencing overt respiratory failure. Diuresis should be instituted as soon as SIRS abates to limit fluid accumulation in the injured post-CPB lung.
- Liberation from mechanical ventilation should be sought at the earliest possible time in all patients. Extubation in most patients can be achieved as soon as they are awake enough to maintain airway patency and achieve adequate spontaneous gas exchange. In patients with significant respiratory compromise, daily assessment of a spontaneous breathing trial is the best method to assess readiness for extubation.
- Aggressive glucose control with a goal of 100 to 140 mg/dL within 24 h of ICU arrival reduces the incidence of death, sepsis, and renal failure after cardiac surgery.

## INTRODUCTION

Over the past 20 years, the cardiac surgery patient has become more acute, with sicker patients being operated upon. As an example, at Johns Hopkins, just in the past several years, the portion of elective cases for coronary artery disease (CAD) has decreased from 75 percent to approximately 40 percent, while urgent cases have increased from 25 percent to over 50 percent. Nevertheless, despite this increase in acuity of disease, the expected mortality for this same population has remained constant, at approximately 2 percent. It is more than possible that these similar outcomes in the face of sicker patients are the result of improvements in intra- and postoperative management strategies. It goes without saying that prevention of complications requires a thorough understanding of the pathophysiologic basis for the development of organ dysfunction after cardiac surgery, the ability to identify high-risk patients, and the ability to execute therapeutic strategies that prevent complications from developing. In many of those patients who develop complications, early diagnosis and treatment prevent further deterioration and limit subsequent morbidity and mortality.

The early management of the postoperative open heart surgery patient can be viewed as an extension of the intraoperative care the patient received, with a focus on recovery from hypothermia, restoring hemostatic capability, recognition and support during the inflammatory condition

provoked by cardiopulmonary bypass (CPB) itself, and optimization of cardiac function as the heart recovers from the transient ischemic injury sustained while undergoing surgery. Our experience at Johns Hopkins suggests that roughly one-half of all open heart surgery patients have recovered sufficiently to be transferred out of the ICU to the step-down unit in a day and a half, and that for isolated coronary bypass procedures, the ICU recovery period lasts for less than 1 day. Nevertheless, 30 percent of patients remain in the ICU for more than 3 days, and more than 10 percent stay for more than 7 days, indicating that in those patients, at a time when the immediate recovery from intraoperative events peculiar to CPB should have been long over, persistent organ dysfunction requiring critical care continues. To a large degree, the disease processes associated with this latter group of patients are similar to those seen in noncardiac surgical intensive care. Nevertheless, whether in the acute recovery period or a more chronic phase of critical illness, effective postoperative management rests on early recognition of pathology and rapid institution of therapy to prevent further clinical deterioration or the development of overt morbidity. This chapter is designed to review those physiologic disturbances specifically related to postoperative cardiac surgery patients as well as the more common illnesses and conditions associated with critical care, in general.

## PATHOPHYSIOLOGY OF ORGAN DYSFUNCTION AFTER CARDIAC SURGERY

Cardiac surgery involves a number of unique anatomic and physiologic stresses that tax the reserve of every organ system and increase the likelihood that clinical morbidity will develop. A list of these stressors and their pathophysiologic and clinical sequelae is shown in Table 26-1.

## GENERAL MANAGEMENT ISSUES IN THE EARLY POSTOPERATIVE PERIOD

The early postoperative period is characterized by instability involving vascular tone, significant fluid shifts, pulmonary and cardiac function, hemostasis, and renal function. This instability is a direct result of the anatomic and physiologic disturbances that take place intraoperatively (see Table 26-1). In general, resolution is rapid because the primary stressors causing instability (i.e., insults related to CPB) are confined to the first 12 to 24 h postoperatively. Once removed from these intraoperative influences, patients recover rapidly, so long as organ systems were not hurt in a more severe fashion and that the insult of CPB was not too severe for the organ systems that may already have been dysfunctional. Intensive monitoring is needed during this initial recovery phase to determine if the patient has deviated beyond what one normally expects during this critical postoperative time period.

### Transfer of Care and Monitoring

Transport of the patient and the transfer of care from the OR to the ICU is an inherently dangerous process. To reduce risk, hemodynamic stability should be assured prior to leaving the OR. Monitoring during transfer should be at a level comparable to that used intraoperatively and should include at a minimum the following: electrocardiogram (ECG), arterial blood pressure (BP), and pulse oximetry.

On arrival in the ICU, all care providers should initially focus on assuring the adequacy of cardiopulmonary function. Although the anesthesia team who knows the patient well should provide guidance to the receiving care team, in general, mechanical ventilation is protocolized, for example, tidal volume set at 7 to 8 $cm^3$/kg ideal body weight with a rate of 16, a positive end expiratory pressure set at 5 $cm^3$ $H_2O$, and the $FIO_2$ at 1.0. At that point, successive blood gases dictate changes required in ventilation while the weaning of $FIO_2$ can be guided by the $SpO_2$. It should be noted that shivering in response to hypothermia increases $O_2$ consumption and $CO_2$ production, thus increasing the workload of the pulmonary system. As a sedated, postoperative patient may not produce adequate respiratory compensation for this increase in work, hypercapnia with significant respiratory acidosis may ensue unless mechanical ventilation is maintained at appropriate levels.

Hemodynamic monitoring should be reestablished at the intraoperative level. All patients should have arterial BP monitoring. In addition, continual ECG monitoring with ST-segment analysis is standard so as to allow for the early detection of arrhythmias and ischemia. The combination of leads allowing the most sensitive detection of ischemia is somewhat controversial. Some authors advocate monitoring leads $II/V_5$ while more recent data support the use of $II/V_3$ or $V_4$. Full 12-lead ECG analysis should occur on arrival to the ICU. At Hopkins, we have also decided to repeat the ECG at 4 and 8 h, as well as daily on POD 1 and 2.

A chest x-ray is mandatory in all patients to verify (1) the positioning of the endotracheal tube, which is generally halfway between the carina and the sternal notch, (2) that there is no undrained effusion, usually the result of inadequate evacuation in the operating room, (3) that there is no pneumothorax, (4) that there are no unexpected infiltrates, and (5) that the invasive tubes and central venous or pulmonary catheters are well positioned. Left lower lobe atelectasis with silhouetting of the left hemidiaphragm is the rule, although this may not be evident until positive pressure ventilation is discontinued. It should not be overinterpreted.

Routine postoperative laboratory tests should include hemoglobin or hematocrit, sodium and potassium, glucose, calcium, and arterial blood gas; these should be obtained every 4 to 8 h or more frequently when clinically indicated. Additional hematologic and chemistry tests need not be routine but should be obtained based on clinical signs/symptoms.

A central venous catheter is mandatory for the administration of vasoactive drugs. However, the need for a central venous catheter versus a pulmonary artery (PA) catheter

**TABLE 26-1: Anatomic, Physiologic, and Clinical Consequences of Cardiac Surgery and Cardiopulmonary Bypass**

| Stressor | Pathophysiologic Sequelae | Clinical Sequelae |
|---|---|---|
| Anatomic | | |
| Aortic cannulation/decannulation | Aortic atheroembolism | Stroke (large vessel) |
| Aortic cross-clamping/unclamping | Myocardial ischemia/reperfusion injury | LV and RV dysfunction/low CO |
| | Aortic atheroembolism | Atrial and ventricular arrhythmias |
| | | Stroke (large vessel) |
| Cardiac manipulation/positioning | Aortic atheroembolism | Stroke (large vessel) |
| | Decreased cardiac output (OPCAB) | Prerenal azotemia, hepatic, mesenteric insufficiency |
| Atrial cannulation | Atrial trauma | Atrial arrhythmias |
| Pericardiotomy | Pericardial inflammation | Atrial arrhythmias |
| Valve replacement | Septal trauma | AV conduction block |
| | Cordal attachment to valve severed (mitral only) | LV dysfunction/low CO |
| Physiologic | | |
| Extracorporeal circulation | Activation of contact activation pathway of coagulation | Need for heparin/protamine coagulopathy |
| | Activation of fibrinolytic systems | Coagulopathy |
| | Activation of systemic inflammation (complement, leukocytes, cytokines) | SIRS |
| | | Capillary leak syndrome |
| | | Inflammatory end organ damage to brain, heart, lung, and kidney |
| | Microembolization | Stroke (small vessel) |
| Controlled hypotension (MAP = 40–60 mm Hg) | Systemic hypoperfusion | Stroke (watershed) |
| | Sympathetic activation | Arrhythmias |
| | Renin–angiotensin release | BP lability |
| | | Prerenal azotemia, hepatic, mesenteric insufficiency |
| Nonpulsatile blood flow | Systemic hypoperfusion | Stroke (watershed) |
| | Sympathetic activation | Arrhythmias |
| | Renin–angiotensin release | BP lability |
| | | Prerenal azotemia, hepatic, mesenteric insufficiency |
| Hypothermia | Decreased efficiency of coagulation cascade | Coagulopathy |
| | Shivering/increased $O_2$ consumption and $CO_2$ production | Hypercarbia/ventilatory insufficiency |
| | Sympathetic activation | Arrhythmias |
| | | BP lability |

LV, left ventricular; RV, right ventricular; CO, cardiac output; OPCAB, off-pump coronary a rtery bypass; AV, atrioventricular; SIRS, systemic inflammatory response syndrome; MAP, mean arterial pressure; BP, blood pressure.

remains controversial. Although the PA catheter can provide hemodynamic information about a patient's status that might otherwise be difficult to determine, it has yet to be incontrovertibly demonstrated that this information improves patient outcome.

For example, one prospective randomized trial in critically ill patients failed to demonstrate the benefit of PA catheter–directed management compared with a central venous catheter alone[1]; however, a prospective, randomized study in postoperative cardiac surgery patients in which goal-directed therapy was protocolized did show benefit.[2] In the face of this evidence, PA catheters probably need not be routinely used, but when hemodynamics are tenuous and incompletely understood, the information gained from better understanding the patient's cardiac output, filling pressures, pulmonary arterial pressures, and oxygen delivery can significantly impact on therapeutic decision making.

## Hypothermia

During cardiac surgery when cardiac arrest is anticipated, hypothermia is deliberately induced intraoperatively to protect organs from ischemic injury during periods of diminished blood flow. The ability of hypothermia to reduce ischemic organ damage, particularly in the brain, has been shown in a number of animal models and clinical settings. In a prospective randomized trial of hypothermic (28°C–32°C) versus normothermic (37°C) CPB for coronary revascularization, normothermia was associated with a worse neurologic outcome.[3] The degree to which hypothermia should be induced has changed; however, temperatures less than 30°C are associated with higher mortality, increased cardiac dysfunction, more renal injury, coagulation factor and platelet dysfunction, an increased inflammatory response, and an increased incidence of wound infections (see Table 26-1). It

now appears that although a few degrees of hypothermia are beneficial for brain preservation, more severe hypothermia than that appears to be deleterious.[4]

To mitigate the adverse effects of hypothermia in the postoperative period, active warming should be initiated postoperatively with a goal of restoring temperature between 36°C and 37°C. Although a number of warming methods are available, forced-air warming devices appear to be the most effective.

## Cardiovascular System

### HEMODYNAMICS

Hemodynamic instability is common in the early postoperative phase of cardiac surgery. Intraoperative insults (see Table 26-1) frequently have an adverse impact on cardiovascular function. For example, preoperative ischemia, ischemia-reperfusion injury, and CPB-related inflammation all contribute to depressed myocardial contractility after cardiac surgery. In most patients, this dysfunction resolves within 24 h; however, inotropic support may be required until this transient dysfunction resolves. Patients with ventricular dysfunction prior to surgery are more likely to require more inotropic support than those with normal ventricular function.

Inadequate preload, the result of relative intravascular hypovolemia, occurs routinely and can be a major contributor to poor cardiac output and unstable hemodynamics. The causes of intravascular volume depletion are threefold: bleeding, which occurs to a variable degree but averages approximately 400 to 500 $cm^3$ per case; warming and the temperature-dependent opening of vascular beds, most notable when patients return to the ICU cold (that is, less than 36°C); and third space losses, the sequelae of CPB-induced abnormalities that result in systemic inflammation. These three determinants of intravascular volume play an active role for the first 6 to 10 h postoperatively. Thereafter, volume resuscitation to maintain adequate preload should not be required. Should significant volume requirements persist to maintain adequate preload in the face of low cardiac output, other adverse clinical causes should be sought, for example, tension pneumothorax, tamponade, valvular dysfunction, or cardiac ischemia. Finally, despite adequate preload and cardiac function, vascular tone can be excessively high from adrenergic hyperactivation or low from CPB-induced systemic inflammatory response syndrome (SIRS). Thus, transient infusions of vasodilators or vasoconstrictors, separate and apart from inotropic agents, may be needed until vascular stability returns, again, almost always within 24 h of surgery.

The goal of hemodynamic management in the early postoperative phase is to maintain adequate oxygen delivery to the tissues by optimizing cardiac performance. In all cases, this relies on the caregiver to optimize preload and afterload, and thereafter, use inotropic agents or mechanical assist devices, most commonly the intra-aortic balloon pump and rarely a ventricular assist device.

Cardiac performance is reflected in the cardiac index, which normally ranges from 2.4 to 4.2 L/min/$m^2$. However, "normal" cardiac performance in patients after cardiac surgery is not clearly defined, and attempting to reach a specific "value," for example, a cardiac index (CI) of 2.4 L/min/$m^2$ can be self-defeating. Ventricular dysfunction is ubiquitous in the early postoperative period; adequacy of perfusion, therefore, must be determined clinically, though frequently guided by a more quantitative assessment of myocardial performance. Clinical targets that reflect adequate cardiac output are (1) a mean arterial pressure (MAP) adequate for renal, splanchnic, and cerebral perfusion, usually 60 to 85 mm Hg; (2) warm extremities with palpable pedal pulses; (3) urine output of 0.5 mL/kg/h; and (4) the ability to mentate. As mentioned earlier, invasive monitors, such as a PA catheter, can be extremely useful to guide therapeutic decision making, but frequently ideal hemodynamics are not possible to obtain. A CI of 2.0 to 2.2 L/min/$m^2$ is generally adequate immediately following cardiac surgery. Monitoring of mixed venous oxygen saturation, from either intermittent blood sampling or continuous invasive cooximetry, can provide data to complement other information. As a general guideline, a mixed venous saturation of 60 to 70 percent, with an arteriovenous oxygen difference of less than 5 to 6 $cm^3$/dL is adequate. Mixed venous oxygen saturations of less than 50 percent and larger A-$Vo_2$ differences are markers of inadequate oxygen delivery. Invariably, poor oxygen delivery results in an increase in the base deficit with the development of a lactic acidosis, so a blood gas and serum lactate level can be used to help track the adequacy of hemodynamic resuscitation.

Patients who do not exhibit adequate perfusion need immediate resuscitation before end-organ compromise occurs. Frequently, direct cardiac output and intracardiac pressure monitoring using a PA catheter can be particularly useful to diagnose the patient's condition and guide therapy. Furthermore, despite an initial ECG and chest x-ray that may have been acceptable, when inadequate perfusion is recalcitrant to what is perceived as adequate intervention, a repeat ECG and chest x-ray are always in order. Furthermore, a cardiac echocardiogram can be very useful, particularly when tamponade and ventricular dysfunction are part of the differential diagnosis.

When adequate perfusion is an issue, a large number of inotropic and vasoactive agents are available to support the circulation. Each of these agents has particular pharmacokinetic and pharmacodynamic properties that may be more or less advantageous in any single patient (Table 26-2). Although there is no evidence indicating a difference in patient outcome based on selection of vasoactive drug, an astute clinician should be familiar with the theoretic advantages of each agent so as to be able to select agents appropriate to the particular circumstance at hand. Regardless, if oxygen delivery is still marginal after optimization of preload and afterload and the addition of significant inotropic agents, strong consideration should be given to placement of an intra-aortic balloon pump. An intra-aortic balloon pump can be expected to increase coronary perfusion due to diastolic augmentation

**TABLE 26-2: Vasoactive Agents, Dosing, Hemodynamic and Adverse Effects**

[a]Loading dose required.

of pressure and to further diminish afterload as a result of active balloon emptying timed to systole. Although increased perfusion may be less than 500 $cm^3$/min as a result of the balloon mechanics itself, clinically the change in the balance of myocardial oxygen supply and demand can be considerable, leading to vastly improved cardiac performance, with improvement in the CI by as much as 50 percent and mixed venous oxygen saturation by as much as 15 to 20 percent.[5,6]

Furthermore, to the degree that the catecholamine requirements are diminished as a result of the balloon pump, adrenergic causes of cardiac arrhythmias can be mitigated and at times, intractable arrhythmias can resolve.

***Myocardial Ischemia.*** The presence of ECG and echocardiographic evidence of myocardial ischemia appears frequently in the first several hours after coronary revascularization and, if indicative of ongoing cardiac ischemia, is predictably associated with an adverse outcome.[7] However, in the majority of patients who undergo cardiac surgery, early ECG changes are nonspecific and do not represent clinically or hemodynamically meaningful ischemia. However, poor cardiac indices, evidence of shock, high central filling pressures, and arrhythmias all suggest ongoing ischemia and poor ventricular function. In this setting, the presence of regional abnormalities on ECG or segmental wall motion abnormalities by echo support the diagnosis of significant myocardial ischemia. Beta-blockade and antiplatelet/anticoagulant therapy, the therapeutic mainstays for myocardial ischemia in other settings, are generally not useful immediately after cardiac surgery because of the invariable need for inotropes, not myocardial depressants, and the risk of exacerbating postoperative bleeding. Intravenous infusion of nitroglycerin or a calcium channel antagonist may be useful, particularly in cases of internal mammary artery (IMA) spasm[8]; however, hypotension often precludes their use as well.

Medical management of myocardial ischemia after cardiac surgery is limited to physiologic manipulations aimed at preventing shock by optimizing myocardial $O_2$ supply and demand. Improving cardiac output, as always, requires optimization of preload and afterload, and then the addition of inotropic agents. Although evidence supports transfusion of red blood cells to a hemoglobin of 10 to 11 g/dL in patients above 65 years of age with ongoing myocardial ischemia, the applicability of this to the postoperative cardiac surgery patients is questionable, as blood transfusions appear to be associated with a poorer outcome in this patient group.[9] Nevertheless, it is hard to argue against the correction of anemia in the face of ongoing myocardial ischemia. Whether or not medical management is successful in the treatment of postoperative shock

due to ongoing ischemia, consideration of invasive therapy is always warranted, including insertion of an intra-aortic balloon pump, percutaneous coronary intervention, or surgical reexploration and repeat coronary bypass grafting.[5]

***Arrhythmias.*** Supraventricular and ventricular arrhythmias occur commonly after cardiac surgery. A number of factors associated with an increased risk of postoperative arrhythmias have been identified: advanced age, preoperative history of arrhythmia, history of congestive heart failure, use of bicaval venous cannulation, and longer duration of CPB. In addition to arrhythmogenic intraoperative events (see Table 26-1), a number of postoperative conditions can incite arrhythmias as well, for example, sympathetic hyperactivity, myocardial ischemia, electrolyte disturbances, atrial distention, mechanical irritation from an indwelling central venous line, and drug therapies. As in all clinical settings, hemodynamically unstable arrhythmias require immediate attention and treatment, often including cardioversion/defibrillation.

**Bradycardia:** Sinus bradycardia, junctional rhythm, and atrioventricular (AV) conduction disturbances comprise the majority of bradycardic rhythms after cardiac surgery. Perioperative drug therapies (β-blockers, digoxin, or amiodarone), hypothermia, electrolyte disturbances, and direct trauma to conductive tissue may all contribute to the development of bradycardia. High-grade conduction blockade (i.e., new bifascicular or trifascicular block and complete heart block) is the most serious of these as it is frequently associated with significant hemodynamic compromise and reflects an intraoperative injury to the conduction system that may be permanent. Infusion of $\beta_1$-agonists (see Table 26-2) frequently can increase heart rate and perfusion, but pacing is the simplest method of treating any postoperative, symptomatic bradycardia. In this circumstance, whenever possible, AV synchrony should be preserved by simple atrial pacing as stroke volume is greater when the electrical impulse is generated at or above the AV node, with the resultant coincident synchrony of ventricular systole.[10] In patients who require pacing, the rule of thumb is that atrial pacing is favored over AV sequential pacing, which is favored over ventricular pacing. Most patients who have significant AV conduction block that persists 5 to 7 days after surgery require permanent pacemaker placement.

**Supraventricular arrhythmia:** Without prophylaxis, supraventricular tachycardia occurs in 30 to 40 percent of patients undergoing cardiac surgery, more frequent after valve surgery than coronary artery bypass grafting (CABG). The vast majority of supraventricular tachycardia after cardiac surgery is atrial fibrillation (AF) or flutter, which most commonly develops between postoperative days 1 and 4, with peak incidence on days 2 and 3. These two rhythm disturbances are associated with an increased length of hospital stay, higher cost, and increased risk of stroke. In poorly contractile ventricles, it can lead to hemodynamic compromise. The incidence of AF can be reduced by approximately 50 percent by the initiation of prophylactic treatment with β-blockers, amiodarone, or sotalol.[11] Preoperative loading with amiodarone is more effective than postoperative loading; however, both methods reduce the incidence of AF. Daily magnesium started preoperatively and continued for 4 days postoperatively has also been shown to reduce the incidence of AF after CABG. When AF does develop, initial therapy should be directed at assuring hemodynamic stability and rate control. Cardioversion should be used in patients who are hemodynamically unstable. A rapid ventricular response can usually be controlled with intravenous β- or calcium channel blockers, although β-blockers may be superior in the perioperative period. Intravenous amiodarone may be preferable for rate control in patients with reduced LV function (ejection fraction below 40 percent) because it is less negatively inotropic than β- or calcium channel blockers. At Johns Hopkins, currently amiodarone is the drug of choice for postoperative AF, both for rate control and conversion to sinus rhythm.

**Ventricular arrhythmias:** Unexpected, prolonged postoperative ventricular ectopy is unusual and ischemia as a cause should be ruled out. In the face of ischemia, antiarrhythmic therapy may be indicated. It goes without saying that patients who develop sustained ventricular tachycardia or ventricular fibrillation should be cardioverted and/or defibrillated and treated with an antiarrhythmic agent. Amiodarone is the pharmacologic agent of choice according to present American Heart Association (AHA) guidelines. Patients who do experience significant ectopy and/or sudden cardiac death (i.e., in-hospital cardiac arrest) without a reversible cause should be considered for an electrophysiologic study. Particularly in the setting of poor ventricular function, implantation of an automatic internal cardioverter defibrillator (AICD) may improve survival.[12]

## Antiplatelet Therapy and Saphenous Vein Graft Patency

Over the past 20 years, advances in harvesting techniques and the recognition of their impact on outcome have increased the use of arterial grafts for coronary artery bypass surgery, as opposed to the sole use of saphenous vein grafts. Indeed, the IMA has become the standard conduit for the left anterior descending (LAD) artery bypass due to its enhanced (90 percent) patency at 10 years, virtually free of disease. This contrasts dramatically to vein grafts, which show only a 60-percent patency at 10 years, with half of the patent grafts containing significant stenosis.[13] Arterial grafts appear protected from the atherosclerosis that occurs with arterialized vein grafts that clearly is one explanation for their superior patency. However, native coronary artery competitive blood flow contributes to early loss of arterial grafts, implying that below a certain threshold of proximal coronary artery stenosis, arterial conduits should not be used. This is particularly true of the radial artery. In situations where atherosclerosis is clear, but stenosis may not be critically tight, vein grafts

appear superior to arterial ones. The above notwithstanding, an improved survival appears to be most affected by utilization of the left IMA to bypass the LAD coronary. Percent utilization of this conduit for the LAD bypass is a requirement for public reporting by all open heart surgery programs as it reflects the quality of the surgery performed. The top 10 percent of cardiac programs use this conduit for the LAD in over 90 percent of coronary bypass procedures.

A great deal of work has been done in attempting to elucidate the mechanisms underlying vein graft occlusion, in an effort to predict risk factors for graft failure, and to develop therapies to prolong vein graft patency. Postoperative occlusion of vein grafts is a major risk factor for the recurrence of symptoms leading to reoperations for coronary occlusive disease. Hyperlipidemia, low ejection fraction, male gender, cigarette smoking, and a history of prior myocardial infarction are clinical predictors of poor long-term graft patency.

However, short-term graft patency (<1 month after surgery) is determined by intraoperative factors, technical errors in distal or proximal anastomoses, the size and quality of the recipient artery, injury to the vein during its harvest, and low flow rates through the conduit after completion of the anastomosis (≤40 mL/min). Approximately 5 to 10 percent of vein grafts are lost by postoperative day 7, most of these grafts occluding silently. In the early postoperative period, when graft loss is suspected and the patient is hemodynamically compromised, reoperation or catheterization with an eye toward percutaneous revascularization may be indicated.

The mainstay of medical therapy to improve early graft patency relies on antiplatelet drugs, most commonly aspirin (ASA), which has been shown to make a significant difference in 1-week- and 1-year vein graft patency. Aspirin irreversibly blocks platelet aggregation by inhibiting cyclooxygenase-1 (COX-1) and preventing thromboxane A2 production. It lasts the lifetime of the platelet (~7–10 days). In the VA Cooperative Study in the late 1980s, its effects were most profound on the bypasses to smaller vessels. The greatest efficacy at maintaining SVG patency with the least risk of bleeding was demonstrated when ASA was given within the first 6 h postoperatively, but not preoperatively. Although ASA therapy does not appear to have any beneficial effects on vein graft patency after the first year (SVG patency is 95 percent at 1 week, 84 percent at 1 year, 80 percent at 3 years, 69 percent at 6 years, and 61 percent at 10 years), most surgeons and cardiologists continue aspirin indefinitely due to its beneficial effects on the myocardium and general vascular health.[14]

Clopidogrel, a thienopyridine antiplatelet agent, inhibits ADP-dependent platelet activation and aggregation, thus acting on platelets in a manner different from ASA. Most of the initial work with clopidogrel was done in patients with acute coronary syndromes (ACSs), the results of which have led to its virtually universal preprocedural administration in patients undergoing percutaneous interventions (PCIs). Although the risk of bleeding with preoperative ASA has been found to be present but manageable, the risk of major bleeding after clopidogrel is much higher, and prompts many surgeons to delay surgery if possible. Postoperatively, daily clopidogrel use has been associated with a 33-percent reduction in the incidence of recurrent ischemic events over a 4- to 5-year period. However, the increased risk of gastrointestinal (GI) complications associated with prolonged clopidogrel use as well as its association with increased bleeding and surgical site infections mitigates against its routine postoperative use. Oral anticoagulation has shown no benefit compared with ASA in improving graft patency or diminishing major adverse cardiac events (MACE), but clearly it increases bleeding complications. Another class of antiplatelet therapy, glycoprotein IIb/IIIa inhibitors, though beneficial in the settings of ACSs, has not been studied in postoperative CABG patients.

In summary, the most recent recommendations from the American Heart Association/American College of Chest Physicians (AHA/ACCP) include the following: (1) All patients undergoing CABG receive 75 to 162 mg ASA per day, starting within 6 h of operation, or as soon as possible if postoperative bleeding events preclude earlier administration; (2) For those patients allergic to ASA, clopidogrel given as a loading dose of 300 mg within 6 h after surgery followed by 75 mg daily is considered equivalent; (3) Patients undergoing CABG for non-ST elevation ACS receive clopidogrel 75 mg daily for 9 to 12 months after surgery in addition to aspirin; (4) Patients already on clopidogrel for an ACS should stop the drug 5 days prior to scheduled CABG; (5) All patients who undergo CABG with IMA grafts receive 75 to 162 mg aspirin daily, indefinitely.[15]

## Statin Therapy

Statin (3-hydroxy-3-methylglutaryl-coenzyme- alpha- reductase inhibitor) therapy has been shown to reduce the risk of adverse coronary events and all-cause mortality in patients with stable CAD, ACS, and in post-cardiac surgery patients. Early therapy after acute coronary events has been shown to improve outcomes in patients with unstable disease. Statin-mediated effects in stable and unstable CAD are hypothesized to be due to the anti-inflammatory and immunomodulatory "pleiotropic" characteristics of the drugs, in addition to their cholesterol-lowering effects. Convincingly, a recent meta-analysis demonstrated that preoperative statin therapy resulted in a 43-percent odds reduction of early all-cause mortality as well as a significant reduction in AF and stroke.[16]

The risks of initiating or continuing preoperative statin therapy in postoperative cardiac patients, particularly as regards rhabdomyolysis, myopathy, hepatotoxicity, and acute renal failure are small, outweighed by the overwhelming evidence of their protective effects on the myocardium and endothelium. The controversy over the optimum dosage, however, has not yet been resolved. Further trials are needed to determine whether benefits of statins when administered in high dosages outweigh their risks. In addition, caution is advised when prescribing these drugs for patients on immunosuppression (e.g., liver or cardiac transplant recipients), or those with evidence of liver failure.

At Johns Hopkins, we have adopted a policy of placing all patients on postoperative statins as soon as they are able

to tolerate oral medications. Most patients who undergo cardiac surgery have been prescribed statins already. We use an elevation of hepatic enzymes of 3 to 4 times normal as a contraindication to starting or continuing statin therapy, although there are no data expressly supporting this cut-off.

## PULMONARY SYSTEM

Cardiac surgery is associated with a marked reduction in pulmonary function that peaks 24 h after surgery and gradually improves over the next several weeks. The pulmonary defect is characterized by a 30 to 50 percent reduction in forced vital capacity (FVC) and forced expiratory volume ($FEV_1$), reflecting a restrictive lung defect in all patients. There is an increase in lung edema, an increase in atelectasis (almost universally, the left lower lobe is collapsed postoperatively), a decrease in pulmonary compliance, widening of the alveolar–arterial $O_2$ gradient, and increase in the work of breathing. The clinical significance of these gas exchange and restrictive lung defects is dependent on the degree of pulmonary compromise present prior to surgery. For patients with normal pulmonary function, the reduction in pulmonary mechanics and gas exchange has limited clinical consequences; but for those with significant preexisting pulmonary deficits, the new abnormalities can lead to respiratory failure. Parenchymal lung injury from CPB-related SIRS and ischemia/reperfusion injury contributes substantially to postoperative lung dysfunction, and the development of respiratory failure is related to the duration of CPB (see Table 26-1). Although a reduction in pulmonary mechanics is ubiquitous, clinically it is uncommon for patients to suffer respiratory failure (defined as the need for mechanical ventilation for more than 72 h). Diaphragmatic dysfunction from phrenic nerve injury may occur in some patients. However, in this setting, significant respiratory insufficiency does not usually occur unless the injury is bilateral.

Because the CBP-injured lung is susceptible to edema formation, even at relatively low filling pressures, fluid management is a key component of strategies designed to reduce pulmonary complications. As a result, management of the postoperative hemodynamics involves a balance between the benefits of preload augmentation and the risks of pulmonary edema formation. As a general rule, postoperative fluids should be administered in a way that assures adequate hemodynamics at the lowest possible filling pressures; when postoperative SIRS abates, diuresis should begin, usually on postoperative day 1.

### Ventilator Management

The vast majority of patients who undergo cardiac surgery are transferred from the operating room to the ICU with an endotracheal tube in place. In the early postoperative period (the first 24 h), the need for mechanical ventilatory support is based on the following principles: (1) airway protection; (2) oxygenation and ventilation; and (3) the provision of a margin of safety for patients who may encounter significant challenges from hemodynamic instability, acute hemorrhage, and acid/base abnormalities. Weaning from mechanical ventilation in this early period is a matter of providing appropriate support for the pulmonary system until the acute, hemodynamic issues resolve, and then determining the adequacy of oxygenation and ventilation with minimal support, for example, 40 percent oxygen, PEEP of 5 $cmH_2O$, and pressure support of 5 $cmH_2O$. At that point, extubation can be undertaken. (Criteria for initiating the weaning/extubation process are listed in Table 26-3.)

Prolonged mechanical ventilation, although often life-sustaining, is associated with significant complications including barotrauma, oxygen toxicity, glottic and tracheal injury, decreased cardiac output, and pneumonia. Extubation should be sought at the earliest possible time in all patients, taking into consideration that patients who are extubated prematurely and require reintubation have an increased risk of nosocomial pneumonia and an increased mortality risk as well. The challenge for the clinician is to recognize those patients ready for weaning and to time their extubation appropriately. At Hopkins, the median time to extubation for all patients is less than 9 h; but intubation for longer than 24 h occurs in 20 percent of patients.

**TABLE 26-3: Ventilator Weaning and Extubation Criteria**

| | |
|---|---|
| **General criteria** | Clinical status improving |
| | Hemodynamically stable[a] (MAP >65, CI >2 L/min/m²) |
| | Chest tube drainage <50 mL/h |
| | 36°C > temp < 38°C |
| | No shivering |
| **Airway protection criteria** | Awake, follows commands |
| | Cough and gag intact |
| | Muscle strength adequate (patient capable of 5-s head lift) |
| | Pulmonary secretions manageable |
| **Gas exchange criteria** | pH >7.32 |
| | $P_{CO_2}$ <52 mm Hg |
| | $P_{a_{O_2}}$ >70 mm Hg on 40% $O_2$, PEEP 5 $cmH_2O$ |
| **Ventilatory reserve criteria** | f/TV <80 during spontaneous breathing trial on pressure support of 5 $cmH_2O$ or T-piece |
| | Respiratory rate <30 |
| | Negative inspiratory force >−25 $cmH_2O$ |
| | Forced vital capacity >10 mL/kg |

MAP, mean arterial pressure; CI, cardiac index; f/TV, frequency of breathing (i.e., respiratory rate)/tidal volume (expressed as liters).

[a]Pressors/inotropes and circulatory assist devices (e.g., intra-aortic balloon pump) are permitted if doses are not escalating and active titration is not required.

In those patients who have sustained a significant perioperative lung injury, ventilator strategies that reduce tidal volumes (≤6mL/kg) and inspiratory pressures (plateau pressure below 30 $cmH_2O$) have been shown to shorten recovery time and improve survival.[17] The fraction of inspired oxygen ($FIO_2$) should be reduced to 0.5 as quickly as tolerated to reduce potential for oxygen toxicity. Increasing PEEP improves V/Q matching in most patients and facilitates reduction in $FIO_2$.

Ventilator-associated pneumonia (VAP) (defined as a pneumonia that develops 48 h or more after initiation of mechanical ventilation) accounts for a significant, often preventable, complication in critically ill patients. The most recent data suggest that while rates (expressed as cases/1000 ventilator days) have decreased over the past decade, the incidence of VAP is still unacceptably high: 8.1 in trauma, 4.9 in surgical ICUs, and 3.9 in cardiac ICUs.[18] Ventilated patients who develop VAP have a higher mortality than those who do not (46 vs 32 percent, respectively), while those with VAP also spend longer on the ventilator, in the ICU, and in the hospital. As a point of reference, cardiac surgery patients have an incidence of postoperative pneumonia of approximately 1 percent, and as mentioned above, a VAP rate of approximately 4 cases per 1000 ventilator-days.

In 2002, VAP bundles (a "bundle" is a group of interventions related to a disease process that, when executed together, results in better outcomes) were first described as interventions to reduce the incidence and adverse sequelae of VAP. Over the past several years, institutions have refined the bundle initially outlined by the Institute for Healthcare Improvement (IHI) such that it now includes the following five elements: head-of-bed (HOB) elevation, daily sedation "holidays" and assessment of readiness to extubate, peptic ulcer disease prophylaxis, deep venous thrombosis prophylaxis, and daily oral care with chlorhexidine.[19] Implementing all these interventions, however, requires buy-in by the relevant multidisciplinary stakeholders, daily goal setting during physician and nursing rounds, and regular process evaluation and feedback. At Johns Hopkins, it is our routine practice to follow the VAP bundle as currently recommended, a care measure that is an integral part of our daily patient care checklist.

In patients experiencing prolonged intubation, traditional strategies for ventilator weaning include a gradual reduction in the rate of intermittent mandatory ventilation (IMV) or in the level of pressure-support ventilation. Some studies suggest a benefit of pressure-support weaning over IMV weaning, others with a simple, once a day trial of spontaneous breathing. The ability to successfully wean patients from mechanical ventilation may be improved by combining daily spontaneous weaning trials with useful elements from other weaning modalities along with highly predictive extubation criteria [e.g., respiratory rate/tidal volume (L) <80 (also called the rapid shallow breathing index)]. At the moment, in patients who have had median sternotomies and have failed to wean from the ventilator, we perform a tracheostomy no sooner than day 10. Although the evidence is scant, we wait until then for fear of an increased risk of a deep sternal wound infection due to the tracheostomy.

## RENAL SYSTEM

Half of all patients who undergo cardiac surgery will experience a significant reduction in renal function (defined as an increase in serum creatinine greater than 25 percent of baseline). Along with the rise in creatinine seen so often, more significant deterioration in renal function requiring dialysis also presents itself all too frequently, occurring in 4 to 5 percent of patients. Analogous to postoperative pulmonary dysfunction, the development of clinically significant renal dysfunction is directly linked to the severity of preoperative renal impairment.[20] Additional preoperative risk factors for the development of renal insufficiency include valve surgery (vs CABG), reduced LV function, peripheral vascular disease, chronic obstructive pulmonary disease (COPD), and the use of an intra-aortic balloon pump. Despite improvements in renal replacement therapy over the past 25 years, mortality for patients who develop acute renal failure remains approximately 50 percent, with mortality now largely attributable to respiratory, infectious, and bleeding complications instead of renal failure per se.

The overwhelming majority of cases of acute renal insufficiency that develop after cardiac surgery are due to acute tubular necrosis (ATN). The pathophysiologic basis for ATN in cardiac surgery stems from a combination of prerenal causes that progress to frank renal ischemia. Systemic inflammation, renal atheroembolization, and nephrotoxins also contribute to the development of renal dysfunction in this setting. As can be seen in Table 26-1, a variety of intraoperative events (e.g., CPB, controlled hypotension, nonpulsatile blood flow, aortic cross clamping, etc.) can promote the development of renal insufficiency. Postoperatively, renal dysfunction can be exacerbated by persistent hemodynamic instability (i.e., low cardiac output, hypotension, and elevated venous pressures, which overall decrease perfusion pressure).

Management of perioperative renal insufficiency can be divided into two overlapping processes: strategies to prevent the development of renal insufficiency and strategies to treat established renal dysfunction. The mainstay of therapy in both processes is to maintain adequate hemodynamics, targeting a CI and BP to provide adequate renal perfusion. Generally, a CI greater than 2.2 $L/min/m^2$ and MAP greater than 65 to 70 mm Hg is adequate. Recognition that normotensive renal insufficiency can play a role is important, since in some patients, renal perfusion and glomerular filtration will be very afferent pressure-sensitive. In this patient population, invariably those with longstanding, uncontrolled hypertension, afterload reduction to facilitate ventricular stroke volume may lead to a significant prerenal state. Tolerance of higher systemic BPs may be required to maintain renal perfusion. The mortality associated with renal failure is so significant that in the face of a rising creatinine, assurance of adequate perfusion is paramount. When unclear, the threshold for invasive monitoring, for example, PA catheterization and cardiac output assessment and echocardiography should be lowered. In addition to hemodynamic management, nephrotoxins should be discontinued whenever possible.

Nonsteroidal anti-inflammatory agents and angiotensin converting enzyme inhibitors are two commonly used drugs that should be avoided in the setting of acute renal dysfunction.

A number of agents including diuretics (furosemide, mannitol), dopamine, and, more recently, fenoldopam (a selective dopamine$_1$ receptor agonist) are purported to be renoprotective. Nevertheless, data do not support their use for prophylaxis against renal failure in cardiac surgery. Unfortunately, once renal dysfunction has occurred there are no specific therapies for its amelioration; treatment is supportive only. The atrial natriuretic peptide, anaratide, initially showed promise for the treatment of ATN, but subsequent investigations have shown no benefit. Another natriuretic peptide, nesiritide, has proven to be of benefit in the treatment of decompensated heart failure and may have benefit in the treatment of postoperative patients with congestive heart failure and concurrent renal dysfunction. Nevertheless, to this point, its benefit is not clear, and its expense and the risk associated with its use (severe hypotension) may outweigh any benefit derived.

The mainstay of treatment for renal dysfunction begins by ensuring adequate hemodynamics and avoiding nephrotoxins. Once prerenal and postrenal causes have been ruled out, management of established renal insufficiency is focused on attempting to maintain appropriate fluid and electrolyte balance. Fluid intake should be kept to a minimum. In oliguric patients, diuretics can be administered in an attempt to improve urine output and facilitate fluid management and the treatment of hyperkalemia. Although nonoliguric renal failure has a better prognosis than oliguric renal failure, data are limited that the use of diuretics to induce a nonoliguric state changes the overall outcome. Nonetheless, fluid and electrolyte management is simplified in patients in whom diuretics improve urine output.

## Dialysis

The indications for dialysis in renal failure following cardiac surgery are the same as in other settings: fluid overload, hyperkalemia, acidosis, and uremia. Renal replacement therapy can be provided as conventional intermittent hemodialysis (IHD) or as continuous hemodialysis (usually as veno–veno hemodialysis, or CVVHD). A comparison of the two modes is shown in Table 26-4. The major advantage of IHD—rapidity of clearance and fluid removal—is also its major disadvantage; it can lead to hemodynamic instability, not encountered to any significant degree with CVVHD. When IHD is chosen for stable patients, recent data demonstrate that daily hemodialysis improves renal recovery and survival better than every-other-day dialysis.

# GASTROINTESTINAL SYSTEM

GI complications occur in approximately 1 percent of patients undergoing cardiac surgery. The most common complication is upper GI bleeding, usually from duodenal or gastric ulceration. Ileus, pancreatitis, and mesenteric ischemia may also occur. Splanchnic hypoperfusion during CPB is purported to be the pathophysiologic mechanism underlying these complications, although embolization to the splanchnic bed during intraoperative aortic manipulation may also play a role. In those patients who develop acute mesenteric ischemia, mortality is high.

Patients undergoing cardiac surgery should receive stress ulcer prophylaxis. Although the appropriate duration of prophylaxis in this particular patient population has not been well studied, therapy should continue for at least as long as the patient remains mechanically ventilated.

## Nutritional Support

Cardiac surgery patients who develop significant postoperative complications are at risk for the development of malnutrition in the same way as other critically ill patients. The acute stress response to critical injury/illness includes the development of a catabolic state characterized by (1) increased glycogenolysis and gluconeogenesis (often with hyperglycemia and insulin resistance), (2) increased proteolysis and nitrogen wasting, and (3) alterations in micronutrients. The extent of muscle wasting and weight loss in the ICU is inversely correlated with long-term survival. Malnutrition is associated with a number of deleterious consequences, including infection, poor wound healing, the formation of decubitus ulcers, overgrowth of bacterial flora, and immune system dysfunction.

Although the presence of malnutrition is clearly associated with adverse outcome, the impact of nutritional support on outcome in the critically ill patient is more controversial. Data that specifically address the utility of nutritional support in cardiac surgery patients are nonexistent; one must

**TABLE 26-4: Comparison of Renal Replacement Therapy Modes**

| | Urea Clearance | CV Stability | Osmolar Stability | Fluid Balance | Cytokine Clearance |
|---|---|---|---|---|---|
| IHD | 200 mL/min<br>22 L/day (4 H × 3/week) | – | – | – | – |
| CVVHD | 25 mL/min<br>36 L/day | + | + | + | + |

CV, cardiovascular; CVVHD, continuous veno–veno hemodialysis; IHD, intermittent hemodialysis; –, disadvantage; +, advantage.

extrapolate from the general surgery literature. In one meta-analysis of randomized trials in patients who underwent general surgery, total parenteral nutrition did not change overall mortality but was associated with fewer major complications than standard care (i.e., oral diet and dextrose infusion). In surgical patients with protein–calorie malnutrition, parenteral nutrition reduced both mortality and infectious complications compared with standard care. However, enteral support is associated with an even lower risk of infectious complications than parenteral support and is therefore preferred if at all possible.[21]

## Glucose Management

Hyperglycemia has been shown to be deleterious to critically ill patients. Various studies have shown a direct relationship between hyperglycemia and infection, need for renal replacement therapy, ventilatory support, blood transfusion, and mortality. More specifically, in postoperative cardiac surgery patients, elevated blood glucose has been linked to an increased incidence of deep sternal wound infections, all-cause infection and sepsis, and mortality. High levels of serum epinephrine and cortisol contribute to this problem of hyperglycemia by producing a state of insulin resistance.

The initial data in postoperative open heart surgery patients, which showed benefit from the lowering of blood glucose, were in diabetics, wherein dramatic improvement in mortality as well as deep sternal wound infections occurred with intravenous insulin therapy. The target blood sugar in the population that benefited was 100 to 150 mg/dL. Subsequent data in a mixed medicine and surgery population in which over half were open heart surgery patients justified even tighter control, between 80 to 110 mg/dL. However, it now appears that the morbidity and mortality associated with the episodes of hypoglycemia associated with such tight control outweigh the benefits,[22] and thus current thoracic society recommendations are blood glucose targets of less than 180 mg/dL for the first two postoperative days, controlled with intravenous insulin infusion.

# INFECTION

Patients undergoing cardiac surgery are at risk for surgical site infections, as with any surgical patient population, and perioperative prophylactic antibiotics are recommended. A first- or second-generation cephalosporin should be given, unless allergic to penicillin, in which case vancomycin should be substituted. These antibiotics should be discontinued in less than 48 h to be compliant with the current guidelines of the Surgical Care Improvement Project.

## Sternal Wound Infections/Mediastinitis

Deep sternal wound infections occur in approximately 1 to 2 percent of patients after open heart surgery, although the literature cites incidences that vary from as low as 0.2 percent up to 8 percent. What is crucial about this particular infection is that the associated mortality can be as high as 50 percent. Furthermore, this complication occurs late, 1 to 2 weeks past surgery, often after discharge.

Risk factors for the development of sternal wound infections include diabetes, obesity, surgical reexploration (for bleeding), the use of the IMA, and prolonged postoperative ventilation and ICU stay. The classic signs and symptoms of mediastinitis are chest pain out of proportion to what should be experienced so many days from surgery, sternal instability, fever, and a significant leukocytosis. Effective therapy requires immediate and aggressive wound debridement with placement of vascularized tissue, muscle, and even omentum, in the anterior mediastinal space. On occasions, the sternum can be saved. Finally, appropriate and prolonged antibiotics are required, as guided by the intraoperative cultures that should always be obtained at the time of the initial mediastinal exploration.

## Venous Catheter Infections

The presence of central venous catheters in cardiac surgery patients is nearly universal. These catheters are useful for administering medications that cannot be safely given peripherally and for monitoring hemodynamic status. However, they are associated with the development of mechanical (pneumothorax, bleeding, venous thrombosis) and infectious complications that occur with an overall frequency of between 5 and 20 percent. Subclavian vein catheterization is associated with a lower complication rate (except for pneumothorax) than with the use of either the femoral or internal jugular vein; therefore, the subclavian site is preferred. Because the incidence of complications from central venous catheters is alarmingly high, an incidence that increases with time, the need for ongoing central venous access should be evaluated on a daily basis. All central venous catheters should be removed at the earliest possible time.

A variety of strategies to prevent infectious complications from central venous catheters have been tested, as demonstrated in Table 26-5.[23] In brief, full barrier protection (i.e., sterile gown and gloves, cap and mask, full-body sterile drape) during catheter insertion and skin preparation with chlorhexidine have proven efficacious in reducing catheter-related infectious complications and should be the standard of care. Antiseptic-coated catheters are effective at reducing infectious complications and are cost-effective when the hospital's rate of catheter-related bloodstream infection (CRBSI) is greater than 2 percent.

Routine scheduled replacement of catheters over a guidewire or placement at a new site does not decrease infectious complications and is associated with an increased risk of mechanical complications. Catheters should be replaced only when there is clinical suspicion of infection. An algorithm for the management of suspected catheter-related infection has been developed, but, briefly, a catheter-related infection should

**TABLE 26-5: Interventions to Prevent Infectious Complications of Central Venous Catheters**

| Type of Intervention | Rationale |
|---|---|
| Avoid scheduled routine catheter changes | Routine catheter changes to new sites do not decrease the risk of catheter-related bloodstream infections (CRBSI); routine rewiring of existing catheters is associated with a trend toward increased CRBSIs |
| Remove catheters as soon as they are not needed any more | Likelihood of colonization and CRBSIs increases over time |
| Use maximal sterile barrier precautions during insertion, including full gown, hat, mask, gloves for all personnel involved in the procedure, as well as full-length sterile drapes | Maximal sterile barrier equipment use reduces cost & infection rates |
| Use the subclavian venous site for catheter insertion | Subclavian catheterization shows the greatest reduction in risk of infection compared with internal jugular and femoral venous cannulation sites |
| Avoid antibiotic ointment applications to central venous insertion sites | Rates of colonization by fungi increased, growth of resistant bacteria encouraged, and infection risk not decreased |
| Disinfect catheter hubs | Hubs are common sites of catheter contamination |
| Use antimicrobial-impregnated catheters | Reduces the risk of CRBSIs, and also cost |

Adapted from McGee DC, Gould MK. Preventing complications of central venous catheterization. *N Engl J Med* 2003;348(12):1123–1133.

be suspected in any patient who has had a central venous catheter in place for 3 days or more and who displays evidence of infection without an identifiable source. If evidence of an exit-site infection is present on examination, the catheter should be removed and a new one placed at a new site. If the exit site is not clearly infected, the catheter should be exchanged over a guidewire and the intracutaneous portion sent for culture. If the catheter culture is positive, the indwelling catheter should be removed and a new one placed at a new site. If the catheter culture is negative, a catheter-related infection is unlikely.[23]

## Sepsis

Sepsis is a systemic response to infection that is defined by (1) a white blood cell count above 12,000, below 4000, or with more than 10 percent bands and (2) two or more of the following: temperature above 38.5°C or below 36.0°C, heart rate above 90 beats per min, respiratory rate above 20 breaths per min, or $PaCO_2$ below 32 mm Hg. Septic shock is defined as sepsis-induced hypotension (systolic BP less than 90 mm Hg or greater than 40 mm Hg reduction from baseline) or the requirement for vasopressors/inotropes in the face of evidence for organ hypoperfusion (e.g., altered mental status, oliguria, lactemia) despite adequate fluid resuscitation. Severe sepsis is associated with a mortality of 30 percent.

The key components of successful management are rapid, effective hemodynamic resuscitation and early administration of appropriate antibiotics for source control. In the emergency room setting, rapid institution of goal-directed therapy (fluids to maintain central venous pressure at 8 to 12 mm Hg, vasopressors to maintain MAP above 65, vasodilators to maintain MAP below 90, and red cell transfusion and/or dobutamine to achieve mixed venous $O_2$ saturation above 70 percent) in patients presenting with sepsis improved in-hospital survival from 30 to 45 percent.[24] These findings contrast with older studies that failed to show a benefit of hemodynamic optimization strategies, but the older studies began goal-directed therapy much later in the septic process. Early, rapid resuscitation with goal-directed therapy appears to be vital to an improved outcome.

The Surviving Sepsis Campaign (SSC) was an effort to consolidate evidence-based best practices identified to reduce the significant mortality and morbidity in patients with sepsis and septic shock. Following these management guidelines, the IHI and the Volunteer Hospitals Association (VHA) put forth a series of interventions that would work synergistically to improve outcomes in sepsis and septic shock. These were organized into the sepsis resuscitation bundle, to be implemented within the first 6 h after diagnosis of severe sepsis, and the sepsis management bundle, to be initiated simultaneously but to be completed within the first 24 h after diagnosis. Although these hopefully do not routinely need to be addressed in the postoperative care of cardiac surgical patients, a thorough knowledge of the sepsis bundles is essential to their care.

Since the publication of the initial SSC guidelines in 2001, updated as recently as 2008, multiple studies have demonstrated significant decreases in mortality and morbidity in septic patients with the implementation of the sepsis bundle. However, it must be stressed that bundles, in and of themselves, are not the answer to managing septic shock. Instead, they serve as tools to implement evidence-based clinical practice guidelines, and encourage a multidisciplinary team-based approach to the complex management of these critical patients.

Regarding steroids in the treatment of septic shock, steroids (hydrocortisone 50 mg q 6 h) improve survival and reduced the need for vasopressor therapy in patients with relative adrenal insufficiency (defined as failure to increase serum cortisol by at least 10 μg/dL during the ACTH stimulation test), but no benefit has been observed in patients without adrenal insufficiency.[26]

## CHECKLISTS AND CLINICAL PATHWAYS IN CARDIAC SURGERY

Checklists have been part of the standard of care in the aviation industry for many years. The crucial role they played in the Michigan Keystone project that dramatically minimized the incidence of CRBSIs in ICU patients has led to their introduction into the field of critical care.[27,28] Critical care and perioperative care have become increasingly complicated, and without utilization of external aids, reliance on individual, physician performance will lead to continued, preventable errors in care and patient management. The creation of checklists that are task-specific can be a cumbersome job, but if undertaken thoughtfully and with an inbuilt plasticity, it can have lasting effects on outcomes. The underlying premise involves the simplification of a process, procedure, or intervention in order to make that process safer. However, simply creating a checklist and handing it to ICU or surgical staff to implement is doomed to failure; the engagement and buy-in of those who will be actively involved in implementing such a tool is crucial to its success. Surgeons are just now beginning to implement tools such as checklists into their practices to attempt to improve outcomes in the perioperative care of their patients (also see the UK Society for Cardiothoracic Surgery's website (www.scts.org)).

Similarly, "critical pathways," defined as "problem-specific protocols designed to move patients along a designated set of intermediate then long-term goals in a timely fashion" have been developed. In cardiac surgery, this is done in an attempt to "fast-track" straightforward cardiac surgery patients toward goals such as earlier extubation, more rapid mobilization, and removal of invasive lines and devices as soon as medically allowed. Many of these protocols use daily checklists that differ based on the postoperative day, and make allowance for the individual variations of each patient, but overall, aim to keep patients "on-track" to early (but safe) discharge.

The common theme to the successful implementation of these types of patient-safety, quality assurance tools is a multidisciplinary approach to their creation and use, with a culture of openness to improvement and revision of the process. In addition, inculcating in the work environment the expectation of performance improvement via measurement of goals, with constant and appropriate feedback, is required if quality is to be maintained. The successful physicians (medical students, residents, and attendings) have made personal checklists for years. Formalizing them and making them a part of the entire caregiving team is now becoming the long overdue norm.

## POSTOPERATIVE MANAGEMENT OF THE CARDIAC SURGICAL PATIENT BOARD REVIEW QUESTIONS (CHAPTER 26)

1. An 87-year-old male with an ejection fraction of 35 percent undergoes an uneventful triple-vessel CABG. He is extubated within 6 h after surgery, and transfers to the step-down unit the next day on aspirin, furosemide, and potassium with a mean blood pressure of 75. Two days later, he is transferred back to the ICU reintubated, hypotensive, in atrial fibrillation with a rapid ventricular response at a rate of 200 bpm. He is successfully cardioverted, and in sinus rhythm at 90, his blood pressure stabilizes. His magnesium and potassium were 2.1 and 4.2 mEq/L, respectively. His oxygen saturation had been 92 percent on room air when he developed atrial fibrillation, and rose with nasal oxygen. His EKG showed no evidence of ischemia. How could this complication have potentially been prevented?
   A. Used nasal oxygen until room air sats were >95 percent on room air, not 92 percent
   B. Administered amiodarone postoperatively
   C. Prescribed only thick liquids to prevent aspiration
   D. Kept this elderly patient in the ICU longer for more intense monitoring
   E. Prescribed warfarin postoperatively

2. A 24-year-old male undergoes a left ventricular (LV) septalmyectomy for hypertrophic obstructive cardiomyopathy (HOCM). He separates easily from bypass with a CVP of 9, and returns to the cardiac ICU in normal sinus rhythm at a rate of 90, with a left bundle branch block (LBBB) and atrial and ventricular epicardial pacing wires in place. During the first hour of his postoperative course, his blood pressure is very labile, with systolic pressures ranging from 70 to 180, and a CVP of 3. What should be the course of action in the immediate postoperative period to stabilize this patient?
   A. Initiation of nitroprusside as an afterload reducing agent
   B. DDD pace at 100 bpm
   C. Add β-blocker to minimize stress on the aortic suture line
   D. Volume resuscitation
   E. Add milrinone at 0.3 μg/kg/min

3. The likelihood of requiring tracheostomy for ventilator-dependent respiratory failure is greatest in which of the following patients?
   A. A 30-year-old Marfan patient after an emergency aortic root replacement for an acute ascending aortic dissection
   B. A 70-year-old patient with baseline room air hypoxia on home oxygen but without evidence of $CO_2$ retention s/p semi-urgent 4-vessel CABG in the setting of a NSTEMI
   C. A 70-year-old 40 pack-year smoker after aortic valve surgery extubated intraoperatively who required reintubation upon arrival to the ICU for a severe respiratory acidosis with somnolence
   D. A 80-year-old 100 pack-year smoker who underwent a redo sternotomy for coronary bypass and rereplacement of his mitral valve, with a bypass time of 270 min and intraoperative IABP placement due to initial inability to separate from CPB
   E. A 72-year-old patient with a juvenile history of Guillain–Barré syndrome requiring a tracheostomy at the time, now s/p 3-vessel CABG

4. A 75-year-old man undergoes a 2-vessel CABG with a LIMA–LAD arterial graft and a saphenous vein graft to his obtuse marginal artery. His 90 percent proximal RCA stenosis is unable to be revascularized due to a poor distal vessel. Two hours after surgery, the EKG shows inferior ST segment elevation. He also has bradycardia with first degree heart block and a rising CVP with no change in the PAD. On epinephrine at 0.15 μg/kg·min and AV pacing at 90, the mean blood pressure is 55 mm Hg, the cardiac index is 1.8 L/min/$m^2$, and the mixed venous oxygen saturation is 48 percent. The next appropriate step in management is:
   A. Immediately place an intra-aortic balloon pump (IABP)
   B. Undergo urgent cardiac catheterization with an attempt to stent the RCA
   C. Add dobutamine to improve cardiac output
   D. Stop pacing and allow patient to have his own AV sequential rhythm
   E. Start amiodarone to prevent ischemia-induced atrial or ventricular arrhythmias

5. Efforts to reduce nosocomial infections in patients after open heart surgery should include which of the following:
   A. Routine central venous catheter changes every 72 h to minimize the risk of catheter-related bloodstream infections
   B. Continuation of antibiotics as long as the patient is intubated and mechanically ventilated to prevent ventilator-associated pneumonia
   C. Removal of the urinary catheter as soon as the patient is extubated, stable, and mobile
   D. Avoidance of providing enteral or parenteral nutrition for patients in critical condition for greater than 5 days
   E. The use of blood glucose control via an insulin sliding scale only after the patient is extubated and eating a regular diet

## ANSWERS

1. **Answer: B.** Prophylactic amiodarone may reduce the incidence of postoperative atrial fibrillation. Postoperative atrial fibrillation has many etiologies, including hypoxia, ischemia, hypomagnesemia, and hypokalemia. Aspiration of liquids in an 87-year-old man resulting in hypoxia-induced atrial fibrillation is unlikely give the patient's stable respiratory status. Prolonged observation in the ICU with more intense monitoring does not prevent arrhythmias. Prophylactic anticoagulation with warfarin has no role in the prevention of postoperative atrial fibrillation. Atrial fibrillation develops in approximately 30 percent of CABG patients, most commonly on the second postoperative day. Although a β-blocker diminishes this incidence as effectively as amiodarone, in this patient with borderline blood pressure, amiodarone is the drug of choice for atrial fibrillation prophylaxis.
2. **Answer: D.** HOCM patients, by the nature of their pathophysiology, demonstrate hypertrophy of their entire left ventricle, not just the septum, and are therefore exquisitely sensitive to preload to maintain an adequate stroke volume. Afterload reducers such as nitroprusside or nicardipine may reduce blood pressure when hypertensive, but will also produce vasodilation, exacerbating the hypotension. AV pacing in a DDD mode at 100 compared to the patient's intrinsic rate of 90 will not increase the patient's cardiac output significantly and will not affect the lability of this patient's blood pressure. β-blockers in the face of LBBB might lead to heart block at this early time period and will exacerbate the hypotension. Milrinone will increase contractility, but in a noncompliant, thick, poorly filled ventricle, might lead to a functional subaortic obstruction, despite its surgical correction. This young, otherwise healthy 24-year old should be aggressively volume resuscitated with crystalloid to provide the hypertrophied LV with adequate preload.
3. **Answer: D.** The incidence of tracheostomy after open heart surgery is less than 2 percent, and the major risk factors include preexisting pulmonary dysfunction and prolonged cardiopulmonary bypass time. The young patient with Marfan syndrome should have no difficulty with extubation, despite the emergent nature of his surgery as long as there is no cerebral ischemic injury. In the chronically hypoxic patient, although oxygenation might be difficult early in the postoperative period, ventilation should be manageable, and current noninvasive techniques to increase the inspired oxygen concentration should allow extubation. Failure of intraoperative or early extubation is most probably due to weakness and residual anesthesia-induced insensitivity to hypercarbia, and should not lead to a prolonged intubation. In patients with a remote history of Guillain–Barré syndrome, residual muscular weakness should not be an issue.
4. **Answer: A.** Placement of an intra-aortic balloon pump (IABP) will improve the hemodynamics by augmenting diastolic blood pressure. This will, in turn, increase coronary perfusion, decrease aortic systolic pressure (a measure of LV afterload), and decrease LV end-diastolic pressure (a measure of preload). The end result is a decrease in myocardial oxygen demand, which should support the patient's hemodynamics during this acute inferior infarction. Although cardiac catheterization is always an option to consider in order to percutaneously revascularize the RCA, this patient will benefit from immediate mechanical support. Dobutamine may exacerbate the hypotension and increase myocardial work. Cessations of pacing and amiodarone have no role in the therapy of ventricular failure with shock.
5. **Answer: C.** Removal of the urinary catheter as soon as the patient is extubated, stable, and mobile. Urinary tract infections are the most common nosocomial infection, and the incidence is directly related to duration of the indwelling bladder catheter. Sterile barrier precautions at the time of insertion, along with timely removal of central venous catheters (not routine replacement of such catheters), diminishes the incidence of central venous line associated blood stream infections. Prolonged antibiotics are ineffective in preventing ventilator-associated pneumonia. Early, aggressive maintenance of nutrition and an anabolic state is beneficial in reducing postoperative morbidity, as is the prevention of hyperglycemia, without undue delay.

# Primary Coronary Artery Bypass Surgery

*G.D. Rushing*
*David D. Yuh*

**KEY CONCEPTS**

- Epidemiology
  - Affecting more than 1.5 million Americans annually, coronary artery disease is the most common form of heart disease, and its complications are the leading cause of death in both men and women.
- Pathophysiology
  - Coronary artery disease is generally caused by atherosclerotic luminal narrowing, resulting in insufficient coronary blood flow to the myocardium. The process consists of subintimal atheroma deposition, leading to arterial luminal stenosis or occlusion and wall thickening.
- Clinical features
  - Typically, significant coronary atherosclerosis becomes manifest as angina, but it can also present with anginal-equivalent symptoms, including dyspnea, dizziness, syncope, and pulmonary edema. Malignant coronary disease leading to ischemic cardiomyopathy is associated with congestive symptoms. Identified factors that contribute to severe atherosclerotic coronary artery disease include obesity, hypercholesterolemia, obesity, diabetes, tobacco use, and sedentary lifestyle.
- Diagnostics
  - Twelve-lead electrocardiography is initially used to diagnose myocardial ischemia. Further investigation consists of exercise stress testing, evaluation of myocardial enzymes (i.e., CPK-MB, troponin), echocardiography, and coronary angiography.
- Treatment
  - Initial medical management of acute myocardial ischemia consists of beta blockade, nitrates, antiplatelet therapy, and supplemental oxygen. After precise delineation of coronary arteriopathy, definitive treatment consists of coronary artery bypass grafting (CABG) or percutaneous angioplasty and stenting.
- Outcomes/prognosis
  - CABG carries an overall mortality of about 3 percent; elective primary coronary bypass carries a mortality rate of approximately 1.7 percent. Complications associated with CABG include renal failure, neurologic injury, heart failure, hemorrhage, respiratory failure, and renal dysfunction. Overall, CABG achieves excellent outcomes with respect to anginal relief and resumption of normal activities. In general, completeness and durability of revascularization is superior with surgical revascularization versus percutaneous interventions.

## INTRODUCTION

Coronary artery disease represents the most common cause of insufficient oxygen delivery to the myocardium, referred to as myocardial ischemia. Understanding the pathophysiology of arterial disease with subintimal atheroma and plaque formation has been a breakthrough of modern medicine. Even with our advanced understanding of heart disease, it remains the most common cause of death for Americans. Cardiovascular disease claims more lives (men and women) than cancer, trauma, and pulmonary disease combined.[1]

The first coronary artery bypass grafting (CABG) operation, using saphenous vein conduit, was performed by Dr. David Sabiston at Johns Hopkins Hospital in 1962 and has evolved into the "gold standard" therapy for patients with multivessel coronary artery disease. Despite advances in percutaneous interventional techniques, CABG remains among the most frequently performed operations in the

United States, associated with approximately US$50 billion in annual health care expenditures.

## NORMAL CORONARY ANATOMY AND PHYSIOLOGY

The right and left coronary arteries originate from the ascending aorta behind their respective aortic valve leaflets, usually in the upper third of the sinuses of Valsalva.[2] By convention, the artery that supplies the posterior descending artery (PDA) determines the coronary *dominance*. The coronary circulation is classified as "right dominant" if the PDA is supplied by the right coronary artery and as "left dominant," when supplied by the left circumflex artery. Occasionally, the PDA is supplied by both the left and the right coronary circulation and is therefore classified as "co-dominant." The coronary circulation is *right dominant* in 85 to 90 percent of normal individuals. This delineation is important when evaluating patients for CABG.

The right coronary artery is usually a singular vessel coursing down the right atrioventricular groove, supplying the anterior right atrial and sinoatrial nodal arteries. It continues over the acute margin of the heart, dividing into the right posterior descending and right posterolateral segmental arteries, perfusing the atrioventricular node and posterior wall of the left ventricle.

The left main coronary artery courses for a distance of 10 to 20 mm from the left sinus of Valsalva between the pulmonary trunk and left atrial appendage. It bifurcates into the left anterior descending (LAD) and circumflex coronary arteries near the left atrioventricular groove. The LAD traverses the anterior interventricular groove toward the apex of the heart, giving off diagonal, septal perforating, and right ventricular branches before terminating at the apex. Occasionally, in 10 to 15 percent of normal individuals, the LAD may collateralize with the PDA or replace it to supply the posterior interventricular groove. The diagonal branches supply the anterolateral wall of the left ventricle. The first diagonal branch may occasionally originate directly from the left main coronary artery and is then referred to as the ramus intermedius coronary artery. The septal perforators supply the anterior two-thirds of the ventricular septum, extending perpendicularly from the LAD. The right ventricular branches supply the anterior surface of the right ventricle.

The circumflex coronary artery courses along the left atrioventricular groove, giving off obtuse marginal branches to supply the lateral wall of the left ventricle, the left atrium, and the posteromedial papillary muscle. Occasionally, the sinus node artery is supplied from the proximal circumflex artery. In most patients, the circumflex coronary artery terminates near the obtuse margin of the left ventricle; in the remaining patients, (i.e., *left dominance*), it may continue and give rise to the posterior descending coronary artery.

Coronary blood flow is regulated by the oxygen demands of the heart.[3] Oxygen stores in the heart are minimal with extraction from the coronary blood flow at near maximal levels (70 percent) under a resting physiologic state. Due to this maximal oxygen extraction, when oxygen demands increase, as in exercise, a majority of oxygen delivery must come from increasing blood flow. Changes in myocardial oxygen requirements bring about a multitude of mechanisms to increase oxygen delivery. The major resistance vessels where these mechanisms are located constitute the arterioles and rich network of capillaries that form interregional collaterals. Myocardial blood flow is under complex regulation by a compilation of metabolic, neurogenic, and hormonal mechanisms.

Adenosine is the primary metabolite of myocyte activity regulating coronary blood flow via $A_2$ receptor-induced smooth muscle relaxation. ATP sensitive $K^+$ channels, hypoxia, and acidosis are other potent metabolic regulators of coronary blood flow. Neurogenic regulation occurs directly and indirectly via sympathetic and vagal innervations. Direct innervations of larger conductance vessels and indirect innervations of smaller resistance arterioles with release of norepinephrine cause vasoconstriction (via $\alpha_1$ receptors) and vasodilatation (via $\beta_2$ receptors). Vagal release of acetylcholine primarily causes vasodilatation of conductance vessels. Hormonal control of coronary blood flow occurs mainly by local endothelial derived substances such as nitric oxide (vasodilatation) and endothelin-1 (vasoconstriction). However, nonlocal paracrine control of coronary blood flow can be influenced by platelet derived mediators such as thromboxane $A_2$ (vasoconstriction), adenosine diphosphate (vasodilatation) and serotonin (both).

Given the near obligatory aerobic physiology of the heart, metabolic, neurologic, and hormonal mechanisms quickly react to increase coronary blood supply and adequate oxygen delivery. With this autoregulatory system, the heart is particularly vulnerable to occlusive arterial disease.

## PATHOPHYSIOLOGY OF MYOCARDIAL ISCHEMIA/INFARCTION

Coronary atherosclerosis is a slow, complex disease process that typically starts in childhood and often progresses with age. Its precise cause still remains incompletely understood. The "Response to Injury" hypothesis was put forth by Ross and Glomset who combined proposals made initially by Virchow and Rokitansky with more modern knowledge of molecular and cellular biology.[4] Infiltration of small lipoprotein particles accumulate in the vessel intima, starting in childhood. Binding of these lipoproteins to proteoglycan make these areas more prone to endothelial injury.[5] Mechanisms of endothelial injury are thought to include: turbulent flow, infectious and immunologic factors, and noxious chemicals. Once leukocytes extravasate into the intima, they become lipid-laden macrophages and multiply. With the release of various chemotactic growth factors and vasoconstrictors such as thromboxane $A_2$, migration and proliferation of smooth muscle cells results in the accumulation of collagen, elastic fibers, proteoglycan, calcium,

complex carbohydrates, and other connective tissues in the intimal and subintimal areas.[6] This deposition progresses to become an atherosclerotic plaque. Within an atherosclerotic plaque, angiogenesis of newly formed small vessels can suddenly bleed, causing plaque hemorrhage and rupture, which can worsen the degree of stenosis and precipitate a myocardial infarction.[7] It is believed that most acute myocardial infarctions result from acute thrombotic occlusion.

Coronary atherosclerosis usually involves the proximal portions of larger epicardial coronary arteries, especially at or just beyond branching sites. Therefore, stenoses of the LAD, circumflex, and right coronary arteries often involve the first of the secondary branchings (i.e., first diagonal, obtuse marginal, and posterior descending branches). When the disease is more severe, origins and main trunks may be involved. The left main coronary artery is significantly diseased in 10 to 20 percent of patients. Diffuse distal disease severe enough to render a coronary artery unsuitable for bypass grafting is relatively uncommon.

With coronary artery disease, myocardial ischemia and necrosis occur when coronary blood flow, impaired by atherosclerotic stenosis, is insufficient to meet oxygen demand. Because the heart has virtually no reserve stores of oxygen and relies entirely on aerobic metabolism, its high rate of energy expenditure results in a sudden, striking decline of oxygen tension and left ventricular functional impairment within seconds of coronary occlusion. Coronary occlusion can cause myocardial ischemia in as little as 60s, and depressed function, or myocardial stunning, in less than 20 min.[8] The subendocardium is most vulnerable to myocardial ischemia because its collateral blood flow is lowest and oxygen consumption highest.[9] Thus, myocardial necrosis progresses toward the epicardium with continued ischemia and is accelerated when there is little collateral flow, marked arterial hypotension (e.g., cardiogenic shock), and elevated oxygen demand caused by inotropic stimulation or tachycardias. Thus blood pressure control and the prevention of tachyarrhythmias are vital during the early postinfarction interval to limit the spread of myocardial damage. The recognition of this time-dependent progression of infarct and the conditions necessary for functional recovery of salvaged myocardium constitute the basis for rapid reperfusion interventions, including thrombolysis and angioplasty. Multiple randomized trials have demonstrated that fibrinolytic therapy within 1 h hour of symptoms remarkably decreases the 30-day mortality of acute myocardial infarction.[10]

Hypercholesterolemia and other conventional risk factors may precipitate or accelerate the process of coronary atherosclerosis. The identified controllable risk factors are:

- Hypercholesterolemia (especially low-density lipoprotein >100 mg/dL)
- Smoking or exposure to tobacco smoke
- High blood pressure
- Diabetes mellitus
- Obesity
- Physical inactivity

Although global risk assessment models like Framingham are useful, up to 20 percent of patients with coronary artery disease have no conventional risk factors and up to 50 percent only have one risk factor. In light of this, additional risk factors for coronary atherosclerosis are being investigated and tested, including C-reactive protein, lipoprotein A, fibrinogen, and homocysteine.

## CLINICAL CORONARY SYNDROMES

### Stable Angina

*Angina pectoris* is the development of chest discomfort or pain with exertion that ceases within 5 to 15 min of rest, or administration of sublingual nitroglycerin. It is typically described as a substernal heavy, dull, or crushing pain with frequent radiation to the left shoulder, arm, and/or neck. Other sensations are more vague, including pressure, numbness, and burning. It is not an inevitable symptom, nor does its absence indicate freedom from coronary artery disease; however, it does signify the presence of reversible myocardial ischemia without cellular necrosis. Decreased myocardial oxygen supply or increased myocardial oxygen demand leads to symptoms. Since angina results from a reduction in coronary flow reserve, the greater the reduction, the more severe the angina. Several classification systems exist, however the Canadian Cardiovascular Society Functional classification has become the most accepted.[11] The severity of angina is categorized into the following four categories:

- Class 1: Angina occurring with strenuous activity. There is no limitation to ordinary activity.
- Class 2: Angina occurring with fast-paced walking or walking up an incline or stairs. There is only slight limitation to ordinary activity.
- Class 3: Angina occurring when walking less than two blocks on level ground or climbing one flight of stairs. There is significant limitation to ordinary activity.
- Class 4: Angina occurring with mild activity. May occur at rest but lasts less than 15 min (beyond which the angina is unstable). There is inability to carry out mild activity.

The clinical presentation of patients with angina varies considerably. Part of this is explained by *fixed threshold* versus *variable threshold* angina. Fixed threshold angina is due to increased myocardial oxygen demands. The level of exertion to precipitate oxygen debt resulting in angina is relatively "fixed" (two flights of stairs). Variable threshold angina includes dynamic vasoconstriction as an important part of decreased oxygen supply, not just atherosclerotic narrowing of epicardial coronary vessels. These patients are noted to have "good days" and "bad days" as their level of exertion that precipitates angina is varied.

Furthermore, as chest pain in general tends to be nonspecific, the differential diagnosis is broad and includes gastrointestinal reflux, biliary colic, peptic ulcer disease, aortic dissection, esophageal disorders, lower respiratory

tract infection, pneumonitis, and a variety of musculoskeletal discomforts. Once other differential diagnoses are ruled out, evaluation with electrocardiography (ECG), exercise or stress testing, and myocardial enzyme levels are necessary to confirm the diagnosis of myocardial ischemia. In general, patients with class 1 and 2 stable angina can be managed medically with coronary angiography as an option following provocative testing for ischemia. Coronary angiography is recommended for patients with class 3 and 4 angina.

## Atypical Anginal Equivalents

Anginal equivalents are described as symptoms of myocardial ischemia other than angina. These symptoms include dyspnea, fatigue, syncope, dizziness, and pulmonary edema. These symptoms are common in the elderly and often due to left ventricular systolic or diastolic dysfunction whenever the myocardium becomes ischemic under stress. Furthermore, a small number of patients exhibit "silent" or asymptomatic ischemia that can be discovered only by continuous ECG monitoring. Nocturnal angina should raise the suspicion of sleep apnea.

## Acute Coronary Syndromes

Acute coronary syndromes are a spectrum of symptomatic and prognostic worsening of coronary artery disease. Included in this spectrum are unstable angina, non-ST-segment elevation myocardial infarction, and Prinzmetal angina. They are predominantly due to plaque rupture and variable thrombosis/occlusion of the coronary arterial system. Other proposed mechanisms of acute coronary syndrome include coronary spasm as seen in Prinzmetal angina and secondary causes of decreased myocardial oxygen demand such as anemia. This clinical situation remains reversible but tends to recur either as further episodes of unstable angina or a fulminant acute myocardial infarction.

Unstable angina is defined as angina pectoris pain (or equivalent) that includes at least one of the following three characteristics: (1) lasting greater than 20 min if not interrupted by medical intervention, (2) being severe and recent (within 1 month of onset), and (3) presents with crescendo patterns (being more painful, longer duration, or increasing frequency). Furthermore, unstable angina can be categorized according to the clinical presentation of each ischemic event: primary unstable angina, secondary angina (i.e., anemia), and postinfarct angina (less than two weeks after myocardial infarction).

Prinzmetal angina is a variant that causes pain and ST-segment elevation at rest. The proposed mechanism has been increased coronary vasomotor tone or spasm. No precise mechanism has been elucidated, but mutations in genes responsible for the production of nitric oxide and endothelium-derived relaxing factors may play a role.[12] The crucial element to diagnose Prinzmetal variant angina is the detection of episodic ST-segment elevation with pain. ST-segment deviations may be present in any leads. Treatment for Prinzmetal variant angina includes smoking cessation, short acting and long acting nitrates, and calcium agonists. Patients with ventricular fibrillation associated with Prinzmetal variant angina may require automatic implantable cardiodefibrillator placement.[13]

Patients presenting with acute coronary syndrome are evaluated with clinical history, ECG examination, and cardiac biomarker (troponin) level measurement. These patients are treated depending on their risk stratification. Those with low risk are treated with an antithrombotic agent such as aspirin, clopidogrel, or an antithrombin, along with β-blockers and nitrates. Patients with positive troponin levels or ST-segment changes (high risk) are treated with the addition of GP IIb/IIIa inhibition as well as coronary angiography with percutaneous coronary intervention (PCI) or CABG if necessary. A calcium agonist is added for patients with Prinzmetal variant angina. Several trials demonstrate that early intervention in high-risk unstable angina patients results in decreasing mortality, myocardial infarction, and rehospitalization rates.[14]

## Acute Myocardial Infarction

Prolonged myocardial ischemia without reperfusion ultimately leads to irreversible cellular necrosis and myocardial infarction. Most acute myocardial infarctions result from subtotal or total coronary artery occlusion by a thrombus associated with acute rupture of an atherosclerotic plaque. Although the acutely occluded coronary artery often was not previously severely stenotic, the mere presence of significant coronary artery disease clearly increases the risk for acute myocardial infarction. For example, patients with severe proximal LAD coronary lesions are particularly prone to suffer acute and often fatal myocardial infarctions. Increased numbers of coronary arteries with stenotic disease also lead to higher probabilities of acute myocardial infarction.

Following an infarction, the location of the coronary arterial occlusion, presence of other diseased vessels, and extent of collateral perfusion will determine the extent of myocardial injury in the early period. Additional detrimental effects of postinfarct arrhythmias, hypotension, left ventricular distention, and increased wall stress can further reduce the viability of borderline regions and increase the ultimate infarct size.

According to the American Heart Association, the updated universal definition of myocardial infarction is[15]: Detection of rise and/or fall of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile of the upper reference limit (URL) together with evidence of myocardial ischemia with at least one of the following:

- Symptoms of ischemia;
- ECG changes indicative of new ischemia [new ST–T changes or new left bundle branch block (LBBB)];
- Development of pathologic Q waves in the ECG;
- Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality.

Typically, patients present with a sudden onset of severe chest pain or their anginal equivalent that is not relieved by rest or sublingual nitroglycerin. Often, there is associated shortness of breath, nausea, diaphoresis, and general malaise. Subendocardial or nontransmural infarctions usually demonstrate new ST-segmental depressions and T-wave inversions on the 12-lead ECG. As the infarction progresses, ST segments may become elevated and later evolve into Q waves that indicate a transmural infarct.

Since less than 25 percent of patients admitted to the hospital with ischemic-type chest discomfort are subsequently diagnosed as having had an acute myocardial infarction and about half of all patients with acute myocardial infarction do not exhibit diagnostic ST-segment changes, myocardial enzyme markers play an essential role in establishing the diagnosis. The classic myocardial creatine kinase isoenzyme CK-MB, which appears within hours after injury and peaks at 8 to 24 h after infarction, lacks sufficient sensitivity and specificity but remains an efficient means of early detection. Levels of troponin, with its cardiac specific subunits I and C, are more sensitive and specific for myocardial infarction. Furthermore, because troponin release is stoichiometrically correlated with the amount of myocardial necrosis, these enzymes can also be used to estimate infarct size and prognosis. Since serum troponin levels may present up to 14 days after infarction, detection of recurrent acute infarction requires concomitant CK-MB measurements.

### Chronic Ischemic Heart Disease

Some patients with progressive coronary artery disease suffer from chronic, recurrent myocardial ischemic episodes rather than a single devastating infarction. Consequently, these patients develop symptoms of chronic ischemic cardiomyopathy and congestive heart failure (shortness of breath and peripheral edema). Myocardial ischemia impairs left ventricular function and increases the workload on normal myocardium. Increasing areas of dyskinesis or akinesis from repeated insults results in greater reduction of both systolic and diastolic function. Often, these patients exhibit symptoms of heart failure associated with recurrent myocardial ischemia. Furthermore, right ventricular function can also be expected to be impaired in patients with chronic ischemic heart disease. This can be due to occlusive disease of the right coronary artery, pulmonary arterial hypertension, dyskinesis of the ventricular septum, and left ventricular dilatation.

There is a great deal of physiologic and functional variability among patients with depressed ventricular function from chronic ischemic heart disease. Therefore preoperative prediction of the efficacy of surgical intervention can be difficult. Some patients have moderately increased left ventricular end-diastolic pressures and reduced exercise capacity but minimal cardiomegaly. Although these patients often have marked ischemic dysfunction, revascularization is indicated to rescue or protect viable myocardium and improve functional capacities. In some cases, poor left ventricular function is due to myocardial "hibernation" or "stunning" and therefore may benefit from revascularization. In general, patients with recurrent heart failure and reversible ischemic episodes are likely to improve after CABG.

In some patients, chronic myocardial ischemia leads to ischemic cardiomyopathy. This is signified clinically by moderate-to-severe cardiomegaly, reduced cardiac output, significantly elevated right-sided venous pressures, hepatomegaly, ascites, and peripheral edema. The advanced left ventricular dysfunction is the result of extensive myocardial scarring due to a sustained reduction in coronary perfusion. These patients tend to have diffuse small vessel coronary disease and are therefore not expected to benefit from revascularization.

## INDICATIONS FOR CORONARY ARTERY BYPASS GRAFTING

With the advent of coronary stent technology, indications for coronary artery bypass surgery are evolving. Indications for coronary artery bypass surgery are predicated on improving the patient's quality of life (i.e., relief of symptoms, increased exercise tolerance, prolonged survival). Based on an extensive review of the literature, a joint task force from the American College of Cardiology and American Heart Association revised the original 1991 guidelines for coronary artery bypass surgery in 2004 (Table 27-1).[16] Nominally, based on several studies showing improved myocardial function following operative reperfusion, emergency surgical revascularization is generally preferred over medical/percutaneous intervention after acute myocardial infarction. There is general agreement that CABG provides a survival advantage as compared with medical therapy in patients with (1) left main stenosis, (2) three-vessel disease, (3) two-vessel disease with proximal LAD stenosis, (4) impaired left ventricular function, and (5) severe ischemia and multivessel disease. Percutaneous interventions are now available, which provide improved symptoms over medical therapy alone; however, survival advantages have not been seen.[17,18]

Several clinical trials have recently compared revascularization between percutaneous and surgical methods. Data are now being collected on the utilization of drug eluting stents (DES), which appear to be associated with lower rates of reintervention than traditional bare metal stents. CABG clearly possesses an advantage over any type of coronary stent if reintervention is required. A recent database study compared CABG and DES in patients with either two- or three-vessel coronary artery disease. Evaluation of New York State Department of Health databases in these patients showed that those who underwent CABG experienced lower mortality, myocardial infarction, and revascularization rates than those who underwent DES placement.[19] The Arterial Revascularization Therapies Study II (ARTS II) also evaluated DES in patients with multivessel coronary artery disease.[20] Rates of major adverse cardiac and cerebrovascular events (MACCE) were observed in 27 percent of patients

## TABLE 27-1: American College of Cardiology/American Heart Association Guidelines for Coronary Artery Bypass Graft Surgery: Indications

**Asymptomatic or mild angina**

**Class I**

1. CABG should be performed in patients with asymptomatic or mild angina who have significant left main coronary artery stenosis. (*Level of Evidence: A*)
2. CABG should be performed in patients with asymptomatic or mild angina who have left main equivalent: significant (greater than or equal to 70%) stenosis of the proximal LAD and proximal left circumflex artery. (*Level of Evidence: A*)
3. CABG is useful in patients with asymptomatic ischemia or mild angina who have three-vessel disease. (Survival benefit is greater in patients with abnormal LV function; e.g., EF less than 0.50 and/or large areas of demonstrable myocardial ischemia.) (*Level of Evidence: C*)

**Class IIa**

CABG can be beneficial for patients with asymptomatic or mild angina who have proximal LAD stenosis with one- or two-vessel disease. (This recommendation becomes a class I if extensive ischemia is documented by noninvasive study and/or LVEF is less than 0.50.) (*Level of Evidence: A*)

**Class IIb**

CABG may be considered for patients with asymptomatic or mild angina who have one- or two-vessel disease not involving the proximal LAD (If a large area of viable myocardium and high-risk criteria are met on noninvasive testing, this recommendation becomes class I). (*Level of Evidence: B*)

---

**Stable angina**

**Class I**

1. CABG is recommended for patients with stable angina who have significant left main coronary artery stenosis. (*Level of Evidence: A*)
2. CABG is recommended for patients with stable angina who have left main equivalent: Significant (greater than or equal to 70%) stenosis of the proximal LAD and proximal left circumflex artery. (*Level of Evidence: A*)
3. CABG is recommended for patients with stable angina who have three-vessel disease. (Survival benefit is greater when LVEF is less than 0.50.) (*Level of Evidence: A*)
4. CABG is recommended in patients with stable angina who have two-vessel disease with significant proximal LAD stenosis and either EF less than 0.50 or demonstrable ischemia on noninvasive testing. (*Level of Evidence: A*)
5. CABG is beneficial for patients with stable angina who have one- or two-vessel CAD without significant proximal LAD stenosis but with a large area of viable myocardium and high-risk criteria on noninvasive testing. (*Level of Evidence: B*)
6. CABG is beneficial for patients with stable angina who have developed disabling angina despite maximal noninvasive therapy, when surgery can be performed with acceptable risk. If angina is not typical, objective evidence of ischemia should be obtained. (*Level of Evidence: B*)

**Class IIa**

1. CABG is reasonable in patients with stable angina who have proximal LAD stenosis with one-vessel disease. (This recommendation becomes class I if extensive ischemia is documented by noninvasive study and/or LVEF is less than 0.50). (*Level of Evidence: A*)
2. CABG may be useful for patients with stable angina who have one- or two-vessel CAD without significant proximal LAD stenosis but who have a moderate area of viable myocardium and demonstrable ischemia on noninvasive testing. (*Level of Evidence: B*)

**Class III**

1. CABG is not recommended for patients with stable angina who have one- or two-vessel disease not involving significant proximal LAD stenosis, patients who have mild symptoms that are unlikely due to myocardial ischemia, or patients who have not received an adequate trial of medical therapy and
   a. have only a small area of viable myocardium or (*Level of Evidence: B*)
   b. have no demonstrable ischemia on noninvasive testing. (*Level of Evidence: B*)
2. CABG is not recommended for patients with stable angina who have borderline coronary stenoses (50–60% diameter in locations other than the left main coronary artery) and no demonstrable ischemia on noninvasive testing. (*Level of Evidence: B*)
3. CABG is not recommended for patients with stable angina who have insignificant coronary stenosis (less than 50% diameter reduction). (*Level of Evidence: B*)

---

**Unstable angina/non-ST-segment elevation MI (NSTEMI)**

**Class I**

1. CABG should be performed for patients with unstable angina/NSTEMI with significant left main coronary artery stenosis. (*Level of Evidence: A*)
2. CABG should be performed for patients with unstable angina/NSTEMI who have left main equivalent: significant (greater than or equal to 70%) stenosis of the proximal LAD and proximal left circumflex artery. (*Level of Evidence: A*)

## TABLE 27-1: American College of Cardiology/American Heart Association Guidelines for Coronary Artery Bypass Graft Surgery: Indications (*Continued*)

3. CABG is recommended for unstable angina/NSTEMI in patients in whom revascularization is not optimal or possible, and who have ongoing ischemia not responsive to maximal nonsurgical therapy. (*Level of Evidence: B*)

**Class IIa**

CABG is probably indicated for patients with unstable angina/NSTEMI who have proximal LAD stenosis with one- or two-vessel disease. ( *Level of Evidence: A*)

**Class IIb**

CABG may be considered in patients with unstable angina/NSTEMI who have one- or two-vessel disease not involving the proximal LAD when percutaneous revascularization is not optimal or possible. (If there is a large area of viable myocardium and high-risk criteria are met on noninvasive testing, this recommendation becomes class I.) (*Level of Evidence: B*)

---

**ST-segment elevation MI (STEMI)**

**Class I**

Emergency or urgent CABG in patients with STEMI should be undertaken in the following circumstances:

a. Failed angioplasty with persistent pain or hemodynamic instability in patients with coronary anatomy suitable for surgery. (*Level of Evidence: B*)
b. Persistent or recurrent ischemia refractory to medical therapy in patients who have coronary anatomy suitable for surgery, who have a significant area of myocardium at risk, and who are not candidates for PCI. (*Level of Evidence: B*)
c. At the time of surgical repair of postinfarction ventricular septal rupture or mitral valve insufficiency. (*Level of Evidence: B*)
d. Cardiogenic shock in patients less than 75 years old with ST-segment elevation or left bundle-branch block or posterior MI who develop shock within 36 h of MI and are suitable for revascularization that can be performed within 18 h of shock, unless further support is futile because of patient's wishes or contraindications/unsuitability for further invasive care (*Level of Evidence: A*)
e. Life-threatening ventricular arrhythmias in the presence of greater than or equal to 50% left main stenosis and/or three-vessel disease (*Level of Evidence: B*)

**Class IIa**

1. CABG may be performed as primary reperfusion in patients who have suitable anatomy and who are not candidates for or who have had failed fibrinolysis/PCI and who are in the early hours (6–12 h) of evolving STEMI. (*Level of Evidence: B*)
2. In patients who have had an STEMI or NSTEMI, CABG mortality is elevated for the first 3 to 7 days after infarction, and the benefit of revascularization must be balanced against this increased risk. Beyond 7 days after infarction, the criteria for revascularization described in previous sections are applicable. (*Level of Evidence: B*)

**Class III**

1. Emergency CABG should not be performed in patients with persistent angina and a small area of myocardium at risk who are hemodynamically stable. (*Level of Evidence: C*)
2. Emergency CABG should not be performed in patients with successful epicardial reperfusion but unsuccessful microvascular reperfusion. (*Level of Evidence: C*)

---

**Poor LV function**

**Class I**

1. CABG should be performed in patients with poor LV function who have significant left main coronary artery stenosis. (*Level of Evidence: B*)
2. CABG should be performed in patients with poor LV function who have left main equivalent: significant (greater than or equal to 70%) stenosis of the proximal LAD and proximal left circumflex artery. (*Level of Evidence: B*)
3. CABG should be performed in patients with poor LV function who have proximal LAD stenosis with two- or three-vessel disease. (*Level of Evidence: B*)

**Class IIa**

CABG may be performed in patients with poor LV function with significant viable noncontracting, revascularizable myocardium and without any of the above anatomic patterns. (*Level of Evidence: B*)

**Class III**

CABG should not be performed in patients with poor LV function without evidence of intermittent ischemia and without evidence of significant revascularizable viable myocardium. (Level of Evidence: B)

(*Continued*)

## TABLE 27-1: American College of Cardiology/American Heart Association Guidelines for Coronary Artery Bypass Graft Surgery: Indications (*Continued*)

**Life-threatening ventricular arrhythmias**

**Class I**

1. CABG should be performed in patients with life-threatening ventricular arrhythmias caused by left main coronary artery stenosis. (*Level of Evidence: B*)
2. CABG should be performed in patients with life-threatening ventricular arrhythmias caused by three-vessel coronary disease. (*Level of Evidence: B*)

**Class IIa**

1. CABG is reasonable in bypassable one- or two-vessel disease causing life-threatening ventricular arrhythmias. (This becomes a Class I recommendation if the arrhythmia is resuscitated sudden cardiac death or sustained ventricular tachycardia.) (*Level of Evidence: B*)
2. CABG is reasonable in life-threatening ventricular arrhythmias caused by proximal LAD disease with one- or two-vessel disease. (This becomes a Class I recommendation if the arrhythmia is resuscitated sudden cardiac death or sustained ventricular tachycardia). (*Level of Evidence: B*)

**Class III**

CABG is not recommended in ventricular tachycardia with scar and no evidence of ischemia. (*Level of Evidence: B*)

---

**CABG after failed PTCA**

**Class I**

1. CABG should be performed after failed PTCA in the presence of ongoing ischemia or threatened occlusion with significant myocardium at risk. (*Level of Evidence: B*)
2. CABG should be performed after failed PTCA for hemodynamic compromise. (*Level of Evidence: B*)

**Class IIa**

1. It is reasonable to perform CABG after failed PTCA for a foreign body in crucial anatomic position. (*Level of Evidence: C*)
2. CABG can be beneficial after failed PTCA for hemodynamic compromise in patients with impairment of the coagulation system and without previous sternotomy. (*Level of Evidence: C*)

**Class IIb**

CABG can be considered after failed PTCA for hemodynamic compromise in patients with impairment of the coagulation system and with previous sternotomy. (*Level of Evidence: C*)

**Class III**

1. CABG is not recommended after failed PTCA in the absence of ischemia. (*Level of Evidence: C*)
2. CABG is not recommended after failed PTCA with inability to revascularize due to target anatomy or no-reflow state. (*Level of Evidence: C*)

---

**Patients with previous CABG**

**Class I**

1. Coronary bypass should be performed in patients with prior CABG for disabling angina despite optimal nonsurgical therapy. (If angina is not typical, then objective evidence of ischemia should be obtained.) (*Level of Evidence: B*)
2. Coronary bypass should be performed in patients with prior CABG without patent bypass grafts but with Class I indications for surgery for native-vessel CAD (significant left main coronary stenosis, left main equivalent, three-vessel disease). (*Level of Evidence: B*)

**Class IIa**

1. Coronary bypass is reasonable in patients with prior CABG and bypassable distal vessel(s) with a large area of threatened myocardium by noninvasive studies. (*Level of Evidence: B*)
2. Coronary bypass is reasonable in patients who have prior CABG if atherosclerotic vein grafts with stenoses greater than 50% supplying the LAD coronary artery or large areas of myocardium are present. (*Level of Evidence: B*)

who underwent DES placement versus 20 percent of patients who underwent CABG at 5 years of follow-up. The most powerful study to date is the SYNTAX trial, prospectively randomizing 1800 patients with left main coronary disease and/or three-vessel disease to either CABG or PCI with the paclitaxel drug eluting stent.[21] Most recently, the SYNTAX 3-year follow-up data revealed statistically significant differences favoring CABG in myocardial infarction, repeat revascularization, and MACCE. Stroke rates, which at one year significantly favored DES-treated patients, were no different between the two groups by three years.

There is a growing body of literature comparing PCI techniques with surgical revascularization. Although useful, the data must be interpreted critically in the context of the selection and exclusion criteria of patients within the trials. Recent technological advances have enlarged the pool of patients with single- or multivessel disease where percutaneous intervention is a reasonable alternative or even a preferred initial approach. However, patients and cardiologists must take into consideration the incidence of recurrent angina and need for repeat revascularization procedures. For patients who are not suitable for percutaneous intervention or when percutaneous intervention has failed, surgery should be strongly considered.

Patients presenting within 6 h of chest pain and an evolving myocardial infarction should be considered for early operation. However, owing to its rapidity in restoring vessel patency, percutaneous intervention has replaced surgery in most centers except in cases of associated mechanical complications (e.g., postinfarction ventricular septal defect, acute mitral insufficiency). An additional subgroup that may benefit from emergency CABG includes patients with acute proximal LAD occlusion and refractory/recurrent angina, since persistent pain reflects continued ischemia of viable myocardium. Emergency CABG is necessary when occlusive complications develop during percutaneous intervention. Most of these complications result from coronary artery dissections that begin as intimal defects caused by guidewire injury or balloon dilatation. In general, in performing emergency coronary artery bypass for these patients or those in cardiogenic shock, the initial goal is to quickly initiate cardiopulmonary bypass support, cardioplegic arrest, and cooling to reduce further myocardial damage. Not surprisingly, operative mortality and morbidity rates associated with emergency coronary bypass are greater than those occurring after elective or even urgent operations. This increased operative risk is often outweighed by the poorer outcome of nonsurgical treatment.

## PREOPERATIVE DATA

Comprehensive evaluation of the patient referred for CABG is obligatory. The cardiac surgeon's attention to detail leads to optimal risk assessment, preoperative preparation, operative planning, and postoperative care; these are all equally critical to the ultimate success of the operation. A complete history and physical is performed by the operative surgeon, with special attention to signs and symptoms of congestive heart failure, extracardiac organ dysfunction, concomitant valvular or peripheral vascular disease, previous conditions that may limit vascular conduit availability, and other comorbidities. Standard laboratory investigations include a complete blood count, electrolyte panel, renal and liver function tests, urinalysis, coagulation profile, and blood type and cross. Recent (e.g., within 1 month) anteroposterior and lateral plain chest radiography is reviewed, with particular attention to the cardiac silhouette, vascular calcifications, and pulmonic processes. At Johns Hopkins, when a plain chest film demonstrates aortic calcification, chest computed tomography is performed to further evaluate the ascending aorta for atherosclerotic plaques. A 12-lead ECG is obtained to establish conduction and ST-segmental baselines. Preoperative myocardial perfusion and viability studies—such as nuclear scintigraphy, stress tests, and magnetic resonance imaging—are reviewed to assist operative strategy and to assess the likelihood of surgical success. When a radial artery conduit is considered, Doppler evaluation of the nondominant hand is performed to assess ulnar artery collateralization. We routinely obtain bilateral carotid artery ultrasonography prior to coronary artery bypass, to screen for hemodynamically significant carotid stenosis.

Coronary angiograms are reviewed by all surgeons involved in the case. The coronary "road map" permits detailed examination of the coronary vessels for size, suitability, and priority for bypass. In addition, the relationships between the diseased vessels and regional wall motion abnormalities must be ascertained. Suggestions of aortic valvular insufficiency and mitral valvular regurgitation on left ventriculography should be further investigated with an echocardiogram.

Preoperative protection of the heart to minimize further myocardial damage is of utmost importance. Administration of β-blockers, nitrates, and calcium antagonists is continued to the operative date. Angiotensin converting enzyme (ACE) inhibitors are held for at least 24 h. For patients with unstable angina or intramural thrombus, intravenous heparin is continued up to 4 h prior to the operation. Placement of an intraaortic balloon pump is indicated when medical management fails to relieve angina or in cases of ischemic cardiogenic shock. Patients who come to surgery having received thrombolytics, such as alteplase, streptokinase, or reteplase, face a heightened risk of perioperative hemorrhage. More recently, the use of antiplatelet-aggregation drugs—such as abciximab (ReoPro), eptifibatide (Integrilin), tirofiban (Aggrastat), and clopidogrel (Plavix)—has become popular. If the patient's coronary syndrome is stable, it is advisable to discontinue these medications at an appropriate time (each has a different half-life) before the operation. At Johns Hopkins, we continue aspirin up to the date of surgery owing to recent data showing improved operative outcomes.

Although potential comorbid conditions affecting CABG outcomes are many, the patient's overall state of health and the potential for complete revascularization remain critically important. Incomplete revascularization due to severe

distal disease or inadequate conduit leads to higher mortality and a poor long-term prognosis. Seven adverse factors are known to influence survival: advanced age, ejection fraction, clinical status (e.g., shock, emergency surgery), female sex, diabetes, previous coronary artery bypass surgery, and congestive heart failure. Other comorbid conditions that should be addressed include previous stroke, history of significant bleeding, hypertension, angina class, concurrent infection (e.g., urinary tract, dental), chronic obstructive pulmonary disease (COPD), and hepatic and renal insufficiencies. Since 1989, the Society of Thoracic Surgeons has established a database of coronary and valvular cardiac operations performed in the United States. Surgeons can now obtain immediate risk stratification data for a given patient simply by entering clinical data online at http://www.sts.org.

## SURGICAL TECHNIQUES

The primary goal of coronary artery bypass surgery is to completely revascularize all significantly stenosed (i.e., 70 percent luminal narrowing or more) coronary arterial trunks and branches with a diameter of at least 1 mm. In patients with multivessel disease with a number of stenosed branches, sequential distal anastomoses may be required to conserve conduit length. The sequence of distal anastomoses usually entails grafting the most ischemic region first to allow early intraoperative administration of cardioplegia. However, pedicled grafts, such as the internal mammary artery, are usually anastomosed last to prevent inadvertent injury to these comparatively fragile tissues. Retrograde delivery of cardioplegia, in addition to antegrade delivery, is often prudent in the setting of significant left main coronary disease, severe three-vessel disease, and aortic insufficiency. When retrograde cardioplegia is used, it may be prudent to perform the right coronary artery distal anastomosis initially for early delivery of antegrade cardioplegia, since there is some evidence that retrograde delivery does not provide optimal right ventricular protection. We use a standard anastomotic sequence consisting of the right/inferior wall (i.e., right or posterior descending coronary) first, the lateral wall (i.e., circumflex marginal) second, and the anterior wall (e.g., LAD) last.

At Johns Hopkins, approximately 80 percent of primary coronary bypass operations are performed with cardiopulmonary bypass support under cardioplegic arrest. Over the last decade, much attention has been given to the application of minimally invasive approaches to coronary artery bypass surgery. Although robot-assisted cardiac surgery remains largely investigational and limited-access techniques on the arrested (e.g., Port-Access, Heartport) or beating heart [minimally invasive direct coronary artery bypass (MIDCAB)] have not been fully embraced, coronary revascularization on the beating heart without the use of cardiopulmonary bypass has gained popularity.

In some centers, off-pump coronary artery bypass (OPCAB) has become the primary method of surgical revascularization. Despite the theoretical benefit of avoiding the sequelae of cardiopulmonary bypass, convincing data demonstrating superior or equivalent graft patency rates as compared with conventional techniques, reduced morbidity and mortality, faster recovery, and lower health care costs are still lacking. In fact, a recent randomized study comparing on versus off-pump bypass procedures demonstrated a worse composite outcome (death from any cause, any revascularization, nonfatal myocardial infarct) at 1 year of follow-up in the OPCAB group.[22] OPCAB techniques are discussed in Chapter 28.

### Choice of Graft Conduits

Table 27-2 lists graft conduit options, their indications and contraindications, and patency rates. Multiple studies clearly demonstrate early and late survival benefits with the use of a pedicled internal mammary artery as a graft to the LAD; this pedicled graft should be used whenever possible. The right pedicled internal mammary artery graft can be used to bypass the right coronary artery or, when sufficiently long, can be tunneled through the transverse sinus to reach targets in the proximal left lateral wall. In patients less than 50 years of age, we routinely use bilateral mammary artery grafts unless the patient has diabetes, is obese, or suffers from severe COPD. There is some evidence to suggest that these conditions predispose to sternal wound complications if both mammary arteries are used. If the internal mammary artery is injured or has suboptimal flow, it can still be used as a free arterial graft.

The greater saphenous vein remains the primary source of free grafts. If it is absent or inadequate, the lesser saphenous vein is an option. When the saphenous vein is anticipated to be inadequate, bilateral radial artery grafts should be evaluated and prepared for harvesting as free grafts. Cephalic veins should be used only as a last resort. The inferior epigastric and gastroepiploic arteries can also be used as free grafts; however, limitations on length, inconsistent availability due to early branching and small caliber, and tedious dissection have made these infrequently used conduits. In our practice, we rarely use such unusual pedicled arterial conduits. Certainly such grafts should be avoided in emergency operations or with excessive cardiac enlargement. Alternative sources of graft conduits include cryopreserved human saphenous vein allografts, bovine internal mammary and sacral arteries, and various small-diameter synthetic (i.e., polyurethane, PTFE) conduits. All these alternative conduits exhibit unacceptably low patency rates or are not in active clinical use.

### Operative Technique

The median sternotomy is followed by internal mammary artery dissection (Fig. 27-1). We routinely inject the internal mammary artery with intraluminal papaverine and wrap the pedicled graft in a papaverine-soaked sponge. A full

**TABLE 27-2: Coronary Artery Bypass Conduit Indications, Contraindications, and Graft Failure Rate**

| | Indication | Contraindication | Failure rate |
|---|---|---|---|
| Left internal mammary artery | Whenever feasible | Emergency surgery | 3–8% at 1 year |
| | | Poor flow or injury | 4–12% at 5 years |
| | | Subclavian artery stenosis/occlusion | 7–12% at 10 years |
| Right internal mammary artery | Young patient | Diabetes (relative) | |
| Free internal mammary artery graft | When internal mammary artery cannot be used as pedicled graft | Atherosclerotic or dissection | 8–25% intermediate term |
| Radial artery | Arterial conduit | Positive Allen test | 15% at 3 months further 7% during next 6 months |
| | | Incomplete palmer arch | |
| | | Prior carpal tunnel operation | |
| | | Prior radial arterial cannulation (relative) | |
| Gastroepiploic artery | Additional arterial conduit | Prior gastric resection | 4% at 2 months 8% between 2 and 5 years |
| | | Atherosclerosis of celiac axis | |
| | | Emergency surgery | |
| | | Large heart | |
| | | Severe LV dysfunction | |
| Inferior epigastric artery | Lack of other conduits | Paramedian abdominal incision | 21% at 5 years |
| | Prior use of internal | Atherosclerosis | |
| | Mammary artery | Previous groin incision (relative) | |
| Greater saphenous vein | Best venous conduit | Too small (<2 mm) | 10–15% in first month |
| | | | 2–3% per year between 1 and 5 years |
| | | | 5% per year after 5 years |
| | | | 50% in 10 years + 25% |

therapeutic dose of heparin (300 U/kg) is given at this time to achieve an activated clotting time (ACT) of 480 s (550s if aprotinin is used). After confirming that the internal mammary artery and saphenous vein grafts are satisfactory, a standard pericardial well is created. At this time, the ascending aorta is palpated to detect potential plaques and select a cannulation site. Obvious calcified plaques are avoided. In some centers, epiaortic echocardiography is used to survey the ascending aorta prior to cannulation. The aorta and pulmonary artery reflection is divided, obtaining adequate space in the aortopulmonary window to permit aortic cross clamping. We use two 2-0 braided purse-string sutures placed in the adventitial layer for aortic cannulation; the preferred position is just inferior to the innominate artery takeoff along the lesser curvature of the aorta. For most adults, a 20F Soft-Flo aortic cannula (Sarns, Inc., Ann Arbor, MI) provides maximal flow rates of up to 5800 mL/min. Once the position of the aortic cannula tip is confirmed, the arterial limb of the cardiopulmonary bypass circuit is connected. For uncomplicated, isolated coronary artery bypass, we prefer using a single dual-stage cannula for venous drainage. Usually a 32/34F cannula is adequate, especially if vacuum assistance is used. Larger patients may require larger cannulas. The venous cannula is placed through a purse-string stitch consisting of 2-0 braided suture placed in the right atrial appendage. For primary elective coronary artery bypass, cardiotomy suction is no longer used to reduce the risk of particulate emboli returning to the bypass circuit. Shed mediastinal blood is returned to the patient via cell-saver recovery. A 4-0 polypropylene horizontal mattress stitch is placed in the midascending aorta to secure the antegrade cardioplegia cannula.

Once a satisfactory ACT is confirmed and the cardiopulmonary bypass lines have been checked for kinks or clamps, cardiopulmonary bypass is initiated and conducted with nonpulsatile flow of 1.8 to 2.2 L/min/$m^2$ with a target mean arterial peripheral pressure of 50 mm Hg, or higher if the patient has significant peripheral vascular disease. The pulmonary artery is routinely vented. The systemic temperature is allowed to drift initially and then is lowered to 34°C or lower when a prolonged bypass period is expected. The cardioplegia line is flushed free of air. We primarily employ antegrade blood cardioplegia with or without retrograde supplementation. At Johns Hopkins, a 2:1 mixture of blood to high-potassium crystalloid solution (50 mEq sodium bicarbonate and 60 mEq

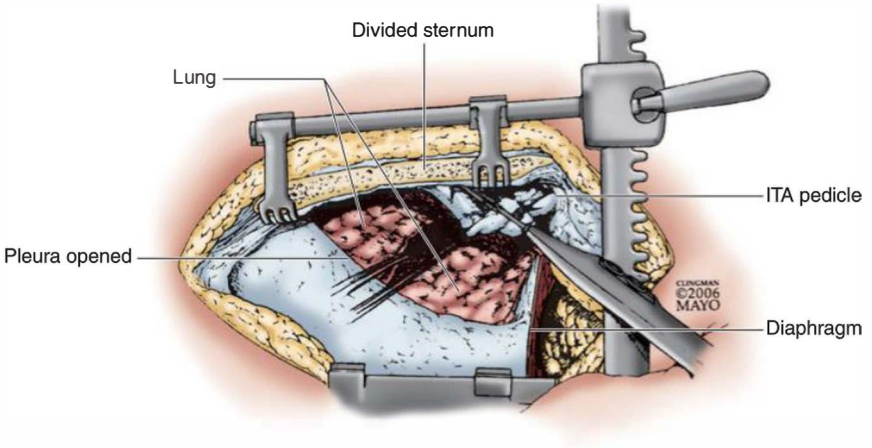

**FIGURE 27-1** Harvesting of left internal thoracic artery. An asymmetrical retractor is used to elevate the left hemisternum. The parietal pleura and endothoracic fascia medial and lateral to the internal thoracic artery and accompanying veins are incised with the electrocautery and then, using a combination of blunt and electrocautery dissection, the pedicle of the internal thoracic artery is separated from the chest wall. Metal clips are used to secure the larger branches. The pedicle can be harvested from the level of the subclavian vein down to the bifurcation of the superior epigastric and musculophrenic arteries. After systemic heparinization, the pedicle is divided distally and flow is assessed. (Reproduced with permission from Mayo Foundation for Medical Education and Research. All rights reserved.)

potassium) is administered approximately every 20 min. If retrograde cardioplegia is used, the coronary sinus pressure is monitored and maintained at 35 mm Hg during infusion.

To initiate arrest, the distal ascending aorta is cross-clamped proximal to the arterial cannula and 800 to 1000 mL of cold blood cardioplegia is administered in an antegrade manner. The surgeon confirms an adequate aortic root pressure and the absence of left ventricular distention. Additional myocardial cooling is provided by continuous topical irrigation with cold saline instilled into the pericardial well; the irrigant is cleared by a discard suction device. Once cardiac arrest is achieved, the heart is elevated to inspect the coronary anatomy and distal graft sites.

Silastic loops are placed proximal and distal to the intended site of the coronary arteriotomy to facilitate anastomosis. The arteriotomy, made at an axial plane to the course of the target artery, is constructed in a standard end-to-side manner with a running 7-0 Prolene suture (Fig. 27-2). Many surgeons elect to perform sequential anastomoses to perfuse two or more coronary arteries with a graft. This entails the construction of one or more side-to-side anastomoses (Fig. 27-3). Besides conserving graft conduit length, this technique augments graft outflow (i.e., lower resistance to flow), which many believe tends to provide greater graft patency. After each free graft distal anastomosis is constructed, the graft is flushed with approximately 100 mL of blood cardioplegia. Bleeding sites on the vein graft and at the anastomosis can then be easily identified and repaired. After all of the distal free graft anastomoses are completed, the mammary artery is dissected free from its pedicle and the tip prepared for anastomosis. Adequate flow in the internal mammary artery is confirmed and the distal anastomosis, usually to the LAD, is constructed in an end-to-side fashion.

Free graft proximal anastomoses are generally performed with the cross-clamp in place. Some surgeons prefer to use a partial occluding clamp to permit coronary perfusion during performance of the proximal anastomoses; others prefer to minimize manipulation of the aorta. Small 4.0-mm aortotomies are created with an aortic punch. Proximal anastomoses are generally constructed with 5-0 or 6-0 Prolene in an end-to-side fashion (Fig. 27-4). Prior to securing the final proximal anastomosis, the pulmonary vent is turned off and the heart is filled with blood. Air is then evacuated from the ascending aorta through the last unsecured proximal suture line, which is subsequently tied. The aortic cross clamp is then removed. The pulmonary arterial vent is removed and its site oversewn. Once the surgeon elects to wean from cardiopulmonary bypass, the anesthesiologist is asked to resume ventilation. Cardiopulmonary bypass is then gradually weaned to off, the heart is decannulated, and heparin reversal with protamine is initiated. Appropriate mediastinal and pleural drains are placed and the chest is closed.

## SPECIAL CONSIDERATIONS

### The Atherosclerotic Aorta

Embolization of atherosclerotic debris from a severely atherosclerotic aorta is generally considered the primary cause

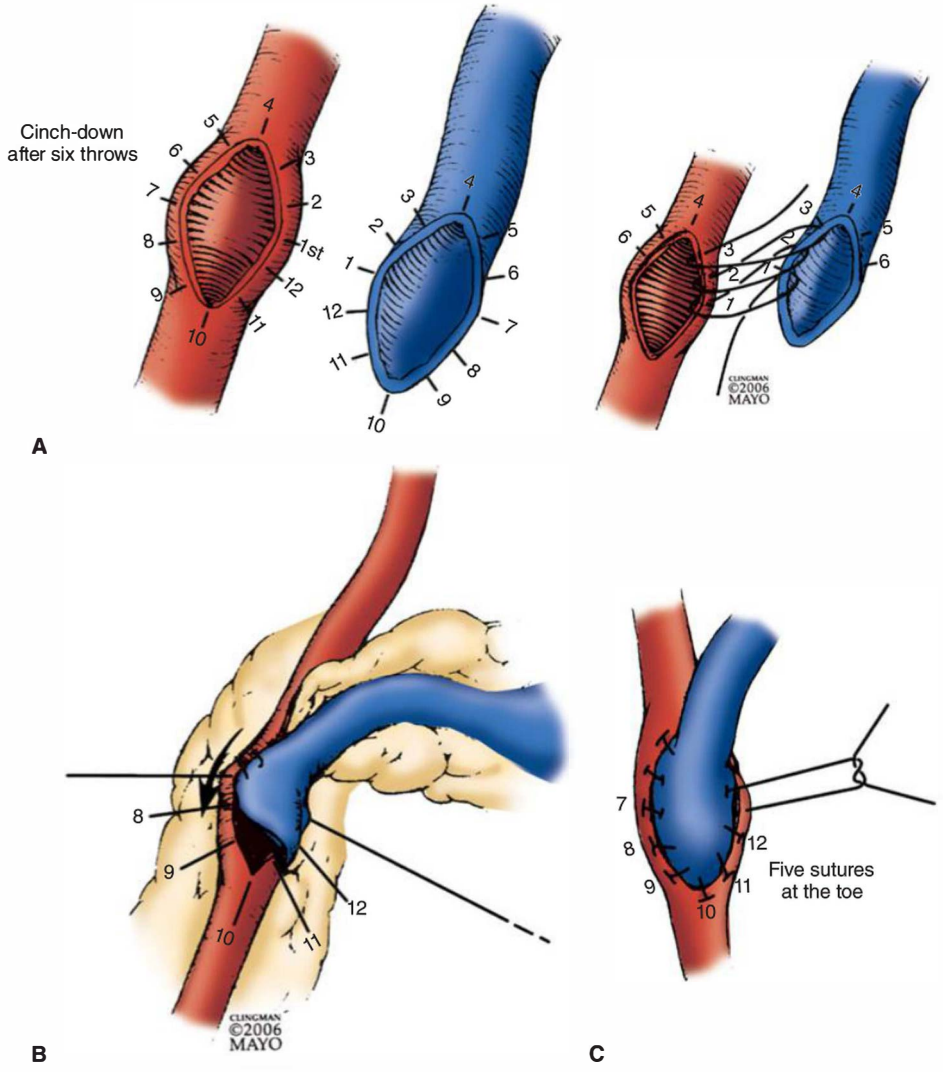

**FIGURE 27-2** Distal anastomosis. **A.** A fine polypropylene suture is passed through the conduit and coronary artery in a running fashion toward and around the anastomotic heel. **B.** After several throws, the conduit is gently parachuted down to the coronary artery. **C.** A suture is continued toward and around the anastomotic toe until the other end of the suture is reached. of perioperative stroke in CABG patients. Aortic plaque can be assessed initially with manual palpation; however, this method can easily miss noncalcified atheromas. The most sensitive modality whereby aortic atherosclerosis can be assessed is epiaortic ultrasonographic scanning.

In some cases of patchy ascending aortic disease, "safe" sites for application of the cross-clamp and construction of proximal anastomoses can be identified. In these cases, side-biting partial aortic clamps should be avoided. When extensive aortic calcification is identified (e.g., "porcelain" aorta), OPCAB is a reasonable alternative to avoid cross-clamping the aorta. Proximal anastomoses can be constructed in this setting with one of several commercial anastomotic device systems. Other alternatives include conducting the surgery under fibrillatory arrest, replacement of the ascending aorta with a Dacron graft, or basing free grafts on the internal mammary artery pedicle.

## Failure to Wean from Cardiopulmonary Bypass

When the patient cannot be successfully weaned from cardiopulmonary bypass, an assessment of the reasons for failure must be efficiently conducted. A review of existing biventricular contractility, adequacy of inotropic/pharmacologic

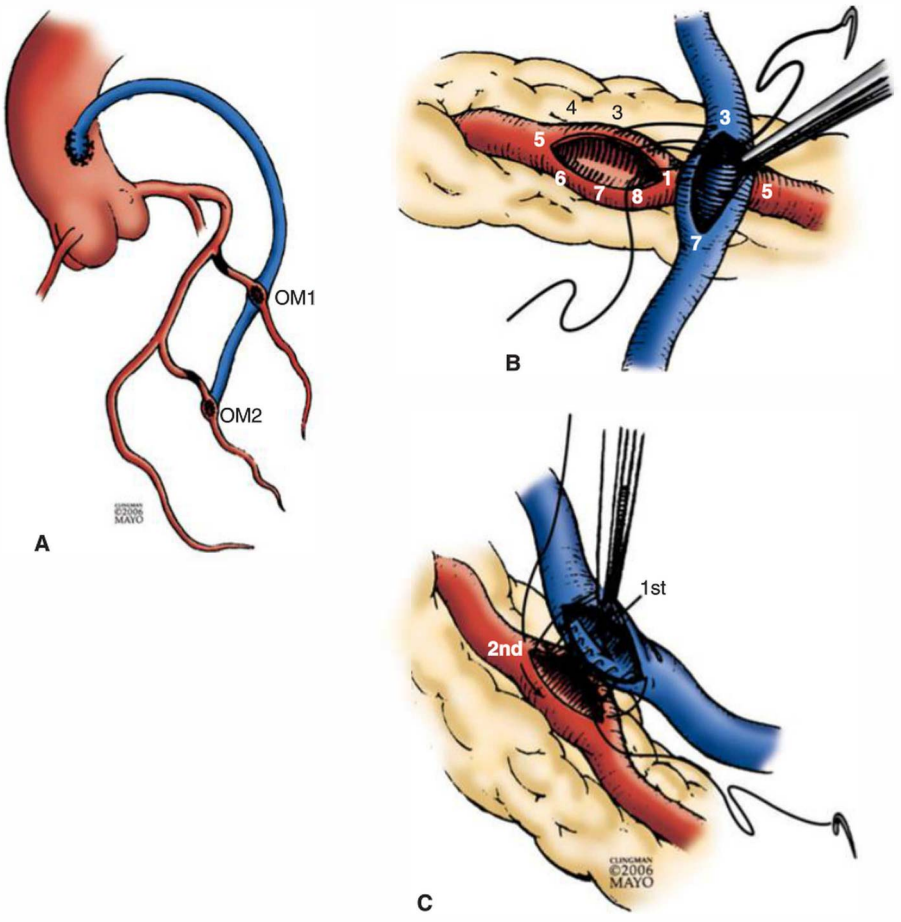

**FIGURE 27-3** Sequential distal anastomosis. **A.** Determination of the appropriate geometric alignment of the conduit and coronary artery. **B.** Coronary arteriotomy and conduit venotomy or arteriotomy are created. **C.** In a manner similar to that described for distal anastomosis, a polypropylene suture is used in continuous fashion beginning near t he heel. (Reproduced with permission from Mayo Foundation for Medical Education and Research. All rights reserved.)

support, optimal cardiac function (e.g., adequate volume and heart rate), metabolic conditions (e.g., acidosis, hyperkalemia), and bypass graft patency must be carefully performed.

Manual palpation of bypass grafts can be misleading, as an occluded graft can display accentuated pulsatility. Doppler ultrasonography with a flow probe can provide an accurate assessment of the patency of either venous or arterial graft conduits. Poor flow in a newly constructed bypass graft is almost always due to technical error; such grafts should be revised prior to further attempts at weaning from cardiopulmonary bypass. It is often prudent to re-review the preoperative coronary angiogram to determine whether nongrafted territories should be addressed. Transesophageal echocardiography is an important modality to (1) identify new or old regional wall abnormalities that may be relieved by additional revascularization and (2) recognize any intracardiac factor, such as valvular dysfunction or previously undetected shunting that may be contributing to the failure to wean.

If, despite optimization of all correctable parameters, separation from cardiopulmonary bypass remains impossible, mechanical assistance is indicated. Intraaortic balloon pump counterpulsation is usually the initial option to improve coronary perfusion and reduce ventricular afterload. Its use and contraindications are discussed elsewhere in this book. Further inability to wean will require the use of formal ventricular assist devices if the patient meets the criteria for their implantation.

## POSTOPERATIVE RECOVERY

Early postoperative management of CABG patients does not differ significantly from that of other cardiac surgical patients and is not covered in detail here. In general, patients who undergo primary coronary artery bypass are quickly weaned off mechanical ventilatory support and extubated.

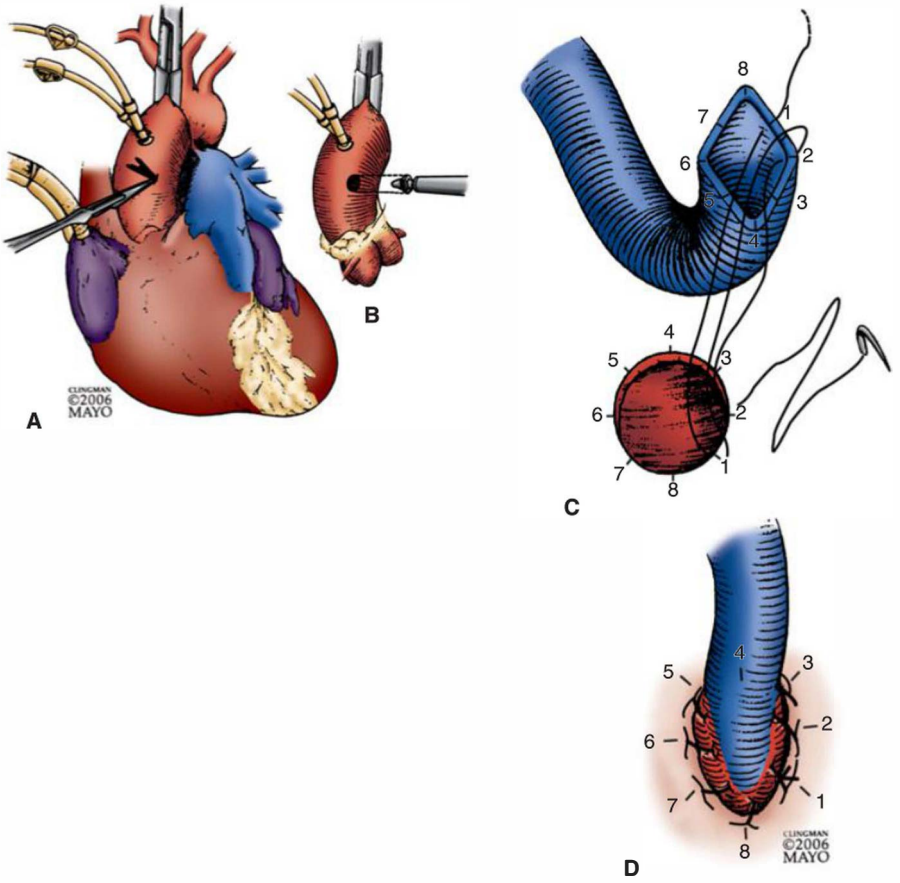

**FIGURE 27-4** Proximal anastomosis. **A.** The technique of single cross-clamping is demonstrated. An aortotomy is created with a knife and punch. Appropriate conduit length and orientation are established and a fine polypropylene suture is used in a running fashion toward and around the anastomotic heel. **B.** The conduit is then carefully parachuted down onto the aorta. **C.** The suture is continued toward and around the anastomotic toe. **D.** The completed anastomoses. Parenteral inotropes and intraaortic balloon pumps are weaned as appropriate. We do not routinely use pulmonary artery catheterization in this patient population; however, when indicated, it can assist in the management of hemodynamic performance in the early postoperative period. A 12-lead ECG is obtained early after the patient arrives in the intensive care unit and compared with a preoperative ECG. Serial ECGs are obtained to detect new ischemia. We do not routinely obtain postoperative cardiac enzyme markers. On the first postoperative day, mediastinal and pleural chest tubes are removed if drainage is less than 30 mL/h for 4 consecutive hours. β-Blockers and aspirin are administered early if there are no hemodynamic or coagulation issues. We now routinely load our patients orally with amiodarone (400 mg/day for 5 days, followed by 200 mg/day) as prophylaxis for atrial dysrhythmias. Some surgeons elect to administer clopidogrel along with aspirin in the early postoperative period to address growing evidence for aspirin resistance in some patients. Since several trials have demonstrated that an aggressive lipid-lowering strategy confers beneficial effects on graft patency, we now routinely administer lovastatin or an equivalent drug postoperatively.

Once deemed stable, patients are transferred from the intensive care unit to a monitored step-down unit and are actively ambulated with the assistance of physical therapists. If pacing wires have been placed and there are no concerning arrhythmias, they are removed by the second postoperative day. A coordinated program of physical therapy and dietary management should be initiated as soon as the patient leaves the hospital. Inpatient or outpatient rehabilitation and physical therapy are arranged as needed. Patients who smoke must give up tobacco; this may require pharmacologic nicotine replacement. Preoperative emphasis on smoking cessation can be invaluable. Other modifiable risk factors for coronary atherosclerosis, such as hypertension and hyperlipidemia, should be monitored and controlled in a comprehensive program to promote graft patency.

## Acute Postoperative Myocardial Ischemia/Infarction

Early postoperative myocardial ischemia and/or infarction, especially when associated with hemodynamic disturbances, can exert major adverse effects on operative outcomes. A postoperative myocardial infarction, defined by new Q waves on the postoperative ECG, occurs in 4 to 5 percent of patients. A new Q-wave myocardial infarction is usually attributed to poor distal perfusion, but it can be also be due to incomplete revascularization, technical graft failure, inadequate myocardial preservation, or inadequate resuscitation in the early postoperative period. Cardiomegaly, prolonged cardiopulmonary bypass, reoperative coronary artery bypass surgery, and bypass grafting combined with other cardiac operations are known risk factors for postoperative myocardial infarction. Other factors identified from the Coronary Artery Surgery Study (CASS) trial predictive of postoperative myocardial infarction include female gender, severe preoperative angina pectoris, severe left main coronary stenosis, and three-vessel disease.[23]

Accurate diagnosis of a myocardial infarction after cardiac surgery requires an integrated approach that combines laboratory and clinical findings. Although new, persistent Q-waves on ECG are suggestive of postoperative myocardial infarction, nonspecific ST–T-segment abnormalities on ECG and typical postoperative elevations of biochemical markers (e.g., creatinine kinase, troponin) are frequently not definitive. Nevertheless, when suspicious ECG changes are associated with hemodynamic and/or rhythm disturbances, postoperative myocardial ischemia should be ruled out. Patients with ST–T-segment elevations and a low cardiac index should prompt consideration of intraaortic balloon pump support. Bedside transthoracic or, when necessary, transesophageal echocardiography can provide valuable supportive data if regional wall motion abnormalities are seen, especially if they correlate with ECG findings. When an integrated review of these diagnostic modalities and clinical indications are highly suggestive of an acute postoperative myocardial ischemia/infarction, immediate coronary angiography is indicated. Subsequent percutaneous intervention or operative rescue is determined based on the clinical situation.

# OUTCOMES

Coronary artery bypass surgery is the most scrutinized operation historically and currently. Public distribution of revascularization outcomes is a modern reality for the cardiac surgeon. There is a tremendous amount of literature analyzing, comparing, and modifying CABG outcomes. Below, we focus upon the nature of early post-CABG mortality, important postoperative complications, and positive outcome variables.

## Perioperative Mortality

Early in-hospital mortality from primary coronary artery bypass surgery has seen a steady decline from the 1970s into the 1990s. Recently, however, the patient population referred for coronary artery bypass has become increasingly complex, hence the decline has plateaued in recent years. Older patients, more advanced and diffuse coronary artery disease, worsening left ventricular function, failure of multiple previous percutaneous manipulations, more serious comorbidities, and a greater frequency of reoperation have contributed to an increase in perioperative risk. Therefore, only risk-adjusted outcome data can be truly informative. Currently, the overall operative mortality rate for CABG is about 3 percent; elective primary coronary artery bypass carries a mortality rate of 1.2 percent, according to the database of the Society of Thoracic Surgeons.

## Perioperative Morbidity

As a consequence of CABG performed on higher-risk patients, most cardiac surgeons have witnessed an increase in the rate of postoperative complications. Perioperative myocardial infarction has been covered previously; this section reports other common operative morbidities.

### HEMORRHAGE

Coagulopathy, platelet dysfunction/depletion, and the release of proinflammatory factors are recognized consequences of cardiopulmonary bypass. Even with OPCAB and the use of antifibrinolytics such as aminocaproic acid (Amicar), significant bleeding still occurs. The rate of reexploration for bleeding following conventional coronary artery bypass ranges from 2 to 6 percent. Risks for bleeding include older age, preoperative aspirin and other antiplatelet agents, reoperation, nonelective surgery, prolonged cardiopulmonary bypass time, and five or more bypass grafts.[24]

### MEDIASTINITIS

Deep sternal wound infections occur in 1 to 4 percent of primary coronary artery bypass patients. This complication clearly increases mortality and may bring long-lasting morbidity to the patient. Obesity, the use of bilateral internal mammary grafts, diabetes, prolonged operation, and prior coronary artery bypass are all risk factors for mediastinitis. Appropriate and timely administration of perioperative antibiotics, meticulous skin preparation, and attention to sterile technique can help minimize this troublesome complication.

### RESPIRATORY INSUFFICIENCY

Prolonged ventilator dependence (e.g., more than 1 day) occurs in approximately 6 percent of CABG patients. Many factors contribute to postoperative respiratory failure, but

preexisting pulmonary disease is the most important predictor. Other factors that are associated with prolonged ventilation include: female gender, BMI less than 20 kg/m$^2$, mitral valve disease, prior CABG, and prior cerebrovascular accident.[25] Coronary artery bypass patients with severe COPD have significantly higher mortality rates (19 percent) than those with mild to moderate or no COPD.

### NEUROLOGIC COMPLICATIONS

Adverse neurologic outcome following coronary artery bypass surgery is the subject of intense investigation. It is a dreaded complication that can manifest in numerous ways. Nearly three-quarters of coronary artery bypass patients experience some degree of neuropsychologic derangement, which tends to be transient. However, persistent or permanent significant neurologic deficits are important causes of postoperative mortality and morbidity. In general, a *type I deficit* is associated with a major focal deficit and/or stupor or coma; a *type II deficit* is characterized by a measurable deterioration of intellectual function and memory. Known factors contributing to type I deficits include older age, ascending aortic atherosclerosis, history of stroke, use of intraaortic balloon pump, diabetes, hypertension, and unstable angina. In a prospective study of just over 5000 patients at our institution, delirium was shown to be an independent risk factor for long-term mortality after CABG.[26]

### ATRIAL FIBRILLATION

Up to 40 percent of CABG patients will experience at least one episode of atrial fibrillation. It is the most frequent post operative rhythm disturbance and usually occurs on the second or third postoperative day. Although usually benign and self-terminating, atrial fibrillation is associated with prolonged hospitalization, hemodynamic instability, and thromboembolism. The stroke risk in patients experiencing postoperative atrial fibrillation is increased threefold. The exact mechanism behind this dysrhythmia is likely multifactorial, including increased endogenous catecholamine levels, atrial ischemia, and atrial reentrant pathways. The recent routine use of β-blockade has significantly reduced its incidence. At Johns Hopkins, we routinely use amiodarone to prevent postoperative atrial fibrillation.

### RENAL DYSFUNCTION

Up to 8 percent of CABG patients develop postoperative renal dysfunction. Nearly 18 percent of these patients required hemodialysis, which significantly increases their mortality rate. Predictors of renal dysfunction include advanced age, baseline renal disease, diabetes, poor cardiac function, previous coronary artery bypass surgery, peripheral vascular disease, and use of intraaortic balloon pump counterpulsation. Coronary angiography is necessary for preoperative planning. However, dye exposure leads to an increase in postoperative renal failure. Angiography performed within 24 h prior to operation increases the rate of postoperative renal failure from 8.8 percent to 31 percent.[27] Although patient convenience is an important goal, elective cardiac catheterization should be performed more than 24 h prior to surgery.

## Angina Relief

Coronary artery bypass surgery is highly effective in relieving anginal symptoms and improving quality of life. Randomized trials consistently show that surgical revascularization confers more durable symptomatic relief than medical or percutaneous therapies. Approximately 80 percent of coronary artery bypass patients are angina-free at 5 years and 63 percent at 10 years.[28] The return of angina has an early phase that peaks at about 3 months postoperatively and a late phase that peaks at 3 years. The early phase is likely due to incomplete revascularization and graft failure, while late phase results from progression of native coronary artery disease and late stenosis/occlusion of bypass grafts. Recurrent angina, whether early or late, indicates repeat coronary angiography to dictate whether percutaneous intervention or reoperation is necessary. Predictors of angina recurrence include female gender obesity, hypertension, incomplete revascularization, and absence of the internal mammary artery graft.

## Return to Work

The ability to return to employment is another important endpoint in CABG outcome analyses. There is no universal agreement on whether coronary artery bypass surgery confers an advantage in obtaining or maintaining gainful employment. Clearly, those patients employed prior to surgery are most likely to return to work after surgery. Also, CABG patients in the middle of their professional productive years are more inclined to continue working. In general, among patients employed shortly before CABG, 80 percent are back to work a year later. Among patients with unfavorable factors—such as older age, return of angina, and preoperative unemployment or disability—less than 20 percent returned to work.[29]

## Long-Term Survival

After an early nadir within the first 6 postoperative months, mortality rates after CABG increase steadily after 1 year. The increase in the hazard ratio at 15 years is twice that at 5 years. Late death is mostly due to noncardiac causes; however, progression of native coronary disease and graft atherosclerosis continues to plague these patients. Updated data obtained from the CASS registry shows that 97 percent of CABG patients are alive at 1 year, 90 to 92 percent at 5 years, 74 to 81 percent at 10 years, and 56 to 66 percent at 15 years.[30]

## SUMMARY

Primary coronary artery bypass surgery remains the cornerstone of treatment for ischemic heart disease. For patients with advanced multivessel coronary artery disease or those with left ventricular functional impairment, surgical revascularization still provides greater symptomatic relief and superior survival rates than medical or percutaneous interventional therapies. Although minimally invasive techniques and OPCAB have generated much investigation and controversy, over three-quarters of all CABGs performed in the United States are performed with conventional cardiopulmonary bypass support. Employment of an all-arterial versus saphenous vein-supplemented conduit strategy is still an active arena of debate.

Despite a steady increase in the proportion of older or "high-risk" patients being referred for surgery, major perioperative mortality and morbidity continues to be low, and long-term outcomes are excellent. Years of surgical innovation and experience have set the standard against which future advances in PCI, molecular therapeutics, and novel surgical approaches will be compared.

## PRIMARY CORONARY ARTERY BYPASS SURGERY BOARD REVIEW QUESTIONS (CHAPTER 27)

1. Which of the following is true regarding coronary artery anatomy?
   A. Ninety percent of people have a right dominant coronary artery system.
   B. The coronary ostia are rarely located outside their respective sinuses.
   C. The most frequent coronary artery anomaly is origin from the noncoronary sinus.
   D. An aberrant circumflex artery is typically large and supplies the majority of the inferior wall.
   E. Congenital aortic stenosis has a higher incidence of left coronary dominance.

2. Which of the following is true regarding morphology of coronary artery disease?
   A. Most acute myocardial infarction results from plaque hemorrhage, swelling, and subsequent coronary occlusion.
   B. Complete occlusion of one coronary is not commonly associated with significant lesions in other coronary arteries.
   C. The LAD and RCA systems are more commonly involved than the circumflex system.
   D. Transmural infarctions are characterized by complete absence of viable muscle cells in the infarct area.
   E. Acute infarction usually occurs in a chronic, severely narrowed vessel.

3. Which of the following is true regarding results of coronary artery bypass?
   A. Average 10-year survival is about 75 percent.
   B. The third rising phase of hazard of death is not affected by IMA grafting.
   C. Cardiopulmonary bypass time is not a procedural risk factor for death.
   D. Risk of death is strongly increased by increasing number of stenosed vessels.
   E. Coronary artery bypass should ideally be performed within one week of acute myocardial infarction to reduce risk.

4. Which of the following statements is true regarding indications for coronary artery bypass?
   A. 50 percent left main stenosis is equally well treated with PTCA or CAB.
   B. Patients with three-vessel disease, good LV function, and mild ischemia should have urgent operation.
   C. CAB is indicated in two-vessel disease and depressed LV function.
   D. Depression of LV function below 20 percent is an absolute indication for CAB.
   E. Acute hemodynamic instability after acute MI is a contraindication to emergent CAB.

5. Which is true regarding outcomes after CAB?
   A. Up to 75 percent of patients have evidence of subtle neurobehavioral deficits.
   B. Gross neurologic deficit occurs in about 20 percent of patients over age 75.
   C. Functional capacity is not improved after operation.
   D. Less than 50 percent of patients have improvement in regional perfusion defects.
   E. Only hypokinetic areas can be expected to have improved systolic function.

## ANSWERS

1. **Answer: E.** Congenital aortic stenosis is associated with nearly a two-fold incidence of left coronary dominance. About 75 percent of people have a right dominant system. Up to 30 percent of right coronary ostia and up to 10 percent of left coronary ostia are located in the tubular portion of the aorta, above the sinus. The most frequent coronary artery anomaly is origin of the circumflex artery from the right coronary sinus. An aberrant circumflex artery is usually diminutive, underdeveloped, and supplies only a small area of the lateral wall.
2. **Answer: C.** Coronary artery disease more commonly involves the LAD and RCA. Most acute infarctions results from plaque rupture and thrombotic occlusion, not swelling. Ninety-five percent of patients with a completely occluded coronary artery will have a significant stenosis of at least one other coronary artery. Most transmural infarctions will have scattered islands of viable myocardial cells and are not completely acellular. Chronically stenotic arteries often have collateral circulation that provides some protection in acute occlusion.
3. **Answer: A.** Ten-year survival after coronary artery bypass is about 75 percent. The rising third phase of hazard is favorably affected by IMA grafting. Increased CPB time is a known risk factor for death after CAB. The number of stenosed vessels is only a weak risk factor. CAB performed within 8 days of acute myocardial infarction is associated with increased risk.
4. **Answer: C.** CAB is indicated for two-vessel disease and depressed LV function. Left main stenosis of 50 percent or greater is best treated with CAB. Medical management is appropriate for patients with three-vessel disease, preserved LV function, and only mild symptomatology. Risk of CAB may outweigh benefits in patients with severely depressed LV function. Emergent CAB can salvage over 50 percent of patients with acute hemodynamic instability after acute MI.
5. **Answer: A.** Up to 75 percent of patients will have subtle neurobehavioral deficits, but only 10 to 30 percent will persist at 3 months. Gross neurologic deficit occurs in about 8 percent of patients over age 75. Both maximal and function capacity are improved after operation. Over 2/3 of patients will have improvement in regional perfusion defects. Hypokinetic, akinetic, and dyskinetic areas can all show improved systolic function after surgery.

# Off-Pump Coronary Artery Bypass

*Eric A. Peck*
*Paul Sergeant*

**KEY CONCEPTS**

- Team approach
  - Although all cardiac operations require a multidisciplinary approach, this is especially true for off-pump coronary artery bypass grafting (CABG). Close and clear communication with the anesthesiologist is critical for the safe performance of the procedure. Similarly, the nursing staff should be included in the dialogue so that it can anticipate each step in the operation and prepare instruments, shunts, and sutures as necessary and in a timely fashion.
- Minimization of risk
  - Off-pump CABG has the potential to reduce morbidity and mortality significantly. However, if done improperly, it can lead to higher complication rates. This is best avoided by minimizing potential intraoperative risk at every possible step.
- Reengineering
  - To achieve optimal results with this technique, it must be realized that this procedure is not just a CABG performed without the assistance of cardiopulmonary bypass. Instead, it requires a complete reengineering of the operative technique and physiologic concepts, including optimizing oxygen supply and demand and maintaining hemodynamic stability before, during, and after cardiac manipulation.

## INTRODUCTION

This will focus on the surgical technique that we feel provides the most effective and safe method of off-pump coronary revascularization.

Off-pump coronary artery bypass (OPCAB) has been practiced to some degree for many years, but it has regained popularity only recently with the development of devices that allow for superb exposure and stabilization of the anastomotic area. This technology continues to develop and improve over time. With the spectrum of patients presenting with coronary disease becoming more complex and higher risk, surgeons have been looking for surgical options that may reduce complications. OPCAB has this potential because it avoids cardiopulmonary bypass (CPB) and the associated morbidity.

OPCAB is not simply the standard coronary bypass operation performed without the assistance of CPB. Rather, it is a concept whose primary goal should be the reduction of morbidity and mortality. The technical result should be identical to that for a standard coronary artery bypass graft (CABG) operation: the same number, location, and quality of anastomoses. Further, OPCAB must be a reproducible technique, allowing it to be taught to other surgeons and incorporated into the training of cardiothoracic surgical residents. This aspect is something that has been studied in a scientific fashion at Gasthuisberg Hospital in Belgium. There are now objective data to support this technique, which can be safely taught to residents and can also be used to retrain established surgeons.[1] Ideally OPCAB should be applicable to the entire spectrum of patients. In Leuven, a practical algorithm is used to determine whether a particular patient has a bypass performed with or without CPB (Fig. 28-1). Obviously, for any patient in extremis, receiving cardiac compressions, or with malignant arrhythmias, emergent institution of CPB is lifesaving and necessary. In this patient subset, the authors perform CABG on CPB, but with a beating heart to minimize further ischemia. In more stable patients, the next branch in the decision tree involves whether the patient has had an acute infarct (within 3 days of surgery). Regardless of other risk factors or comorbidities (e.g., complexity of coronary lesions, cardiomegaly,

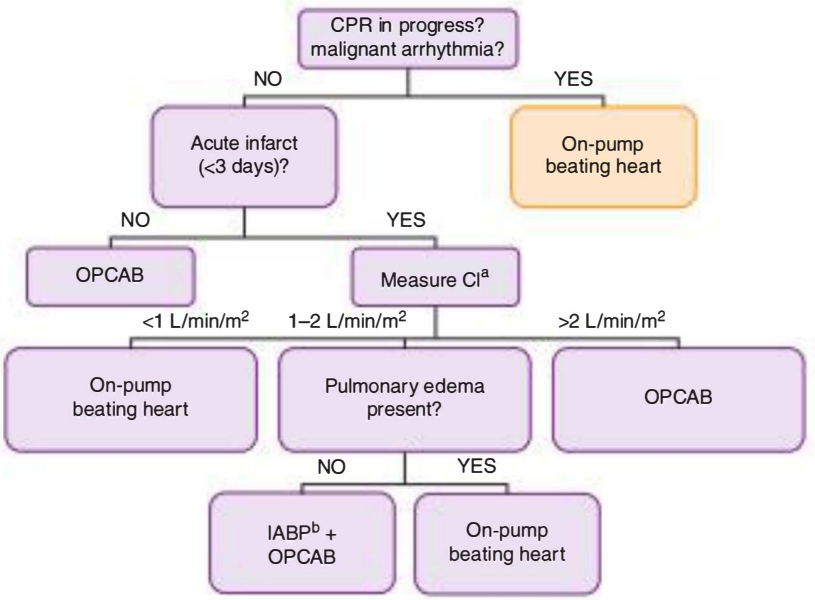

**FIGURE 28-1** Algorithm used to determine method for performing off-pump and on-pump coronary artery bypass grafting. (With permission from Peck EA, Sergeant PL. Leuven, Belgium.)

redo surgery, ejection fraction), if the infarct is more than 3 days old, the procedure is performed off-pump. For an acute infarct, a pulmonary artery (PA) catheter is placed and the cardiac index (CI) is measured. If the CI is less than 1 L/min/m$^2$, the patient is placed on CPB and the revascularization is completed with the heart beating. For patients with a CI greater than 2 L/min/m$^2$, procedures are performed off-pump. In patients with a CI between 1 and 2 L/min/m$^2$, a determination is made as to the presence or absence of pulmonary edema. The authors believe that pulmonary vascular congestion is an indication of severe left ventricular dysfunction and indicates a patient who probably will not tolerate cardiac manipulation and may need assistance with oxygenation. These patients undergo CABG with CPB, but with the heart beating.

A less evident component of a successful OPCAB program is the ability to perform these procedures without undue stress on the operating team: surgeons, anesthesiologists, and nurses. Many teams feel averse to performing OPCAB because of the level of anxiety that results from conducting this technique under suboptimal conditions. Hemodynamic instability, ischemia, unpredictability, and perhaps an open confrontation between the anesthetic and surgical teams all contribute to this. The structured environment and organized, stepwise technique developed by one of the authors (Dr. Sergeant) has created an atmosphere of collegiality and open communication, eliminating these stressful triggers and leading to a pleasant operating environment.

This approach involves a number of factors geared toward minimizing risk and enhancing the safety of the procedure. The key to this is the optimization of intraoperative patient hemodynamics (i.e., heart rate/rhythm, blood pressure, cardiac filling pressures, electrolytes, and body temperature) before cardiac manipulation. This provides a stable platform that allows the surgeon to enucleate the heart from the pericardium safely during the anastomotic period. Further, it optimizes the myocardium to tolerate any transient ischemia that is produced. Without proper anesthetic conditioning, the entire concept of OPCAB can be unsafe and the operation should not be performed. Each step in the authors' technique is designed to eliminate or reduce the risk associated with off-pump revascularization. Not all steps are essential for every coronary anastomosis in every patient. However, it is challenging to predict which circumstances will produce instability for any specific patient and/or anastomosis, and it is for this reason that the authors use the safeguards in every patient and for every anastomosis. Without such stringent controls, a certain percentage of patients will require urgent/emergent conversion to on-pump CABG, which clearly has been shown to result in significant morbidity and mortality.[1-3]

Surgeons also must be able to perform anastomoses in smaller spaces and on vessels that may be at unfamiliar angles. To maintain hemodynamic stability, the heart must be manipulated so that mitral insufficiency is not created or worsened and the right heart may fill properly. In many cases this leads to the anastomoses being more technically challenging than what is encountered on-pump. It is important that the OPCAB surgeon retrain to become competent in creating high-quality anastomoses that are durable and achieve patency rates equivalent to those of anastomoses completed with CPB and an arrested heart. Methods to accomplish this are discussed later in this chapter.

## REENGINEERING

The motivation for adopting the OPCAB approach to surgical coronary revascularization should focus upon reducing complications while preserving excellent long-term outcomes. In evaluating whether to use a new technique in one's practice, it is important to identify the "drivers" that influence the decision. Inappropriate drivers probably will lead to failure of the reengineering process. Examples of inappropriate drivers include marketing, ambition, and excitement about a novel technique. In the authors' early experience with OPCAB, we did not have the proper motivation and for that reason did not perform more than about 10 percent of CABGs off-pump. Further, these cases were very stressful and unpredictable in light of the authors' desire to try out a new technique.

Coronary bypass surgery has achieved unparalleled long-term results that have been studied more extensively perhaps than the results of any other surgical procedure. Although surgeons have relied on this record to maintain patient referrals, the advent of drug-eluting intracoronary stents has produced excellent results as well. Percutaneous stenting, however, is associated with vastly reduced early morbidity and mortality. It was this realization that led the authors to the proper "driver" toward OCPAB surgery: the goal of eliminating early complications while maintaining the outstanding long-term results expected for CABG surgery. With this goal in mind, a technique was developed that minimizes risk for the patient at every possible step.

### Economic Impact

It is important to discuss the impact of the OPCAB approach on the real costs of surgical coronary revascularization. There are two methods by which OPCAB may influence cost. The first is a "production line" effect that involves eliminating over 50 CPB-related instruments as well as the CPB circuit and reducing operating room personnel (e.g., no perfusionist, fewer surgeons/nurses). A second effect is realized in terms of reduced morbidity as a consequence of the new technique. This effect (e.g., reducing stroke or renal failure rates) may apply only to a very small number of patients but constitutes a huge cost benefit. Combined, these effects lead to dramatic overall cost reductions once a complete reengineering toward OPCAB has been realized.

### Team Approach

A successful OPCAB program requires that all operating room staff (surgeons, anesthesiologists, and nurses) work together as a team with open lines of communication. This ensures that all members are able to anticipate each step and its potential complications so that they are prepared to correct any abnormalities. The authors also believe that it is essential for the surgeon and the anesthesiologist to engage in frequent collegial communication during the procedure so that both parties agree as each step in the operation is performed. This has the added benefit of producing a stress-free environment for all members of the operating team and leads to improved multidisciplinary care for the patient. If at any point and for any reason the anesthetist does not feel that the patient is stable enough to proceed, the manipulation is delayed until the hemodynamics have been optimized.

## SURGICAL TECHNIQUES

The authors' OPCAB technique has evolved over time. Since 1999, new devices have become available and the authors' experience with optimal anesthetic management and surgical manipulation has improved greatly. This goal of safe OPCAB and zero tolerance for conversion to CPB requires that every effort be made to ensure safety.

### Patient Conditioning

The first step in a successful OPCAB procedure begins before the incision is made. It is critical that the patient's hemodynamics be optimized to tolerate the stresses that surgical intervention will apply. To this end, patient hemodynamics must be "conditioned" adequately before any surgical manipulation of the heart. Thus, patients must have a normal heart rate [50–70 beats per minute (bpm)], normal systemic and pulmonary arterial pressures, normothermia, and normal electrolytes. For these reasons, monitoring in the authors' institution includes radial arterial catheterization, central venous and Swan–Ganz catheterization, and transesophageal echocardiography (TEE) for all OPCAB cases. TEE permits the detection of new wall motion abnormalities that may indicate early myocardial ischemia. PA monitoring is used to follow diastolic pressures as an early indicator of cardiac ischemia; alternatives include direct left atrial or pulmonary arterial pressure monitoring. It is the role of the anesthesiologist to adjust the patient's filling pressures to achieve pulmonary arterial diastolic (PAD) pressures between 10 and 15 mm Hg. In patients with certain preoperative conditions (e.g., atrial fibrillation, left ventricular hypertrophy), higher PADs are tolerated, reflecting the need for higher filling pressures. This is the exception, however, and the vast majority of patients will have the safest operation with PADs in the lower range. As will be described below, during most of the anastomotic period the heart lies outside the pericardium and the triangle of Einthoven, making detection of ischemia by electrocardiography (ECG) and TEE more difficult. Hence, the authors use the Swan–Ganz catheter as the primary mechanism to detect, treat, and follow this occurrence.

Another important role of the anesthesiologist is to optimize myocardial oxygen metabolism; this is achieved primarily by maintaining a normal heart rate. Patients are β-blocked adequately before surgery, with heart rates usually maintained around 60 bpm. However, if a patient has a heart rate greater

than 80 bpm, intravenous metoprolol is given to ensure that the heart is well protected from catecholamine surges. Any patient whose heart rate is below 60 bpm has atrial pacing wires placed and is paced atrially throughout the procedure. Atrioventricular sequential pacing is used for patients with additional conduction abnormalities. Oxygen demand is optimized through the strict avoidance of any inotropic medications, maintenance of filling pressures by leg elevation without Trendelenburg and volume infusion, and nitrates and $\alpha_1$-agonists as needed to optimize coronary perfusion pressure.

Serum electrolytes and acid–base balance also must be normalized to minimize triggers of arrhythmias. Serum potassium levels are checked hourly and repleted if they are less than 4.0 mEq/L as a protective measure against extrasystoles, atrial fibrillation, ventricular tachycardia, and ventricular fibrillation. In the authors' concept, extrasystoles [premature ventricular contractions (PVCs)] are considered abnormal and should never occur. When a PVC does occur, its etiology must be determined. The surgeon may have caused the PVC by touching the heart, and if this is the case, the anesthesiologist is notified and the operation proceeds. However, if the PVC was spontaneous, the patient's potassium level is checked. Levels below 4.0 mEq/L are repleted, but if they already are in the normal range, the abnormal beat is considered ischemic in origin until proved otherwise. The ECG–ST segments should be evaluated, as should the PA diastolic pressure and TEE for wall motion abnormalities. Only when all the members of the team are convinced that there is no ongoing ischemia does the operation continue. The authors have noticed, for instance, that a slightly misplaced stabilizer device may occlude coronary vessels, causing ischemia, which manifests as multiple PVCs. Only by adhering to these stringent principles can problems be identified and corrected in a timely fashion, avoiding hemodynamic compromise in the patient.

The patient's body temperature is regulated by two means. First, the room is kept warm until the patient is prepped and draped. Subsequently, it may be lowered to a comfortable temperature for the surgical staff. Second, a heated water blanket is placed underneath the patient and maintained at 40°C throughout the procedure. With these techniques, it is rare for a patient to leave the operating theater with a core temperature below 36.3°C.

## Incision

A median sternotomy is the incision of choice to perform OPCAB. This approach provides the most complete exposure for completion of all potential anastomoses while optimizing technical precision. Any coronary artery may be grafted with this exposure, and complex arterial reconstructions may be performed. Minimally invasive coronary artery bypass (MIDCAB) permits the use of a smaller minithoracotomy but is limited mainly to isolated revascularization of the anterior wall. More complex reconstructions are not possible. There also is concern that the quality of these anastomoses is reduced; this may translate into poorer long-term graft patency. For all these reasons, the authors strongly advocate a full median sternotomy for the optimal performance of OCPAB in all situations.

After the internal mammary artery (IMA) is mobilized from the chest wall, the pericardium is opened longitudinally, extending to the apex of the heart and completely along the diaphragm. The left pericardial edge is suspended from the retractor/drapes, but the right pericardial edge is left alone. This serves to rotate the heart slightly to the right, bringing the left anterior descending (LAD) artery closer to the midline of the operating field.

## Conduit Harvest

It is the standard of care to use at least one IMA for coronary revascularization. Usually the left IMA is harvested, but there are certain circumstances in which either right or bilateral IMA grafting is indicated. Patients with a patent dialysis shunt in the left upper extremity are at risk for a steal syndrome if a left IMA conduit is used. Also, an IMA should not be harvested ipsilateral to a subclavian artery stenosis. Patients with extensive atherosclerosis may benefit from angiography of the IMAs and the subclavian arteries during cardiac catheterization. For younger patients who are not diabetic, many surgeons choose to use both IMAs to provide two pedicled arterial grafts; this technique has demonstrated long-term patency. The specific technique for taking the IMA off the chest wall is beyond the scope of this chapter. The authors routinely open the pleura during IMA harvest, but this is a matter of surgeon preference. The authors routinely leave the right pleura intact and do not place the heart into the right chest.

A reversed saphenous vein is the most common conduit for the remaining grafts. This conduit is easy to harvest, is usually in good supply, is easy to work with, and has well-documented long-term patency in most situations. Newer techniques of endoscopic harvesting have further popularized the use of the saphenous vein because this technique reduces lower extremity wound complications and discomfort dramatically. This has now become standard practice for most coronary revascularization procedures requiring saphenous vein harvest.

Alternative choices for a conduit are generally more difficult to harvest, are often more difficult to work with, and have lower long-term patency rates. These choices include the lesser saphenous vein, the cephalic/basilic vein, a radial artery, the gastroepiploic artery, and cryopreserved vein. Only in situations in which conduit availability is severely limited should these other choices be considered.

## Anticoagulation

Anticoagulation consists of an intravenous heparin bolus administered at the completion of IMA harvesting to achieve

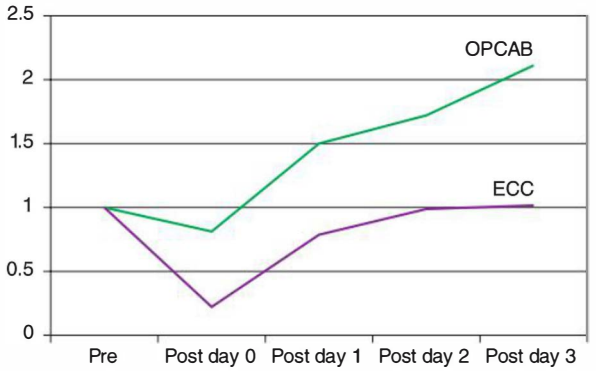

**FIGURE 28-2** Hypercoagulable profile of OPCAB patients. These data represent coagulation indices (CI) compared to baseline for patients undergoing standard CABG surgery (ECC group) compared with OPCAB. As expected, the group on-pump has a reduction of the coagulation index perioperatively (more likely to bleed) secondary to the effects of cardiopulmonary bypass. This returns to normal by POD#3. In contrast, the OPCAB group does not have a perioperative reduction in the CI but ends up being significantly hypercoagulable. These results were obtained by thromboelastography. (Data from Quigley RL, et al. Off-pump coronary artery bypass surgery may produce a hypercoagulable patient. *Heart Surg Forum* 2003;6:94–98. With permission from Forum Media Publishing.)

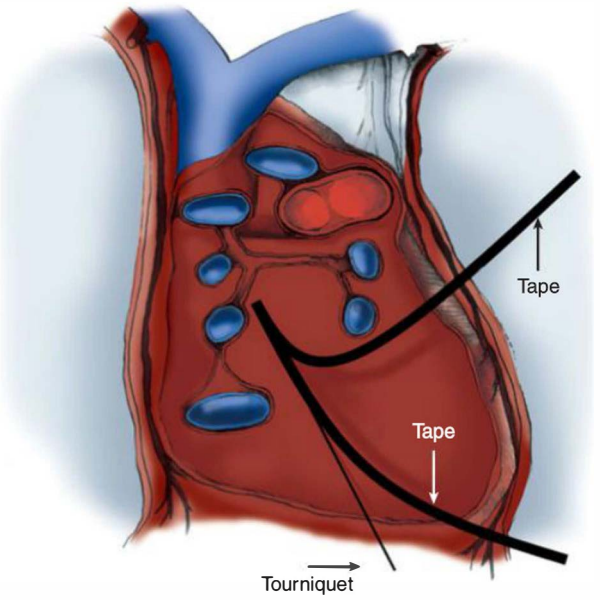

**FIGURE 28-3** Position of anchor stitch. The anchor stitch should be placed as far to the right side as possible, adjacent to the right inferior pulmonary vein. (With permission from Sergeant PL. Leuven, Belgium.)

a target activated clotting time (ACT) of 400 s or more; the heparin dose is usually 300 U/kg. ACT measurements are repeated every 20 min, and additional heparin is administered as necessary. Many authors routinely use a target ACT of 250 s despite a lack of evidence that this level is safe or prevents graft thrombosis. If the ACT level is too low to begin with or is not measured with adequate frequency, there is the potential for graft thrombosis. Furthermore, some data suggest that patients undergoing OPCAB have intrinsic hypercoagulable states (Fig. 28-2).[3] The authors feel that full-dose heparin should be used in all circumstances during the anastomotic period to maximize graft patency. Because OPCAB patients do not develop coagulopathies related to CPB, the authors feel strongly that performing vascular anastomoses with only partial anticoagulation confers a significant risk of thrombotic complications. Full protamine reversal is instituted at the completion of all anastomoses.

## Enucleation

In contrast to conventional CABG surgery, the left IMA to the LAD coronary artery is usually the first graft anastomosis performed in OPCAB procedures. This is the case because it is often the easiest to complete, requires minimal cardiac manipulation, and provides revascularization of the most critical myocardial region, conferring added protection from hemodynamic stability and arrhythmias during the remainder of the operation. The details of exposure for this anastomosis are described later in this chapter. After this step, the heart is enucleated from the pericardium so that the other coronaries may be visualized, stabilized, and grafted. This process is simple and consists of two parts.

First, a deep pericardial anchor stitch is placed with a long, heavy monofilament suture. The location of this stitch is of the utmost importance (Fig. 28-3). It should lie adjacent to the right inferior pulmonary vein, as far to the right as possible. This serves to lift the heart very effectively up out of the pericardium, bringing the atrioventricular groove closer to the surgeon. There has been much discussion in the literature regarding the use of various sling techniques[4,5] and we firmly believe this technique optimizes exposure with minimal risk if performed properly. Even more important, however, is the fact that this position prevents any distortion of the atrioventricular axis so that mitral insufficiency is not created or worsened if it is already present. A long sponge (opened up lengthwise) then is passed through the suture, and a tourniquet is advanced until the sponge is at the anchor stitch.

Second, the two "arms" of the sponge are used to lift the heart up and out of the pericardium. The assistant slowly pulls up and toward the patient's left with both arms of the sling, making sure to keep the mass of the heart supported (Fig. 28-4). It is critical that this step be performed slowly (about 2 mm with each cardiac contraction) to ensure stable hemodynamics. If at any time the filling pressures rise or the sponge appears to be constricting the left ventricle, the arms are lowered and the process is repeated. It is very unusual for any problems to occur during this procedure, and in fact, the authors have noticed that the heart functions in a superb

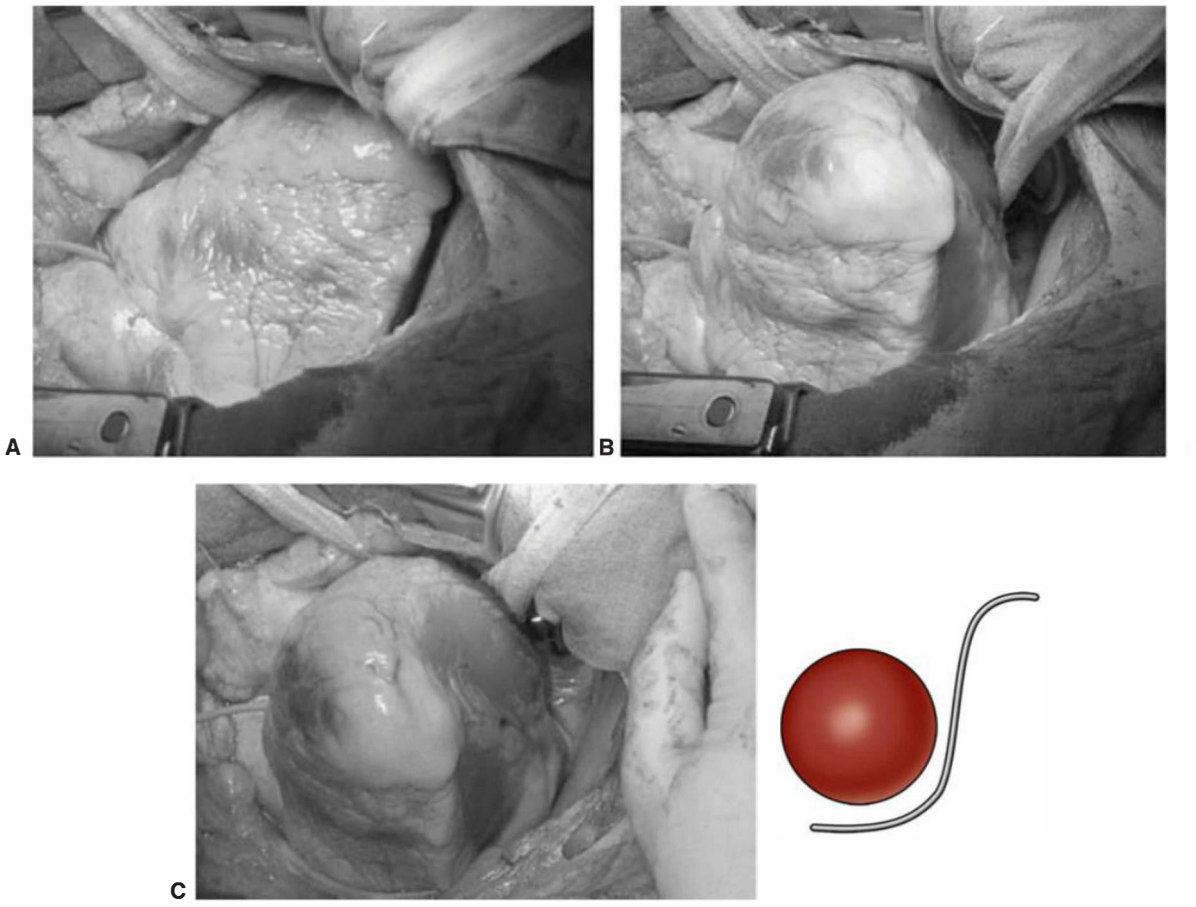

**FIGURE 28-4** Enucleation of the heart from the pericardium. As the arms of the sponge are pulled to the left, the heart rises out of the pericardium. This should be done slowly and should proceed without difficulty even with enlarged hearts or in patients with reduced ejection fractions. Note that the heart is globular and not in its normal configuration. (With permission from Sergeant PL. Leuven, Belgium.)

manner when elevated in this fashion. It is important after enucleation to readjust the right atrial filling pressures by means of leg elevation and volume infusion. The right ventricle should be inspected to make sure it does not distend as a result of malposition of the sling or the anchor stitch. Finally, the position of the sling on the left ventricular mass is checked and adjusted as needed; this may require subtle repositioning of the sling arms.

## Visualization

After successful enucleation, visualization is optimized in two steps: table rotation and apical suction. The operating table is rotated 30° toward the surgeon (the patient's right), ensuring that the patient's right leg is protected from falling by a secured padded block. A standard safety strap or belt would serve the same function. This table rotation causes the heart to move slightly toward the patient's right side, opening the space between the retractor and the lateral wall of the heart. Usually the circumflex marginal branches become visible after this step. It is important to remind the anesthesiologist to re-zero the pulmonary arterial catheter transducer after this maneuver.

Next, the apical suction device is placed near the ventricular apex in an area devoid of coronary vessels to prevent occlusive ischemia. Care must be taken to avoid the diaphragmatic surface of the heart, where the device may entrain air and become dislodged. With the apical suction device used in conjunction with the sling support, the authors have found that only 200 mm Hg of suction is required to maintain contact with the heart. This low degree of suction has the added benefit of reducing epicardial trauma. The function of the apical device is three fold: axial stabilization, reformatting of the ventricle, and axial displacement. Axial stabilization occurs once the device is secured in the desired position while preserving the ability of the heart for rotational contractility. After suction is applied to the apical suction device, the ventricular shape is reformatted from a globular to a more normal configuration by gently pulling the heart anteriorly. While the ventricle is maintained in its optimal configuration, the axis is displaced both superiorly

and to the patient's right (in the direction of the patient's right shoulder). This allows adequate exposure of lateral wall vessels while avoiding right-sided filling impairment from kinking or compression.

## Stabilization

The final preparatory step before the first coronary arteriotomy is made involves stabilization of the specific target coronary vessel. This has become much easier with the development of newer stabilizing devices over the last few years. These devices usually require 450 mm Hg of suction to stabilize the heart for a technically perfect anastomosis. In addition to the stabilizer, 4-0 braided sutures can be placed superficially in the epicardium adjacent to the coronary artery target and placed under gentle traction with hemostats to enhance the stabilization. A number of strategies may be employed in light of the particular anatomy confronted during this step. It is important not to apply suction directly over a coronary artery, however, as this may result in ischemia. A technique that often helps to prevent this problem involves placing bone wax in one or two of the suction holes that must lie atop a coronary artery.

Exposure of all target coronaries is identical with the exception of the LAD and the right coronary proximal to the take-off of the posterior descending artery. Because the LAD anastomosis is performed first, the sling support and apical suction are not placed initially. After the pericardium is suspended, additional horizontal sutures are placed along the lateral aspect of the left pericardium from cephalad to caudad, pulled anteriorly, and fastened to the surgical drapes. This rotates the heart about 15° toward the midline and brings the LAD into the middle of the operative field. At this point, target stabilization may proceed, followed by coronary shunting and completion of the graft anastomosis. In certain circumstances, diagonal vessels also may be revascularized using this exposure. However, if they lie more toward the lateral wall, the standard enucleation exposure is preferred.

The exposure of the right coronary proximal to the posterior descending coronary artery is also unique. Similar to exposure of the LAD, this is performed without the sling support or the apical suction device. Epicardial traction sutures are placed on the inferior wall near the acute margin and pulled in a cephalad direction, bringing the right coronary more anteriorly and into view. This allows for target coronary stabilization with a combination of the suction stabilizer and additional epicardial traction sutures (Fig. 28-5).

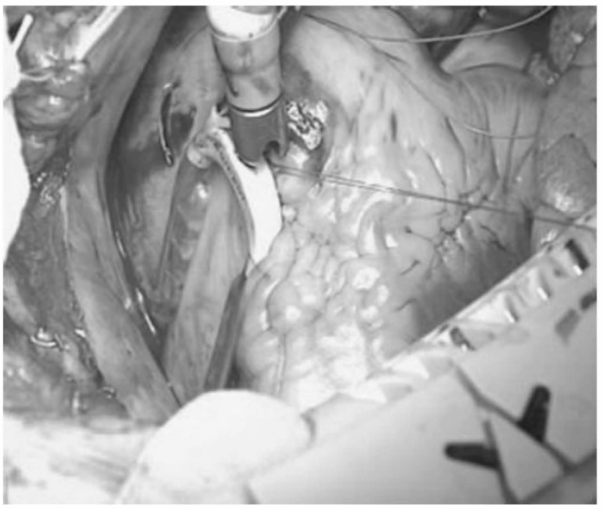

**FIGURE 28-5** Stabilization of the right coronary artery. This image demonstrates stabilization of the right coronary artery proximal to the posterior descending. Note the combination of epicardial traction sutures and target vessel stabilizer. There is no sling support for this exposure. (With permission from Sergeant PL. Leuven, Belgium.)

## Shunt Insertion

The primary objective of placing an intracoronary shunt during anastomotic construction is the avoidance or minimization of ischemia. Some surgeons never shunt, some do selectively, and some shunt with every anastomosis. The authors firmly believe in the third approach. The techniques described in this chapter are focused on reducing risk at every step to avoid hemodynamic instability and conversion to CPB. Thus, a shunt should be used for every anastomosis. The majority of coronary anastomoses probably can be completed safely without shunting. However, it is not possible to predict when shunting will be needed to avoid ischemic complications; thus, the only way to minimize risk fully is to shunt every time.

Flow through a shunt varies according to its internal diameter. All shunt sizes greater than 1.00 mm provide adequate blood flow to the distal coronary territory.[6] The maintenance of distal coronary flow has been further demonstrated to preserve myocardial function compared with temporary coronary occlusion.[7] This translates into a more stable operative environment, lower stress for the surgical team, and facilitates the construction of a technically perfect coronary anastomosis.

A frequently unmentioned advantage of placing intracoronary shunts is the improved visibility and exposure of the coronary artery walls. The shunt not only serves to keep blood out of the anastomotic area, it also keeps the vessel open to prevent suturing the back wall and improves visualization of the toe and heel areas. Furthermore, careful manipulation of the shunt can facilitate technically challenging anastomoses by opening space between the coronary wall and the shunt itself.

The main criticism of routine shunt placement during OPCAB is concern about endothelial damage; this concern is supported in the literature. For surgeons who choose not to shunt, the alternative is to occlude the coronary with Silastic slings and use a $CO_2$ blower/mister. However, when studies

have compared endothelial damage resulting from shunts with damage from vessel occlusion, shunts appear to be less traumatic.[8] In addition, the blower/mister device has been associated with severe complications, including endothelial damage and air embolism.[9,10] In considering all the risks and benefits of shunting for OPCAB, the authors believe the data firmly support the routine use of shunts to facilitate a safer procedure and the creation of technically perfect anastomoses.

Certainly, it also is reasonable to expect that the shunt insertion technique influences the degree of intimal disruption. The tip of the shunt should be placed in a "gooseneck" orientation rather than being pushed directly in, minimizing intimal trauma. The longer of the two shunt ends always is inserted first. The direction, whether proximal or distal, in which to insert the long end depends on the coronary anatomy. It should be placed away from coronary branches so that it will not lead to selective perfusion. These techniques are not part of routine surgical training, often need to be performed with the surgeon's nondominant hand, and can be challenging. For this reason, it is recommended that this technique be practiced in a model, re-creating the various angles and narrow spaces that will be encountered during OPCAB surgery. This enhances the surgeon's skill and ease at placing shunts so that the risks will be minimized during an actual operation.

## Distal Anastomoses

This is the final common step for each target vessel. For IMA conduits the authors recommend 8-0 polypropylene sutures and use 7-0 polypropylene for saphenous vein conduits. In the following paragraphs, a brief summary of the exposure and graft technique is given.

The LAD most often is revascularized first as it is the easiest to perform and, once completed, permits OPCAB to proceed more safely. Good exposure of lateral wall coronary targets requires that the heart be enucleated after placement of the deep pericardial anchoring stitch and sling support. Visualization is enhanced with table rotation and axial stabilization/displacement with the apical suction device, facilitating stabilization of the circumflex marginal vessels, although in a somewhat narrow space (Fig. 28-6). This space can be optimized by refinements in positioning the axial stabilizer, further widening of the sternal retractor, and adjustment of the vessel stabilizer itself. Opening of the right pleura with placement of the heart in the right chest is not only unnecessary but potentially harmful if venous return is impeded.

The inferior wall vessels (posterolateral and posterior descending arteries) are performed similarly, usually after completion of the lateral wall grafts. The heart is enucleated and apical suction is applied with displacement of the heart superiorly and to the right. This brings the inferior wall into a vertical alignment away from the diaphragm and allows for target vessel stabilization. The exposure of the right coronary proximal to the posterior descending (mid-right coronary artery) has been described and does not require enucleation or apical suction (Fig. 28-5).

## Proximal Anastomoses

Standard techniques of partial aortic occlusion for construction of the proximal graft anastomoses have mostly been discarded due to the increased aortic manipulation and corresponding embolization risk. Clampless devices have been developed and improved, which allow for safe and effective proximal vein anastomosis to the aorta. These connections are completed with 6-0 polypropylene suture in the standard fashion and will not be discussed further here.

## Revascularization Strategies

A frequent criticism of OPCAB is that fewer anastomoses are performed, especially on the lateral wall. In inexperienced hands this may be true, but with a technique that is safe and effective, all potential coronary targets should be accessible. Multiple studies demonstrate that all coronary targets are accessible with current off-pump techniques. Furthermore, there is evidence that suggests selection bias may play a role in fewer grafts being performed in OPCAB versus traditional CABG.[11] In other words, patients requiring fewer grafts are more likely to be chosen as OPCAB candidates.

The performance of OPCAB also does not preclude the surgeon from completing an all-arterial revascularization. In contrast, the concept of reducing complications while maximizing benefit in OPCAB is concordant with this strategy, and it is technically feasible to do so. Unless a patient is extremely morbidly obese or older than age 80 years, the authors prefer to use bilateral IMAs with the right mammary artery being a free graft, sequentially grafted around the lateral and inferior walls. Since the authors' transition to OPCAB surgery, the percentage of arterial anastomoses and all-arterial revascularization has increased dramatically.

At KU Leuven, the authors avoid all manipulation of the aorta whenever possible to reduce the risk of embolic stroke. For this reason, the standard coronary revascularization scheme consists of the left IMA grafted to the LAD and a free right IMA graft taken off the proximal left IMA and sequentially anastomosed around the lateral and inferior walls. If there is a contraindication for the use of bilateral IMA grafts, the saphenous vein is used. In an elderly patient with significant comorbid conditions and a good-quality small-caliber vein, this also may be taken off the proximal left IMA before being sequenced around the lateral and inferior walls. When the left IMA is used as an inflow source for a free graft, the anastomosis is placed as proximal on the left IMA as possible, where the vessel caliber is maximal; a shunt also is placed to ensure a technically perfect anastomosis. There has been no increased incidence of LIMA-to-LAD graft failure as a

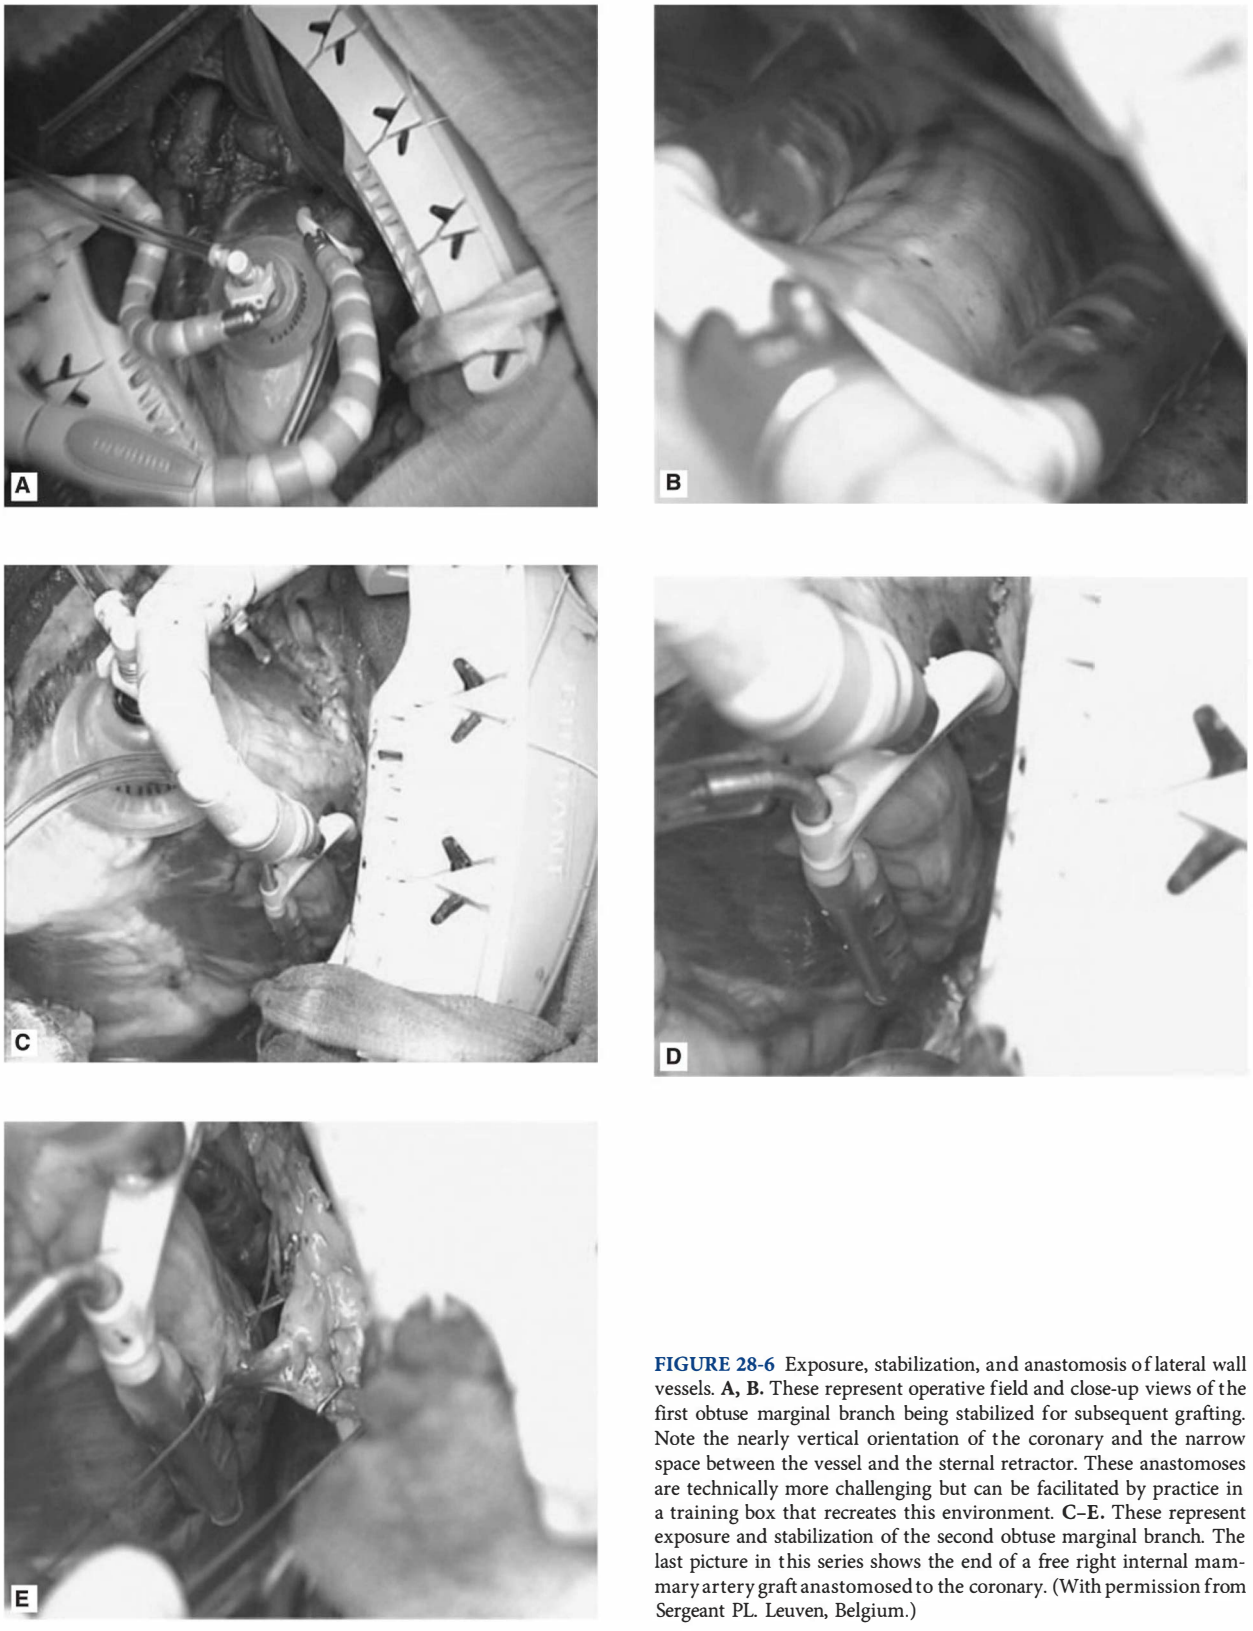

**FIGURE 28-6** Exposure, stabilization, and anastomosis of lateral wall vessels. **A, B.** These represent operative field and close-up views of the first obtuse marginal branch being stabilized for subsequent grafting. Note the nearly vertical orientation of the coronary and the narrow space between the vessel and the sternal retractor. These anastomoses are technically more challenging but can be facilitated by practice in a training box that recreates this environment. **C–E.** These represent exposure and stabilization of the second obtuse marginal branch. The last picture in this series shows the end of a free right internal mammary artery graft anastomosed to the coronary. (With permission from Sergeant PL. Leuven, Belgium.)

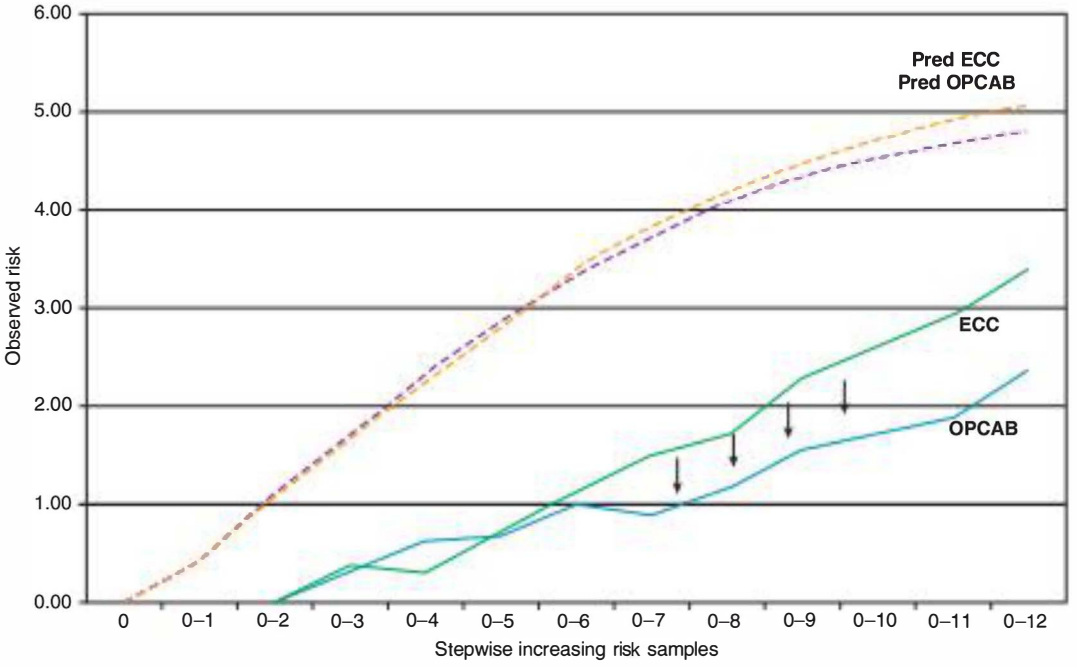

**FIGURE 28-7** Comparison of expected to observed mortality. This graph shows that patients with CABG on-pump (ECC) have much better mortality than predicted on the basis of risk. Observed mortality in OPCAB patients is even better than that for the ECC group in patients with increasing risk. Note: Expected mortality was the same for both groups. (With permission from Sergeant PL. Leuven, Belgium.)

consequence of this strategy. In some cases, though, there is no alternative to placing a graft on the ascending aorta. In this situation, the surgeon should avoid placing a partial occlusion clamp by using novel technologies such as HeartString or other connector devices that are less likely to shower emboli.

# OUTCOMES

## Literature

It is important to remember that in reviewing the literature regarding a specific surgical technique, the data represent the specific technique described and must be powered adequately for the reader to draw conclusions. It is easy to make any technique appear unsuccessful if it is performed by inexperienced surgeons or if the components of the operation are not the most effective. Furthermore, outcomes cannot be evaluated if the specific technique does not incorporate all measures to minimize risk. Conclusions pertain only to the exact circumstances that existed in the study.

Although there are certain reports, which seem to indicate less than ideal outcomes with OPCAB compared to standard CABG, the preponderance of evidence in the surgical literature clearly demonstrate overall improved mortality, morbidity, and cost with OPCAB.[12–15]

## Mortality

A number of studies have documented a significant improvement in mortality in OPCAB patients compared with on-pump CABG,[16] as do data from KU Leuven (Fig. 28-7). Risk cannot be reduced where none is present. Therefore, low-risk patients tend not to have a mortality benefit from OPCAB. However, for patients with increasing risk, here defined by Euroscore, the improvement in mortality, both in-hospital and at 3 months is substantial. There is also a much more significant reduction in expected-to-observed mortality with OPCAB compared with conventional CABG.

## Morbidity

Avoidance of CPB and its associated complications tends to result in improvements in outcomes for all organ systems. Below is a summary of the literature pertaining to this along with data from KU Leuven.

### NEUROLOGIC

This category includes two distinct areas of injury: stroke and neurocognitive dysfunction. Stroke is a more clearly defined outcome, and because of its low incidence, it is difficult to demonstrate an improvement without very large patient cohorts. Nonetheless, various studies in the

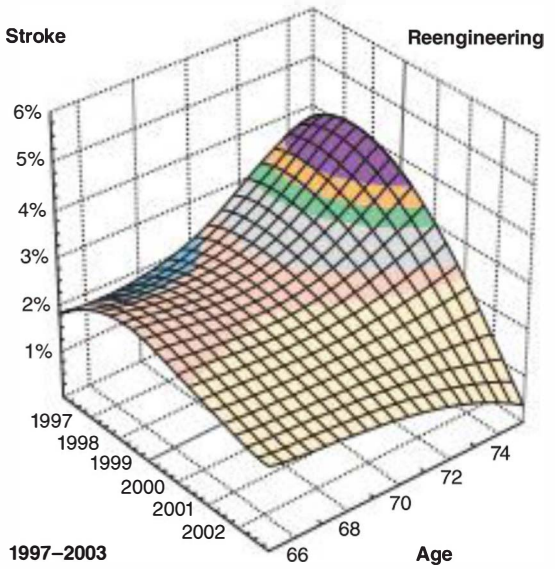

**FIGURE 28-8** Stroke rate in high-risk patients. These data represent patients with preoperative carotid stenosis greater than 80 percent. This cohort consists of 200 patients in each group and achieves statistical significance ($p = 0.02$) with a relative risk reduction of 68 percent. (With permission from Sergeant PL. Leuven, Belgium.)

literature have demonstrated either equivalent or reduced stroke rates for patients undergoing OPCAB compared with those receiving on-pump CABG. This beneficial effect may be somewhat mitigated in patients who have a history of preoperative neurologic events.[17] Similarly, data from KU Leuven show that intraoperative stroke essentially has been eliminated by the routine performance of OPCAB. Furthermore, data now also demonstrate significant improvement in stroke by utilizing "no-touch" OPCAB techniques, avoiding any clamping or manipulation of the ascending aorta.[18,19] Postoperative strokes still occur as a result of hypotension and atrial fibrillation with cerebral embolization. Lower stroke risk is also evident when stroke is stratified according to patient age. These data become statistically significant when patients at high risk for stroke are compared (Fig. 28-8).

## PULMONARY

This category often is represented by the "time to extubation" metric. Many OPCAB centers have demonstrated significantly reduced extubation times that translate into shorter lengths of stay in the intensive care unit (ICU).[20] Furthermore, a number of reports have advocated the safe extubation of OPCAB patients in the operating room at the conclusion of the procedure.[21]

## CARDIAC

These complications can be separated into myocardial infarction (MI) and enzyme release not associated with acute infarction. Graft failure also can be included in this subsection because acute graft occlusion often leads to infarction. Although many studies have demonstrated no difference in the incidence of perioperative MI with OPCAB, some authors have found a reduction in this event in patients undergoing OPCAB.[16] Logic dictates that avoiding ischemic cardioplegic arrest will reduce myocardial injury during CABG procedures. Data from KU Leuven do not reveal any reduction in the incidence of MI in OPCAB patients.

The significance of elevated troponin values after OPCAB remains uncertain. Certainly, no data about the "normal" levels of troponin after this procedure are conclusive. A few studies have investigated enzyme release after OPCAB,[22] and the results seem to indicate a trend toward reduced troponin levels but no specific correlation with reduced infarct rates.

Graft failure rates with OPCAB generally seem to be equivalent to those for conventional on-pump CABG.[23] One article that placed international focus on poor graft patency in OPCAB[24] demonstrated only that the specific technique used by those authors and performed by those surgeons was less than satisfactory. This finding should not be generalized to a belief that all OPCAB procedures are doomed to similarly poor outcomes with respect to graft failure. Only by minimizing risk and maximizing safety (e.g., full anticoagulation, use of intracoronary shunts) can the full benefits of OPCAB be realized.

## RENAL

Perhaps the area of greatest benefit in OPCAB patients is the renal system. Patients with preexisting renal dysfunction who undergo conventional CABG have a significant propensity for postoperative renal complications, including temporary or permanent hemodialysis. For patients with normal kidney function, the risks are quite low, and thus OPCAB results suggest no benefit. However, in high-risk cohorts it has been proved clearly that avoiding CPB leads to dramatically reduced renal complications.[25] OPCAB also seems the more appropriate technique for patients already requiring dialysis prior to their operation in terms of reducing blood transfusions, MI, and hospital mortality.[26] This is in agreement with data from KU Leuven, which have shown a 26-percent reduction in the relative risk for postoperative hemodialysis or ultrafiltration.

## HEMATOLOGIC

The literature supports the notion that OPCAB patients experience less blood loss from surgery in addition to having lower transfusion requirements. This results from increased thrombin generation and reduced fibrinolysis in the presence of intact, functioning platelets. Various authors have hypothesized about ideal antiplatelet regimens to prevent postoperative thromboembolic complications in OPCAB patients. There also appears to be a protective effect against gastrointestinal ischemia by avoiding CPB in these patients.[27]

### LENGTH OF STAY

The performance of OPCAB has been shown to reduce the length of stay of cardiac surgical patients. This probably is a result of reduced systemic inflammation, decreased fluid requirements, and quicker time to extubation. Furthermore, lower morbidity rates also lead to earlier patient discharge from the hospital. Evidence from KU Leuven supports these findings as well, especially when patients are stratified by age or Euroscore.

### COST

Economic savings in OPCAB patients are realized by two means: (1) small, production-line advantages that result from every patient undergoing surgery (e.g., reduced operating room charges, reduced personnel charges) and (2) large savings in a small number of patients who avoid severe complications (e.g., reduced incidence of stroke and renal failure). Therefore, OPCAB can lead to dramatic cost savings. The literature continues to support this claim.[28]

### RACE/GENDER

Historical data on OPCAB outcomes by race and gender have been limited. Newer studies, however, have been more successful in identifying whether OPCAB can influence morbidity and mortality in females and minorities specifically. OPCAB has now been shown to be a safe and effective modality for both low- and high-risk female patients. However, when late outcomes are compared by gender, women seem to have only equivalent, or perhaps higher, complication rates as men.[29]

Data now available for African American patients seem to suggest that short- and long-term outcomes remain worse than for Caucasian patients, even when OPCAB is performed.[30]

## SUMMARY

OPCAB is much more than a simple alternative to conventional CABG surgery without the assistance of CPB. It is a concept that emphasizes patient safety and long-term benefit. To achieve this, a multidisciplinary approach must be employed, involving nursing, anesthesia, and surgery. When all efforts are made to minimize risk and provide a stress-free operating room environment, great benefit for the patient may be achieved. Although there is some disagreement in the literature about short- and long-term outcomes with OPCAB, one must be cognizant of the specific techniques used and the experience of the surgeons involved in a study. There is surely more than one successful OPCAB technique. With perseverance and diligent training and retraining, OPCAB should become applicable to the entire spectrum of patients presenting for surgical coronary revascularization.

## OFF-PUMP CORONARY ARTERY BYPASS BOARD REVIEW QUESTIONS (CHAPTER 28)

1. The primary goal of OPCAB is:
   A. Achieving the greatest number of grafts
   B. Performing all-arterial grafting
   C. Reducing cost of CAB
   D. Decreasing morbidity and mortality
   E. Increasing patient referrals

2. Which of the following settings is most appropriate for OPCAB?
   A. Elective
   B. Acute MI with cardiac index less than 1 L/min/$m^2$
   C. Pulmonary edema with cardiac index between 1 and 2 L/min/$m^2$
   D. None of the above
   E. All of the above

3. Which of the following is true regarding anticoagulation for OPCAB?
   A. Full-dose heparin (300 units/kg) should be used.
   B. ACT should be maintained around 250 s.
   C. Repeat ACT should be performed every 20 min.
   D. A and C
   E. All of the above

4. Intracoronary shunts should be used according to which of the following criteria?
   A. Rarely due to high risk of endothelial damage
   B. Selectively based on arterial size
   C. Selectively based on artery location
   D. Selectively based on ischemia during vessel occlusion
   E. Routinely after thorough simulator training

5. Which of the following is true regarding outcomes after OPCAB?
   A. Statistically significant results are often achieved even with relatively small patient cohorts
   B. OPCAB confers a higher intraoperative risk of stroke
   C. "No-touch" technique on the aorta has been repeatedly shown to reduce stroke
   D. Atrial fibrillation and hypotension both contribute to intraoperative stroke
   E. There is no statistically significant improvement in stroke when high-risk patients are compared.

## ANSWERS

1. **Answer: D.** The primary goal of coronary artery bypass grafting, whether with or without cardiopulmonary bypass, is to reduce morbidity and mortality from coronary artery disease.
2. **Answer: A.** Certain clinical conditions warrant the use of cardiopulmonary bypass, including patients undergoing CPR, acute myocardial infarction with low cardiac index, and pulmonary edema with reduced cardiac performance.
3. **Answer: D.** Full dose heparin should be used and the ACT should be maintained at above 400 s. A lower ACT may be associated with a higher risk of graft failure in the setting of OPCAB. The ACT should be repeated every 20 min.
4. **Answer: E.** Following the principle of minimizing risk, shunts should be routinely placed for every anastomosis. Improper placement can cause endothelial damage and it is recommended that surgeons have thorough training and practice using a simulator model to reduce the risk of shunt placement.
5. **Answer: C.** Only the "no-touch" technique has been conclusively shown to reduce stroke. In general, large cohorts of patients are required to demonstrate statistical significance, as stroke is an uncommon event.

# Reoperative Coronary Artery Bypass Surgery

*Christopher J. Barreiro*
*George J. Arnaoutakis*
*Jay G. Shake*

## KEY CONCEPTS

- Epidemiology
  - Among the 200,000 coronary bypass operations performed annually in the United States, reoperative coronary artery bypass surgery (redo-CAB) accounts for approximately 5 percent of all isolated coronary artery bypass grafting (CABG) procedures. Recent data from the Society of Thoracic Surgeons database show that there has been a decrease in the number and percentage of redo-CAB procedures (2000, $N = 8929$, or 6.1 percent; 2009, $N = 8189$, or 4.3 percent).
- Pathophysiology
  - Reoperative coronary artery surgery is performed for patients in whom there is definite demonstrated myocardial viability with associated symptomatology. A multivariate analysis demonstrated that preoperative angina, use of vein grafts only, previous myocardial infarction, incomplete revascularization, female gender, and smoking at a younger age were independent risk factors for recurrent angina and a potential need for reoperation.
- Clinical features
  - In more recent years, the reoperative candidate population has evolved to include older patients, with diminished left ventricular function, triple-vessel coronary artery disease (CAD), and graft failure becoming the predominant etiologic factors. Recently, however, there appears to be an increase in number of reoperative candidates with progression of their native disease distal to their patent conduit graft sites.
- Diagnostics
  - Diagnostic tests include those used to assess viable myocardium and those used for planning the operation. The tests frequently used for detecting viable myocardium include thallium scintigraphy, dobutamine echocardiography, magnetic resonance imaging, and positron emission tomography. Coronary angiography is the gold standard for determining the need for revascularization and the appropriate targets. Standard computed tomography (CT) can be used to assess the substernal structures. However, with the development of multislice CT and three-dimensional (3-D) reconstruction, accurate pictures of the cardiac anatomy and the relationships of bypass grafts to mediastinal structures as well as the sternum can be demonstrated vividly.
- Treatment
  - Reoperative surgery for CAD requires knowledge of mediastinal structures and a staged entry into the chest with the use of an oscillating saw and scissors for division of the outer and inner tables, respectively. Femoral artery and vein cannulation may be necessary if it is anticipated that cardiac structures are in jeopardy of being injured upon reentry. Careful dissection in the area of previous vein grafts that may be atherosclerotic is important, as downstream debris from these vein grafts is the most common cause of mortality in this high-risk group of patients.

## INTRODUCTION

Coronary artery bypass grafting (CABG) is the most common cardiac surgical procedure, with nearly 200,000 operations performed annually in the United States according to the Society of Thoracic Surgeons (STS) database. Reoperative CABG accounts for approximately 5 percent of all isolated CABG procedures and is often the result of graft failure, progression of native coronary disease, or incomplete revascularization.[1,2] Recent STS data show that there has been a decrease in the number and percentage of isolated redo-CABG operations (2000, $N$ = 8929, or 6.1 percent; 2009, $N$ = 8189, or 4.3 percent). There are probably many reasons for this trend, including improved medical management and interventional cardiology. Most redo-CABG procedures today are performed more than 10 years after the primary CABG, and are technically more challenging because of the difficulty of sternal reentry, the presence of patent bypass grafts, and limitations of potential bypass conduits. In addition to the technical complexities, the risk profile of reoperative candidates continues to increase. Redo-CABG patients are older, have greater extent of coronary artery disease (CAD), and have worse left ventricular (LV) function. However, these obstacles have been offset by improvements in operative techniques and perioperative care, resulting in improved survival and postoperative outcomes in redo-CABG patients.

## CLINICAL FEATURES

Surgical reintervention rates and recurrent symptoms are two of the primary outcomes used to gauge the success of the initial CABG procedure. In two large cohort studies, freedom from redo-CABG at 1, 5, 10, and 15 years was 99, 97, 89, and 72 percent, respectively.[2,3] In addition, freedom from recurrent angina after initial CABG surgery has been approximately 80 percent at 10 years.[4] In a multivariable analysis, preoperative angina, use of vein grafts only, previous myocardial infarction (MI), incomplete revascularization, female gender, smoking, and younger age were found to be independent risk factors for recurrent angina.[5] Another large study defined diffuseness of CAD using a validated diffuseness score, and found that diffuse CAD was an independent predictor of morbidity and mortality.[6]

Reoperative candidates include patients with recurrent symptoms and jeopardized viable myocardium due to progression of CAD or graft failure. Predictors of redo-CABG include young age at initial operation, male gender, worse symptom severity, absence of internal mammary artery (IMA) grafts, incomplete revascularization, impaired functional status, and multivessel disease.[7,8] Initially, incomplete revascularization or worsening atherosclerosis of the native coronary arteries accounted for the majority of redo-CABG operations. As the redo-CABG population has evolved to include older patients with worse LV dysfunction and triple-vessel disease, graft failure has become the predominant etiologic factor. More recently, however, there has been an increase in the number of reoperative candidates with progression of their native disease distal to patent arterial graft anastomoses.[8]

Choice of graft conduits at the primary operation has been shown to be a significant factor in determining the need for reoperation. The increased use of arterial conduits, including IMA and radial artery grafts, instead of saphenous vein graft (SVG) conduits, has reduced the rate of reoperation significantly in recent years. IMA patency rates after primary CABG surgery exceed 90 percent at 10 years; in contrast, SVGs begin to deteriorate rapidly after 5 years and have a 50 percent patency rate at 10 years.[9] Furthermore, nearly 20 percent of SVGs occlude by 1 year.[10] Although some debate remains, there are several large retrospective studies that support improved survival in patients receiving total arterial revascularization, in both primary and redo-CABG procedures.[11] Because of improved patient survival and patency rates of arterial grafts, the IMA has become the choice conduit—when available—for primary CABG as well as for redo-CABG surgery for SVG stenosis.

Early SVG stenosis within the first year of primary CABG often is due to intimal hyperplasia. The increased intimal thickness presumably is due to exposure of the vein to systemic arterial pressures. This proliferative process results in vein graft atherosclerosis, which is the leading cause of late occlusion and accelerates dramatically after 5 years. SVG atherosclerosis has a worse prognosis than does native vessel atherosclerosis. The lesion in a vein graft is often diffuse and prone to plaque rupture, with increased rates of thromboembolic phenomena. As a result, even minimal manipulation of SVGs or antegrade cardioplegia during redo-CABG surgery can dislodge atheromatous emboli and result in MI. This represents the most common cause of operative mortality in patients undergoing redo-CABG surgery. Arterial grafts are much less prone to occlusion, although they can develop neointimal proliferation, most commonly at the distal anastomotic site.

## PREOPERATIVE CONSIDERATIONS

Preoperative planning is of even greater importance in redo-CABG surgery than it is in primary procedures. For the reoperation to occur safely, adequate preoperative assessment and analysis are critical (Table 29-1). The patient's history must be reviewed thoroughly, with close attention not only to all previous cardiac surgery, but also to any relevant

**TABLE 29-1: Preoperative Assessment**

procedures or comorbidities that may affect the surgeon's approach to the reoperation. For example, a patient with a previous history of mediastinitis should be considered for a thoracotomy incision as an alternative to redo-sternotomy if the coronary anatomy is favorable for this approach. Medications should be reviewed carefully so that any drugs affecting platelet function or coagulation can be discontinued at least 1 week prior to the operation. Most importantly, it is essential to have a clear and complete understanding of the patient's native coronary and bypass graft anatomy before undertaking a reoperation. This information can be ascertained from previous operative records and coronary angiograms. The surgeon must also determine if bypassing potentially graftable vessels will improve perfusion to viable regions of myocardium. In addition to determining the feasibility of beneficial revascularization, adequate bypass conduits must be available.

## Bypass Conduits

The surgeon should have a preoperative plan for the selection of bypass conduits. Venous Doppler studies often are used to determine the adequacy of saphenous vein segments. Vein mapping is a simple, accurate, and noninvasive method to predict the course of the vein and identify venous anomalies. On occasion, venous mapping can influence the surgeon's choice of the venectomy site. Arterial Doppler studies can assess the radial arteries. In addition, an Allen's test can help ensure that digital perfusion will remain adequate if the radial artery is harvested as a potential conduit. Abnormalities in the IMA also can be detected with Doppler studies. IMA ultrasound studies may reduce the need for invasive preoperative assessment of patency and length, and allow for postoperative assessment of coronary artery flow reserve. However, IMA angiography provides a more complete evaluation of these arteries and should be used whenever possible.

# DIAGNOSTIC MODALITIES

## Chest X-ray and Computed Tomography

The surgeon can evaluate the risk of sternal reentry by means of radiography. A posteroanterior and lateral chest x-ray can give the surgeon an idea of the proximity of important cardiac structures to the sternum. Steel clips that are visible on a chest radiograph also can be used to trace the path of patent IMA grafts. If deemed necessary, CT offers an enhanced view of substernal structures. CT scans can determine the size and position of cardiac chambers as well as the course of bypass conduits. This information can guide sternal reentry. In a series of 167 redo-CABG patients, high-risk findings by preoperative CT imaging led to more frequent adoption of preventive surgical strategies.[12] In patients at high risk for hemorrhage or injury to substernal structures, femoral dissection should be performed to allow for peripheral and expeditious institution of cardiopulmonary bypass (CPB). Alternative incisions should be considered if they are deemed necessary on the basis of this evaluation. In addition to standard CT scanning, intravenous angiography multislice CT and 3-D reconstruction is a recent technological advancement that has been found to be extremely accurate in detecting CABG patency and occlusion (Fig. 29-1).[13] This imaging modality also provides clear and accurate pictures of the cardiac anatomy and the relationships of bypass grafts to mediastinal structures; however, standard angiography remains the modality of choice for assessing native coronary circulation (Fig. 29-2).

## Coronary Angiography

Coronary angiography is a necessary step in the complete preoperative assessment of potential redo-CABG patients. To gain a better understanding of the patient's coronary anatomy, previous angiograms and operative notes should be reviewed and are invaluable tools for the reoperative surgeon as well as the interventional cardiologist performing the angiogram. The coronary angiogram can be used to estimate the severity of atherosclerotic and thrombotic lesions. The severity of native coronary and SVG stenosis often is underestimated on the basis of a single angiographic view. Therefore, multiple projections are required to visualize the entire native coronary circulation as well as the previously constructed bypass grafts. The angiogram also can aid in determining the presence of graftable target vessels. To ensure that this is performed accurately, the angiographer must inject all relevant branches and allow enough time for the filling of the coronaries by collaterals. It is important that angiography supplement the surgeon's intraoperative assessment of the patient's coronary anatomy.

## Assessing Viable Myocardium

Impaired LV function secondary to ischemic heart disease is not always permanent, and may improve considerably with revascularization. Restoration of blood flow to chronically underperfused and ischemic myocardium often can restore contractile function. However, revascularization of scar tissue will not result in functional improvement. Given the considerable operative morbidity and mortality for patients with LV dysfunction undergoing surgical revascularization, especially redo-CABG, it is essential to differentiate between viable and nonviable myocardium. Several noninvasive imaging modalities are used to identify physiologic markers of myocardial viability in regions with contractile dysfunction. The most commonly used techniques to ascertain viability include positron emission tomography (PET), thallium scintigraphy, dobutamine echocardiography, and cardiac magnetic resonance imaging (cMRI). PET is an established method for demonstrating preserved

metabolic activity through the use of $^{18}$F-fluorodeoxyglucose as a marker of myocardial glucose utilization. Thallium scanning is used to assess myocardial perfusion and membrane integrity, whereas the myocardial contractile reserve is best evaluated by using dobutamine echocardiography or cMRI. The chief advantage of cMRI is the ability to simultaneously detect ischemic myocardium, calculate ventricular chamber size and volumes, and assess viability and scar formation.[14]

## MEDICAL THERAPY

### Nonsurgical Interventions

Redo-CABG carries with it significantly higher morbidity and mortality as compared with patients without a history of CABG. Therefore, various nonsurgical approaches to revascularization, such as percutaneous coronary interventions (PCI) with intracoronary stenting have become much more widespread in recent years. As the line begins to blur between candidates for surgical versus nonsurgical revascularization, many studies have been performed to compare these two techniques for primary revascularization. However, the data are more limited in patients in need of reintervention who already have undergone CABG. The AWESOME trial was a nationwide, prospective, multicenter effort, which demonstrated that PCI is a viable alternative for patients with medically refractory myocardial ischemia and risk factors for adverse outcome with CABG. This registry demonstrated

that for the specific subset of patients with prior CABG, both the physicians and patients chose PCI by a 2:1 margin, and a survival advantage with PCI was shown in the patient-choice cohort. For the 142 randomized patients to either redo-CABG or PCI, similar survival results were found with an overall 3-year survival of 76 and 73 percent, respectively.[15] However, redo-CABG is associated with greater success in providing complete revascularization as well as a reduced need for subsequent revascularization procedures. In a review of patients referred for reoperation versus PCI at the Cleveland Clinic, those undergoing redo-CABG were more likely to be male and have diabetes, hypertension, valvular disease, and severe LV systolic dysfunction. These patients generally had fewer functioning venous and arterial grafts and a larger region of myocardium in jeopardy. Although reoperation is associated with a higher risk of in-hospital complications than is PCI, it has potential long-term benefit when there is a lack of functioning bypass grafts or a lack of a patent arterial graft to the left anterior descending (LAD) coronary artery.[16] SVG stenosis also can be treated with stenting; however, stenting usually is limited to grafts with focal or discrete disease. Outcomes are much poorer for diffusely degenerated SVGs. The risk of embolization from SVG atherosclerosis to the distal coronary bed is also greater compared with intracoronary or arterial graft stenting. Recent advances in percutaneous techniques include catheter-based systems designed to capture atheromatous debris. These advances are believed to decrease procedural morbidity and long-term graft restenosis rates. However, further studies are necessary to compare the long-term outcomes of these newer techniques with the outcomes from operative revascularization.

## SURGICAL THERAPY

The increased complexity of redo-CABG surgery is due to various unique anatomic considerations including the risks of sternal reentry, potential injury to stenotic or patent bypass grafts, difficulty with cannulation of the reoperative aorta, an increased risk of embolic phenomena, and a limitation of remaining bypass conduits (Table 29-2). The significant amount of sternal adhesions often encountered during sternal reentry increases the risk of hemorrhage as well as injury to underlying structures. Native structures that are often adherent to the posterior sternum can include the right ventricle, right atrium, aorta, innominate vein, and lung. In addition, functioning venous and arterial bypass conduits from the initial operation can be placed at risk. If difficulty with the sternotomy is anticipated, preparations for peripheral CPB should be instituted. Harvesting and preparation of the new venous and arterial conduits should be undertaken before resternotomy. Arterial cannulation for peripheral CPB can be performed through the femoral artery, or it can be performed through the axillary artery if the patient has significant aorto-iliac disease. The femoral vein is used most commonly for venous cannulation.

The use of a sagittal oscillating saw is often considered the safest approach during resternotomy (Fig. 29-3A). Sternal wires should be cut anteriorly but left in place. The oscillating saw then is used to divide the outer table of the sternum, using the wires as a guide for the depth of the cut. In this way, the intact wires posterior to the sternum provide added protection to underlying structures during sternal reentry but are removed as the inner table is divided. The inner table is divided with Mayo scissors (Fig. 29-3B). After the sternum has been opened, meticulous dissection must be employed to

**TABLE 29-2: Technical Challenges of Redo-CABG Surgery**

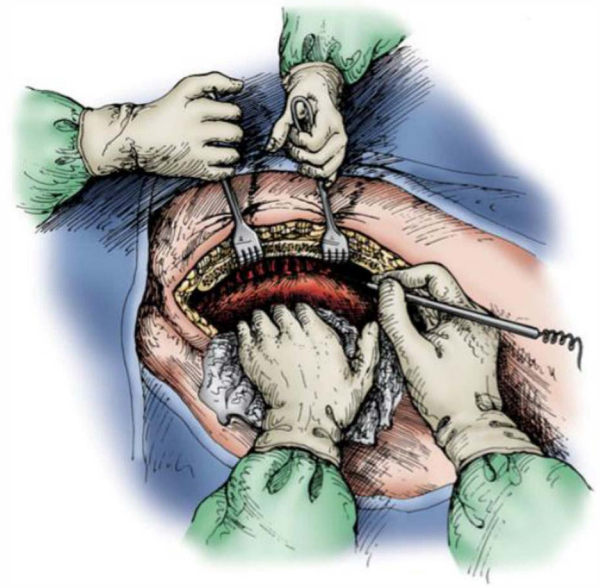

**FIGURE 29-4** Use of the electrocautery unit to separate adhesions from the sternum and chest wall.

separate adherent mediastinal structures from the chest wall (Fig. 29-4). Care must be taken to avoid excessive manipulation of venous bypass grafts because this can lead to the dissemination of atheromatous emboli. Intrapericardial dissection then continues in preparation for cannulation. Once the aorta is dissected out, it must be examined for the presence of significant atherosclerotic disease, which could lead to embolic phenomena upon cannulation. This is accomplished through palpation and epiaortic scanning to identify the most disease-free portions of the aorta. If the degree of atherosclerotic disease of the aorta is thought to be too great, the femoral or axillary arteries are other possible cannulation sites, as was mentioned above.

Myocardial protection can be provided through a combination of both antegrade and retrograde cardioplegia during redo-CABG surgery. Although antegrade cardioplegia alone may be adequate during a primary CABG, this is not the case during reoperations. Antegrade cardioplegia may be ineffective in providing protection to areas of the myocardium supplied by in situ arterial grafts and also can increase the risk of dislodging atheromatous debris from previously placed SVGs. In contrast, retrograde cardioplegia is delivered via the coronary sinus and the coronary venous system and can avoid the problems associated with antegrade cardioplegia. However, the adequacy of retrograde cardioplegia must be assessed in terms of the coronary sinus pressure, uniformity of myocardial cooling, and distention of the coronary venous system. To ensure uniform cardioplegic protection, patent in situ arterial grafts also must be occluded.

Once intrapericardial dissection of the heart is complete, the native coronary vasculature and initial bypass conduits are assessed. In conjunction with preoperative angiographic data, an operative strategy is formulated. The vessels to be bypassed and the SVGs to be replaced are determined. SVG atherosclerosis is present in a large majority of vein grafts. For this reason, replacement of all older SVGs must be considered. However, this often is not feasible because of the limitation of available bypass conduits. Unnecessary manipulation of SVGs must be avoided to prevent atheroemboli from forming. Therefore, the operative plan must be individualized, and relatively disease-free SVGs will be left in place even if they are more than 5 years old.

Many technical decisions must be made to revascularize ischemic myocardium that is being perfused by a stenotic SVG: The present SVG can be left alone or divided, and it can be replaced with a new SVG or an arterial graft. Every effort must be made to bypass left anterior descending LAD artery disease with the left IMA if this was not done at the initial operation because of the superior long-term patency rates. However, studies have shown that when new arterial grafts are used and the old vein grafts are interrupted, a hypoperfusion syndrome may develop, resulting in worsened myocardial ischemia or infarction. In addition to being a risk factor for hypoperfusion, an IMA-to-LAD graft with interruption of an old SVG was found to be an independent predictor of operative mortality.[17] This is due to an initial period of decreased flow through the arterial graft compared with the previous vein graft. The risk of hypoperfusion outweighs the risk of atheroemboli from an old SVG; therefore, old SVGs should be left in place when a new arterial graft is used to bypass the same coronary vessel. However, hypoperfusion is often not an issue when an old SVG is replaced with another SVG. Therefore, the old SVG should be interrupted in those situations.

The site of both the distal and proximal anastomoses is another challenge faced by the surgeon during redo-CABG surgery. The distal anastomotic site from the primary operation often can be reused when one is replacing an old SVG with a new one. However, progression of native vessel disease distal to this site may require the placement of a second bypass conduit on this more distal vessel. A challenge to the proximal anastomosis is posed by the often limited sites available on the reoperative aorta. This can be avoided by using sequential vein grafts that have multiple distal anastomoses but only one proximal anastomosis. In situ arterial grafts are optimal not only because they have excellent long-term patency but also because they have no proximal anastomoses. The proximal anastomosis of arterial-free grafts can be sewn to the hood of an old SVG graft, which is often free from atherosclerosis. Arterial-free grafts also can be anastomosed proximally to another arterial graft to form a composite T- or Y-type graft configuration.

## Surgical Interventions

Alternative surgical treatment strategies have become more prevalent in recent years in an effort to minimize the

potential complications associated with redo-CABG surgery. Long CPB time has been identified as an independent predictor of mortality after redo-CABG, and therefore off-pump CABG (OPCAB) has been employed as an alternative strategy for myocardial revascularization. A large, 10-year retrospective review of 296 patients undergoing redo-OPCAB demonstrated lower early mortality compared with those undergoing on-pump redo-CABG (3.3 vs 5.5 percent, $p = 0.066$).[18] The redo-OPCAB patients also had less need for prolonged ventilation or inotropic support and shorter ICU and hospital lengths of stay, as compared with conventional redo-CABG patients. However, the potential disadvantages of redo-OPCAB must also be noted. The operation becomes technically more challenging, which brings into question completeness of revascularization and graft patency. Studies have shown higher rates of incomplete revascularization in patients undergoing redo-OPCAB (17.7 vs 5.9 percent, $p < 0.01$), and showed that incomplete revascularization was an independent risk factor for cardiac death at 5 years.[19] There is an increased risk for embolization from atherosclerotic but patent vein grafts during dissection of a beating heart, and the need for the use of a partial occluding clamp on the aorta is also a disadvantage of the off-pump method. In addition, redo-OPCAB has been observed to be less effective at relieving symptoms. In one study, patients undergoing redo-OPCAB had a higher rate of angina recurrence and an increased use of nitrates at follow-up.[20] Until a large randomized-controlled trial becomes available to substantiate the benefits of redo-OPCAB, it should be used selectively after an individualized risk assessment is performed.

Sternal reentry jeopardizes structures potentially adherent to the underside of the sternum such as the aorta, right ventricle, and patent grafts that may cross the midline. A patent left IMA crossing the sternal midline can be detected on the preoperative coronary angiogram. Preoperative imaging is essential to delineate the postsurgical anatomy from the primary CABG, and peripheral cannulation with CPB may be necessary in particularly risky patients. The risks of sternal reentry can be minimized through the use of alternative incisions. If it is not necessary to revascularize multiple vascular territories of the heart, a limited thoracotomy incision can be a viable alternative to gain access to specific vessels. Anterior coronary artery revascularization can be accomplished via an anterior thoracotomy, circumflex revascularization via a lateral thoracotomy, and distal right coronary artery revascularization via an epigastric approach.[21] These limited alternative incisions can be performed in conjunction with peripheral CPB or even without CPB. Studies have shown that off-pump surgery through a thoracotomy does not increase the risk and reduces mortality and postoperative complications.[22] The proximal anastomosis or inflow vessel can be the left subclavian, the left axillary, or descending thoracic aorta, and can be accomplished with a partial occluding clamp (Fig 29-5). Since complete revascularization is usually not possible via these limited incisions, these approaches should only be considered in patients at relatively high risk with a resternotomy who require only one or two grafts.

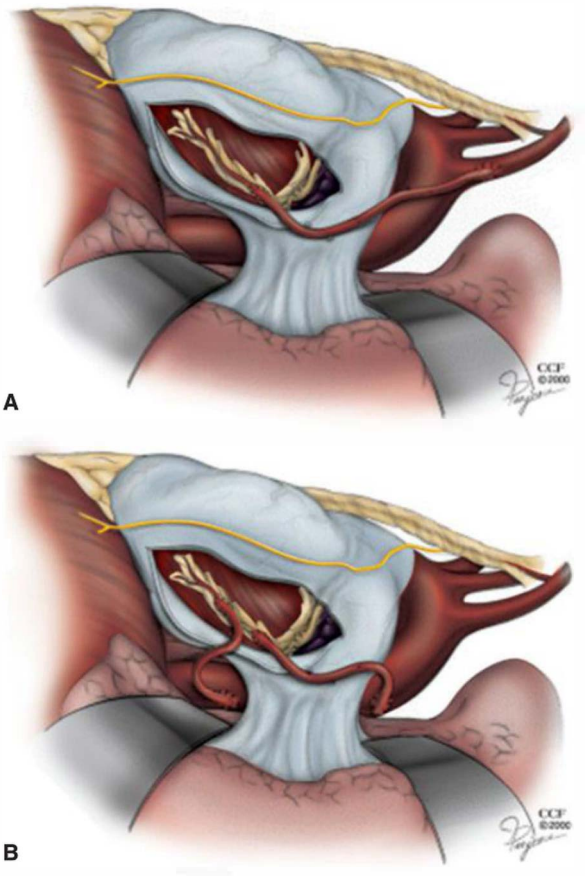

**FIGURE 29-5** **A.** View through left thoracotomy. The pericardium is opened posterior to the phrenic nerve. A previously placed vein graft to the circumflex marginal is evident. The new vein graft originates at the subclavian artery and is routed anterior to the pulmonary hilum. **B.** Same view as in A. The new vein graft originates from the descending thoracic aorta and follows a smooth course anterior to the pulmonary hilum or is routed beneath the pulmonary hilum. (Reprinted from Azoury FM, et al. Off-pump reoperative coronary artery bypass grafting by thoracotomy: Patient selection and operative technique. *Ann Thorac Surg* 2001;71(6):1959–1963. With permission from Elsevier.)

Minimally invasive direct coronary artery bypass (MIDCAB) is performed under direct vision without sternotomy or CPB. This technique is also used in reoperative patients through various incisions to revascularize one or two areas of the heart. The procedure is best suited to access anterior coronary vessels through a left anterior minithoracotomy. MIDCAB can also be combined with PCI to provide complete revascularization. Anterior coronary vessels are grafted with the left IMA if it has not been used previously. However, harvesting of the IMA is technically more difficult with the limited exposure offered by the mini-thoracotomy incision. Additional small incisions allow access to individual regions of the heart. A midline epigastric incision is made to graft posterior vessels, using the gastroepiploic

artery as the bypass conduit. Lateral coronaries can be bypassed with radial artery or SVGs via a posterior minithoracotomy. A recent study of 46 patients undergoing reoperative MIDCAB with a LIMA to the LAD on the beating heart demonstrated an in-hospital mortality of 4.7 percent with a reoperation rate of 2.3 percent.[23] Despite its limitations, studies have shown that reoperative MIDCAB can have lower rates of supraventricular arrhythmia and transfusion than traditional redo-CABG. MIDCAB also avoids the risks of resternotomy, aortic manipulation, and CPB, but does not offer an advantage for mortality, stroke, or MI. In cases in which single-territory revascularization is indicated, MIDCAB can offer a valuable treatment alternative to traditional redo-CABG.

## OUTCOMES/PROGNOSIS

### Survival

Redo-CABG is more hazardous than primary revascularization because of the increased surgical complexity as well as the vulnerable patient population undergoing reoperation. Redo-CABG patients are a substantially higher risk subgroup than patients undergoing a primary operation in terms of perioperative morbidity and mortality, relief of cardiac symptoms, and long-term survival. Overall operative mortality rates have been reported to be from 1.8 to 3.2 percent for primary CABG compared with 4.8 to 11.4 percent for redo-CABG.[1,24] Operative mortality rates are even higher for patients undergoing emergency redo-CABG, with one series citing 16.4 percent mortality.[25] The principal cause for higher operative mortality with redo-CABG is increased risk of perioperative infarction.[1] Causes of MI include incomplete revascularization as a result of distal coronary disease, vein graft thrombosis, IMA graft failure, emboli from vein grafts, injury to patent grafts, and hypoperfusion from inadequate arterial grafting (Table 29-3). Similarly, the late results for redo-CABG are less favorable than those for a primary operation. In a retrospective study of 2030 patients at Emory University, 5- and 10-year survival after reoperation were 76 and 55 percent, respectively.[25] In contrast, 56 percent of patients were alive at 15 years after primary CABG in the Coronary Artery Surgery Study (CASS) of 8221 patients.[26] In another study of 6591 primary CABG patients, 5- and 10-year actuarial survival was 90 and 75 percent, respectively. This is in contrast to the 5- and 10-year actuarial survival of 80 and 65 percent, respectively, in 508 redo-CABG patients.[27]

### Predictors of Mortality

In a series of 200 redo-CABG patients, only angina status and preoperative MI were identified as risk factors for operative mortality on a multivariable analysis.[28] In a separate large series of redo-CABG patients, low ejection fraction, increased age, female gender, history of arrhythmia, emergency operation, and the development of postoperative complications were all associated with increased risk of perioperative mortality.[24] Risk factors correlating with reduced long-term survival after redo-CABG surgery are older age, impaired LV function, hypertension, diabetes, congestive heart failure, emergency surgery, and female sex.[25] Despite advances in technical strategies, large national registry data suggest redo-CABG remains an independent risk factor for operative mortality.[1]

The time interval that has elapsed between the primary operation and redo-CABG impacts operative risk and mortality. Very early reoperation (1 year or less) can be correlated with a much higher mortality rate than later reoperation. Studies demonstrate mortality rates as high as 21 percent in patients after very early reoperation versus 8 percent in those reoperated on greater than 1 year after the initial operation.[29] However, as the time interval extends beyond 10 years, increased mortality rates have been observed. In one study, patients with a reoperative interval of 1 to 10 years had a 6.0 percent mortality rate, compared with 17.6 percent for those patients in whom the interval between operations was greater than 10 years.[27]

### Multiple Reoperations

Some patients require additional redo coronary revascularization procedures; however, this patient population represents a small fraction of all redo-CABG patients. In one large series, only 1 percent of all redo-CABG procedures were third- or fourth-time CABG operations.[21] Disease complexity and the risk of the operation increase with each subsequent redo-CABG. In addition, the availability of potential bypass conduits may become a limiting factor. The indications for additional operative revascularization remain the same as for first-time redo-CABG, and patients often present with disabling angina unresponsive to medical therapy. As expected, perioperative mortality and MI rates in these patients are higher than they are in first-time redo patients. The largest study to date of 150 third-time CABG patients cited an in-hospital mortality of 12 percent, and a nonfatal perioperative MI rate of 5 percent. Actuarial survival of these patients at 5 years was 76 percent.[30] More recent data show that the in-hospital mortality has improved to approximately 6.5 percent.[21] Consistent predictors of increased mortality in the patients after a third operation include age greater than

65 years and LV dysfunction with an ejection fraction less than 40 percent.[30] Despite the increased perioperative risks involved, these patients have reasonable long-term survival and symptomatic improvement after multiple redo-CABG procedures. In more recent years, some of these patients have lesions that are amenable to angioplasty and stent placement.

## SUMMARY

Redo-CABG remains a viable alternative for a number of patients, especially as the interval from the initial procedure lengthens. The treatment modalities available to patients experiencing recurring symptoms of ischemic heart disease also continue to increase in number. In addition to improvements in surgical technique, the cardiac surgeon must remain familiar with advances in percutaneous catheter interventions to devise the most appropriate treatment strategy for each patient. The differences between primary and reoperative procedures cannot be underestimated, and the surgeon must recognize the unique challenges involved. Preoperative assessment and critical analysis of each patient's anatomy are of paramount importance. With an awareness of the technical complexities and risk profile of the patients, redo-CABG can be performed with relatively low morbidity and mortality, and good long-term relief of symptoms. As operative technique and surgical technology continue to evolve, the outlook for patients who need repeat coronary revascularizations remains promising.

## REOPERATIVE CORONARY ARTERY BYPASS SURGERY BOARD REVIEW QUESTIONS (CHAPTER 29)

1. Which of the following has not been identified as an independent risk factor for recurrent angina after coronary artery bypass grafting?

   A. Previous myocardial infarction
   B. Use of only vein grafts
   C. Incomplete revascularization
   D. Diabetes
   E. Female gender

2. Which of the following is a predictor of reoperative coronary artery bypass grafting?

   A. Older age at initial operation
   B. Male gender
   C. Use of internal mammary artery graft
   D. Single vessel disease
   E. Preserved functional status

3. The most common cause of operative mortality in patients undergoing reoperative CAB surgery is:

   A. Myocardial infarction
   B. Refractory dysrhythmias
   C. Perioperative hemorrhage
   D. Sternal dehiscence
   E. Stroke

4. When a new arterial graft is being placed on a vessel which has previously been bypassed with a vein graft, the old vein grafts should be:

   A. Ligated
   B. Ligated and divided
   C. Left in place
   D. Opened for endarterectomy
   E. Completely excised

5. Which of the following diagnostic tests is not used to assess myocardial viability prior to reoperative coronary artery bypass?

   A. Nuclear stress testing
   B. Magnetic resonance imaging
   C. Dobutamine echocardiography
   D. Coronary angiography
   E. Cardiac PET scanning

## ANSWERS

1. **Answer: D.** Diabetes has not been shown on multivariate analysis to be an independent predictor of recurrent angina after CAB. Factors that have been shown to be associated with recurrent angina include preoperative angina, use of only veins grafts, previous myocardial infarction, incomplete revascularization, female gender, smoking, and younger age at initial operation.
2. **Answer: B.** Male gender has been associated with an increased risk for reoperative CAB. Other predictors of redo-CAB include young age at initial operation, worse symptom severity, absence of an IMA graft, incomplete revascularization, impaired functional status, and multivessel disease.
3. **Answer: A.** The principal cause of mortality after reoperative CAB is myocardial infarction. This can be due to incomplete revascularization, vein graft thrombosis, IMA graft failure, embolism from atheromatous old vein grafts, injury to patent existing grafts, and hypoperfusion from inadequate arterial grafting.
4. **Answer: C.** Old vein grafts should simply be left in place. Excessive manipulation can result in embolization of atheromatous debris.
5. **Answer: D.** Coronary angiography provides anatomic details about the degree of coronary insufficiency but does not give information about viability. Nuclear stress testing and dobutamine stress echocardiography are important for establishing myocardial viability. Cardiac MRI and PET scanning are newer modalities that provide high levels of detail about myocardial function and viability.

## KEY CONCEPTS

- Epidemiology
  - Stroke is a major complication of cardiac surgery, with an incidence ranging from 2.1 to 5.2 percent. As many as 22 percent of coronary artery bypass graft (CABG) candidates have hemodynamically significant carotid disease, which is a risk factor for perioperative stroke. This percentage is likely to increase as the population continues to age and CABG is used in increasingly older patients. Although carotid disease is associated with an increase in perioperative stroke risk, it is responsible for only a minority of strokes associated with CABG. In addition, it is important to note that carotid stenosis has never been shown to be an independent risk factor for perioperative stroke while controlling for aortic arch atherosclerosis.
- Pathophysiology
  - Several mechanisms have been proposed for perioperative strokes after CABG; the most important are arterial emboli and cerebral hypoperfusion. It is theoretically possible for carotid lesions to act through either mechanism, showering emboli through plaque rupture or causing hypoperfusion via thrombosis and/or obstruction of arterial flow. However, the perioperative stroke risk associated with carotid stenosis may also be related to emboli originating from aortic arch atheromas.
- Diagnostics
  - On physical examination, the most important finding is the presence of a carotid bruit. Although a carotid bruit is not pathognomonic for carotid stenosis, studies at the Johns Hopkins Hospital suggest a 40-percent positive predictive value for carotid stenosis (in excess of 70 percent) in CABG populations. From a demographic perspective, increased age, cerebrovascular disease (CVD), and peripheral vascular disease also greatly increase the likelihood of carotid disease. For patients at risk for carotid disease, duplex ultrasound represents a noninvasive means of assessing carotid disease quantitatively. Magnetic resonance angiography, cerebral angiography, and computed tomography (CT)–angiography represent more costly and/or invasive methods of assessing the degree of stenosis that may be useful in confirming duplex findings and in instances in which duplex results are indeterminate.
- Treatment
  - Treatment of patients with combined coronary and carotid disease centers on medical management with antiplatelet therapy and/or cholesterol-lowering agents and carotid endarterectomy (CEA). Patients who are candidates for CABG and in whom CEA also is indicated can be approached with one of three strategies: "staged" but separate procedures with CEA performed before CABG, the "combined" procedure with CEA and CABG performed under the same anesthesia, and "reverse-staged" procedures with CABG performed before CEA. In their practice, the authors advocate treating the symptomatic territory (i.e., carotid or coronary) first and reserving combined procedures for patients with severe symptoms in both territories. Percutaneous carotid angioplasty with or without stenting is an emerging technique that is being applied in concert with CABG in a similar fashion at select centers.
- Outcomes
  - In the absence of large prospective randomized trials, there is no high-grade evidence to support the

contention that CEA lowers perioperative stroke risk in the context of CABG. However, the most recent meta-analyses indicate that myocardial infarction (MI) is more common in patients undergoing the staged procedure and stroke rates are higher in those undergoing the reverse-staged procedure. The risk of stroke and MI is similar for the combined procedure, although overall mortality is higher than for either the staged or reverse-staged procedures. However, the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the Asymptomatic Carotid Atherosclerosis Study (ACAS) have provided strong evidence that CEA reduces long-term stroke risk in symptomatic patients with stenosis greater than 50 percent and asymptomatic patients with stenosis greater than 60 percent. Generally, the tighter the carotid stenosis, the greater the benefit from CEA on long-term stroke risk.

- Screening
  - Many centers now screen all or a majority of CABG patients for carotid disease despite strong evidence suggesting that most perioperative strokes are caused by unrelated mechanisms. Mandatory screening is difficult to justify in the current fiscal environment given its associated costs and the lack of any proven benefit of mandatory screening over selective screening. Based on research at the Johns Hopkins Hospital, the authors advocate screening only patients who are over age 65, have a carotid bruit, or have physical symptoms of CVD [i.e., transient ischemic attack (TIA) or stroke].

## INTRODUCTION

The relationship between atherosclerotic coronary artery and carotid disease is an intuitive association well supported by clinical data. These two regions of the vasculature are closely approximated and share important similarities in structure and embryological origin. Within a given individual, these vascular beds share a common genetic background and are subject to virtually the same environment throughout the individual's lifetime. It is therefore no surprise that the finding of coronary artery disease virtually assures that there is some degree of carotid pathology and vice versa. From the standpoint of the cardiothoracic surgeon, this means that up to 22 percent of candidates for coronary artery bypass surgery will have significant carotid disease.[1] This number is likely to increase as the population continues to age and coronary artery bypass grafting (CABG) is extended to more elderly patients.

Although the importance of combined coronary and carotid disease is straightforward, its treatment is complex and controversial. Historically, the procedures to address each condition were developed separately and have been evaluated using different metrics. Traditionally, the clinical benefits of CABG were measured as reductions in the rates of myocardial infarction (MI), reintervention, and mortality rates whereas those of carotid endarterectomy (CEA) have been measured as reductions in stroke and mortality. Each procedure is associated with complications that the other is intended to prevent; MI and stroke are well-recognized complications of both CEA and CABG, respectively. Furthermore, one must consider that although carotid disease is often present in coronary bypass patients, the majority of these patients experience no symptoms from their cerebrovascular disease (CVD). In deciding which procedure(s) is appropriate for each subpopulation, one must bear in mind its impact on all endpoints (e.g., MI, stroke, death) weighed against the likelihood of all complications. Lastly, less invasive procedures such as "off-pump" CABG and carotid stenting have become more widespread in recent years, adding a further layer of complexity to surgical treatment options. This chapter guides cardiothoracic surgeons through the challenges of identifying and managing carotid disease in coronary bypass patients and reviews the evidence for and against current treatment options.

## CAROTID DISEASE AND PERIOPERATIVE STROKE ASSOCIATED WITH CORONARY ARTERY BYPASS SURGERY

Stroke is one of the most prevalent and debilitating complications of coronary artery bypass surgery and one that frequently negates the benefits of coronary revascularization. Clinically speaking, perioperative stroke is defined as an acute neurologic event secondary to circulatory impairment lasting more than 24 hours and occurring within a specified period of time following surgery. Nearly all centers define stroke in this manner and most obtain radiologic imaging [i.e., computed tomography (CT) or magnetic resonance imaging (MRI)] to delineate the distribution and extent of cerebral injury after a perioperative stroke. Although there is variability in the definition of perioperative stroke (e.g., 14 vs 28 days), most strokes present within the first 3 days after coronary bypass surgery. Over the past 2 decades, the incidence of perioperative stroke in the general CABG population has remained fairly constant, ranging from 2.1 to 5.2 percent.[2,3] A variety of risk factors have been identified for perioperative stroke in CABG patients (Table 30-1) and several closely related mechanisms have been proposed (Table 30-2), the most important of which are arterial emboli and cerebral hypoperfusion. It is theoretically possible for carotid lesions to affect strokes by either of these mechanisms in the postoperative period, incurring emboli though plaque rupture,

**TABLE 30-1: Risk Factors for Perioperative Stroke in Coronary Bypass Patients**

| Demographic | Preoperative | Intraoperative |
|---|---|---|
| Age >65 retired | Hypertension | Cardiopulmonary bypass time |
| | Diabetes mellitus | Use of intra-aortic balloon pump |
| | Carotid bruit | Mean cross-clamp time |
| | Prior CVA | |
| | Prior CVD (CVA or TIA) | Use of membrane oxygenator |
| | Left main disease >50 | |
| | Tobacco use >10 pack-years | |

CVA, cerebrovascular accident; CVD, cerebrovascular disease; TIA, transient ischemic attack.

thrombosis, or diminished arterial flow. However, since the carotid arteries are not surgically manipulated during CABG and carotid thrombi are rarely seen on imaging, it has been postulated that carotid stenosis and/or occlusion cause strokes primarily via cerebral hypoperfusion during low cardiac output states (e.g., while on cardiopulmonary bypass or in the early postoperative period).
